

The background of the image is an abstract, textured pattern. It consists of numerous overlapping, fan-like or crystalline shapes that resemble biological structures or mineral formations. The color palette is dominated by various shades of blue, ranging from deep navy to bright cyan, and green, ranging from lime green to forest green. The lighting creates a sense of depth and highlights the sharp edges of the crystalline structures.

## GENES ARE DNA

### 1.1.1 Introduction

---

#### Key Terms

The **genome** is the complete set of sequences in the genetic material of an organism. It includes the sequence of each chromosome plus any DNA in organelles.

**Nucleic acids** are molecules that encode genetic information. They consist of a series of nitrogenous bases connected to ribose molecules that are linked by phosphodiester bonds. DNA is deoxyribonucleic acid, and RNA is ribonucleic acid.

A **gene (cistron)** is the segment of DNA specifying production of a polypeptide chain; it includes regions preceding and following the coding region (leader and trailer) as well as intervening sequences (introns) between individual coding segments (exons).

An **allele** is one of several alternative forms of a gene occupying a given locus on a chromosome.

A **locus** is the position on a chromosome at which the gene for a particular trait resides; a locus may be occupied by any one of the alleles for the gene.

**Linkage** describes the tendency of genes to be inherited together as a result of their location on the same chromosome; measured by percent recombination between loci.

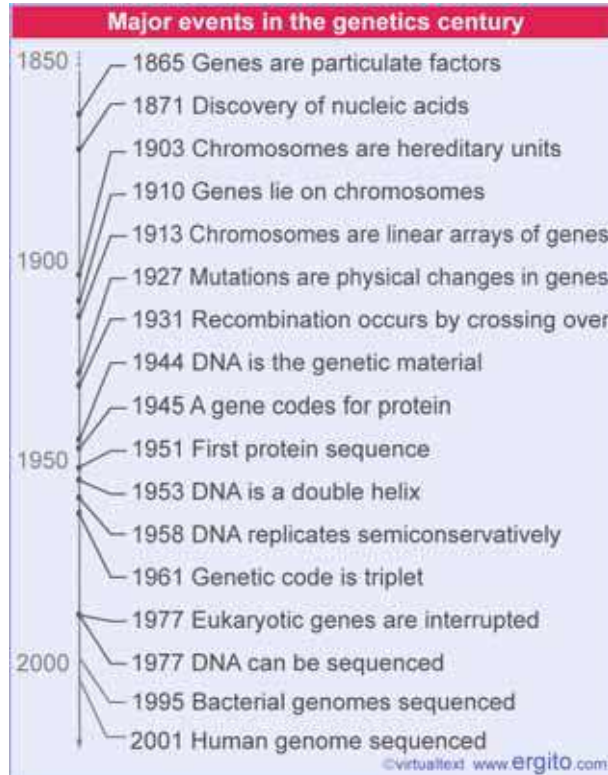

---

The hereditary nature of every living organism is defined by its **genome**, which consists of a long sequence of **nucleic acid** that provides the *information* need to construct the organism. We use the term "information" because the genome does not itself perform any active role in building the organism; rather it is the sequence of the individual subunits (bases) of the nucleic acid that determines hereditary features. By a complex series of interactions, this sequence is used to produce all the proteins of the organism in the appropriate time and place. The proteins either form part of the structure of the organism, or have the capacity to build the structures or to perform the metabolic reactions necessary for life.

The genome contains the complete set of hereditary information for any organism. Physically the genome may be divided into a number of different nucleic acid molecules. Functionally it may be divided into **genes**. Each gene is a sequence within the nucleic acid that represents a single protein. Each of the discrete nucleic acid molecules comprising the genome may contain a large number of genes. Genomes for living organisms may contain as few as <500 genes (for a mycoplasma, a type of bacterium) to as many as >40,000 for Man.

In this Chapter, we analyze the properties of the gene in terms of its basic molecular construction. **Figure 1.1** summarizes the stages in the transition from the historical concept of the gene to the modern definition of the genome.

**Figure 1.1** A brief history of genetics.

The basic behavior of the gene was defined by Mendel more than a century ago. Summarized in his two laws, the gene was recognized as a "particulate factor" that passes unchanged from parent to progeny. A gene may exist in alternative forms. These forms are called **alleles**.

In diploid organisms, which have two sets of chromosomes, one copy of each chromosome is inherited from each parent. This is the same behavior that is displayed by genes. One of the two copies of each gene is the paternal allele (inherited from the father), the other is the maternal allele (inherited from the mother). The equivalence led to the discovery that chromosomes in fact carry the genes.

Each chromosome consists of a linear array of genes. Each gene resides at a particular location on the chromosome. This is more formally called a genetic **locus**. We can then define the alleles of this gene as the different forms that are found at this locus.

The key to understanding the organization of genes into chromosomes was the discovery of genetic **linkage**. This describes the observation that alleles on the same chromosome tend to remain together in the progeny instead of assorting independently as predicted by Mendel's laws (see *Molecular Biology Supplement 32.3 Linkage and mapping*). Once the unit of recombination (reassortment) was introduced as the measure of linkage, the construction of genetic maps became possible.

On the genetic maps of higher organisms established during the first half of this century, the genes are arranged like beads on a string. They occur in a fixed order, and genetic recombination involves transfer of corresponding portions of the string between homologous chromosomes. The gene is to all intents and purposes a mysterious object (the bead), whose relationship to its surroundings (the string) is unclear.

The resolution of the recombination map of a higher eukaryote is restricted by the small number of progeny that can be obtained from each mating. Recombination occurs so infrequently between nearby points that it is rarely observed between different mutations in the same gene. By moving to a microbial system in which a very large number of progeny can be obtained from each genetic cross, it became possible to demonstrate that recombination occurs within genes. It follows the same rules that were previously deduced for recombination between genes.

Mutations within a gene can be arranged into a linear order, showing that the gene itself has the same linear construction as the array of genes on a chromosome. So the genetic map is linear within as well as between loci: it consists of an unbroken sequence within which the genes reside. This conclusion leads naturally into the modern view that the genetic material of a chromosome consists of an uninterrupted length of DNA representing many genes.

A genome consists of the entire set of chromosomes for any particular organism. It therefore comprises a series of DNA molecules (one for each chromosome), each of which contains many genes. The ultimate definition of a genome is to determine the sequence of the DNA of each chromosome.

The first definition of the gene as a functional unit followed from the discovery that individual genes are responsible for the production of specific proteins. The difference in chemical nature between the DNA of the gene and its protein product led to the concept that a gene *codes* for a protein. This in turn led to the discovery of the complex apparatus that allows the DNA sequence of gene to generate the amino acid sequence of a protein.

Understanding the process by which a gene is expressed allows us to make a more rigorous definition of its nature. **Figure 1.2** shows the basic theme of this book. A gene is a sequence of DNA that produces another nucleic acid, RNA. The DNA has two strands of nucleic acid, and the RNA has only one strand. The sequence of the RNA is determined by the sequence of the DNA (in fact, it is identical to one of the DNA strands). In many, but not in all cases, the RNA is in turn used to direct production of a protein. *Thus a gene is a sequence of DNA that codes for an RNA; in protein-coding genes, the RNA in turn codes for a protein.*

**Figure 1.2** A gene codes for an RNA, which may code for protein.

From the demonstration that a gene consists of DNA, and that a chromosome consists of a long stretch of DNA representing many genes, we move to the overall organization of the genome in terms of its DNA sequence. In *Molecular Biology 1.2 The interrupted gene* we take up in more detail the organization of the gene and its representation in proteins. In *Molecular Biology 1.3 The content of the genome* we consider the total number of genes, and in *Molecular Biology 1.4 Clusters and repeats* we discuss other components of the genome and the maintenance of its organization (for review see 1; 2; 5).

## GENES ARE DNA

### 1.1.2 DNA is the genetic material of bacteria

---

#### Key Terms

**Transformation** of bacteria is the acquisition of new genetic material by incorporation of added DNA.

**Avirulent** mutants of a bacterium or virus have lost the capacity to infect a host productively, that is, to make more bacterium or virus.

The **transforming principle** is DNA that is taken up by a bacterium and whose expression then changes the properties of the recipient cell.

**Deoxyribonucleic acid (DNA)** is a nucleic acid molecule consisting of long chains of polymerized (deoxyribo)nucleotides. In double-stranded DNA the two strands are held together by hydrogen bonds between complementary nucleotide base pairs.

#### Key Concepts

- Bacterial transformation provided the first proof that DNA is the genetic material. Genetic properties can be transferred from one bacterial strain to another by extracting DNA from the first strain and adding it to the second strain.
- 

The idea that genetic material is nucleic acid had its roots in the discovery of **transformation** in 1928. The bacterium *Pneumococcus* kills mice by causing pneumonia. The virulence of the bacterium is determined by its *capsular polysaccharide*. This is a component of the surface that allows the bacterium to escape destruction by the host. Several types (I, II, III) of *Pneumococcus* have different capsular polysaccharides. They have a smooth (S) appearance.

Each of the smooth *Pneumococcal* types can give rise to variants that fail to produce the capsular polysaccharide. These bacteria have a *rough* (R) surface (consisting of the material that was beneath the capsular polysaccharide). They are **avirulent**. They do not kill the mice, because the absence of the polysaccharide allows the animal to destroy the bacteria.

When smooth bacteria are killed by heat treatment, they lose their ability to harm the animal. But inactive heat-killed S bacteria and the ineffectual variant R bacteria together have a quite different effect from either bacterium by itself. **Figure 1.3** shows that when they are jointly injected into an animal, the mouse dies as the result of a *Pneumococcal* infection. Virulent S bacteria can be recovered from the mouse postmortem.

**Figure 1.3** Neither heat-killed S-type nor live R-type bacteria can kill mice, but simultaneous injection of both can kill mice just as effectively as the live S-type.

In this experiment, the dead S bacteria were of type III. The live R bacteria had been derived from type II. The virulent bacteria recovered from the mixed infection had the smooth coat of type III. So some property of the dead type III S bacteria can *transform* the live R bacteria so that they make the type III capsular polysaccharide, and as a result become virulent (371).

**Figure 1.4** shows the identification of the component of the dead bacteria responsible for transformation. This was called the **transforming principle**. It was purified by developing a cell-free system, in which extracts of the dead S bacteria could be added to the live R bacteria before injection into the animal. Purification of the transforming principle in 1944 showed that it is **deoxyribonucleic acid (DNA)** (372).

**Figure 1.4** The DNA of S-type bacteria can transform R-type bacteria into the same S-type.

## GENES ARE DNA

### 1.1.3 DNA is the genetic material of viruses

---

#### Key Concepts

- Phage infection proved that DNA is the genetic material of viruses. When the DNA and protein components of bacteriophages are labeled with different radioactive isotopes, only the DNA is transmitted to the progeny phages produced by infecting bacteria.
- 

Having shown that DNA is the genetic material of bacteria, the next step was to demonstrate that DNA provides the genetic material in a quite different system. Phage T2 is a virus that infects the bacterium *E. coli*. When phage particles are added to bacteria, they adsorb to the outside surface, some material enters the bacterium, and then ~20 minutes later each bacterium bursts open (lyses) to release a large number of progeny phage.

**Figure 1.5** illustrates the results of an experiment in 1952 in which bacteria were infected with T2 phages that had been radioactively labeled *either* in their DNA component (with  $^{32}\text{P}$ ) *or* in their protein component (with  $^{35}\text{S}$ ). The infected bacteria were agitated in a blender, and two fractions were separated by centrifugation. One contained the empty phage coats that were released from the surface of the bacteria. The other fraction consisted of the infected bacteria themselves.

**Figure 1.5** The genetic material of phage T2 is DNA.

Most of the  $^{32}\text{P}$  label was present in the infected bacteria. The progeny phage particles produced by the infection contained ~30% of the original  $^{32}\text{P}$  label. The progeny received very little – less than 1% – of the protein contained in the original phage population. The phage coats consist of protein and therefore carried the  $^{35}\text{S}$  radioactive label. This experiment therefore showed directly that only the DNA of the parent phages enters the bacteria and then becomes part of the progeny phages, exactly the pattern of inheritance expected of genetic material (373).

A phage (virus) reproduces by commandeering the machinery of an infected host cell to manufacture more copies of itself. The phage possesses genetic material whose behavior is analogous to that of cellular genomes: its traits are faithfully reproduced, and they are subject to the same rules that govern inheritance. The case of T2 reinforces the general conclusion that the genetic material is DNA, whether part of the genome of a cell or virus.

## GENES ARE DNA

### 1.1.4 DNA is the genetic material of animal cells

#### Key Terms

**Transfection** of eukaryotic cells is the acquisition of new genetic markers by incorporation of added DNA.

#### Key Concepts

- DNA can be used to introduce new genetic features into animal cells or whole animals.
- In some viruses, the genetic material is RNA.

When DNA is added to populations of single eukaryotic cells growing in culture, the nucleic acid enters the cells, and in some of them results in the production of new proteins. When a purified DNA is used, its incorporation leads to the production of a particular protein (2486). **Figure 1.6** depicts one of the standard systems.

**Figure 1.6** Eukaryotic cells can acquire a new phenotype as the result of transfection by added DNA.

Although for historical reasons these experiments are described as **transfection**

when performed with eukaryotic cells, they are a direct counterpart to bacterial transformation. The DNA that is introduced into the recipient cell becomes part of its genetic material, and is inherited in the same way as any other part. Its expression confers a new trait upon the cells (synthesis of thymidine kinase in the example of the figure). At first, these experiments were successful only with individual cells adapted to grow in a culture medium. Since then, however, DNA has been introduced into mouse eggs by microinjection; and it may become a stable part of the genetic material of the mouse (see *Molecular Biology 4.18.18 Genes can be injected into animal eggs*).

Such experiments show directly not only that DNA is the genetic material in eukaryotes, but also that *it can be transferred between different species and yet remain functional*.

The genetic material of all known organisms and many viruses is DNA. However, some viruses use an alternative type of nucleic acid, *ribonucleic acid (RNA)*, as the genetic material. The general principle of the nature of the genetic material, then, is that it is always nucleic acid; in fact, it is DNA except in the RNA viruses.

## GENES ARE DNA

### 1.1.5 Polynucleotide chains have nitrogenous bases linked to a sugar-phosphate backbone

---

#### Key Concepts

- A nucleoside consists of a purine or pyrimidine base linked to position 1 of a pentose sugar.
- Positions on the ribose ring are described with a prime ( ' ) to distinguish them.
- The difference between DNA and RNA is in the group at the 2 ' position of the sugar. DNA has a deoxyribose sugar (2 ' -H); RNA has a ribose sugar (2 ' -OH).
- A nucleotide consists of a nucleoside linked to a phosphate group on either the 5 ' or 3 ' position of the (deoxy)ribose.
- Successive (deoxy)ribose residues of a polynucleotide chain are joined by a phosphate group between the 3 ' position of one sugar and the 5 ' position of the next sugar.
- One end of the chain (conventionally the left) has a free 5 ' end and the other end has a free 3 ' end.
- DNA contains the four bases adenine, guanine, cytosine, and thymine; RNA has uracil instead of thymine.

---

The basic building block of nucleic acids is the nucleotide. This has three components:

- a nitrogenous base;
- a sugar;
- and a phosphate.

The nitrogenous base is a purine or pyrimidine ring. The base is linked to position 1 on a pentose sugar by a glycosidic bond from N<sub>1</sub> of pyrimidines or N<sub>9</sub> of purines. To avoid ambiguity between the numbering systems of the heterocyclic rings and the sugar, positions on the pentose are given a prime ( ' ).

Nucleic acids are named for the type of sugar; DNA has 2 ' -deoxyribose, whereas RNA has ribose. The difference is that the sugar in RNA has an OH group at the 2 ' position of the pentose ring. The sugar can be linked by its 5 ' or 3 ' position to a phosphate group.

A nucleic acid consists of a long chain of nucleotides. **Figure 1.7** shows that the backbone of the polynucleotide chain consists of an alternating series of pentose

(sugar) and phosphate residues. This is constructed by linking the 5' position of one pentose ring to the 3' position of the next pentose ring via a phosphate group. So the sugar-phosphate backbone is said to consist of 5'–3' phosphodiester linkages. The nitrogenous bases "stick out" from the backbone.

**Figure 1.7** A polynucleotide chain consists of a series of 5'–3' sugar-phosphate links that form a backbone from which the bases protrude.

Each nucleic acid contains 4 types of base. The same two purines, adenine and guanine, are present in both DNA and RNA. The two pyrimidines in DNA are cytosine and thymine; in RNA uracil is found instead of thymine. The only difference between uracil and thymine is the presence of a methyl substituent at position C<sub>5</sub>. The bases are usually referred to by their initial letters. DNA contains A, G, C, T, while RNA contains A, G, C, U.

The terminal nucleotide at one end of the chain has a free 5' group; the terminal nucleotide at the other end has a free 3' group. It is conventional to write nucleic acid sequences in the 5' → 3' direction – that is, from the 5' terminus at the left to the 3' terminus at the right.

---

## GENES ARE DNA

### 1.1.6 DNA is a double helix

---

#### Key Terms

**Base pairing** describes the specific (complementary) interactions of adenine with thymine or of guanine with cytosine in a DNA double helix (thymine is replaced by uracil in double helical RNA).

**Complementary** base pairs are defined by the pairing reactions in double helical nucleic acids (A with T in DNA or with U in RNA, and C with G).

**Antiparallel** strands of the double helix are organized in opposite orientation, so that the 5' end of one strand is aligned with the 3' end of the other strand.

The **minor groove** of DNA is 12Å across.

The **major groove** of DNA is 22Å across.

A helix is said to be **right-handed** if the turns run clockwise along the helical axis.

**B-form** DNA is a right-handed double helix with 10 base pairs per complete turn (360°) of the helix. This is the form found under physiological conditions whose structure was proposed by Crick and Watson.

A stretch of **overwound** DNA has more base pairs per turn than the usual average (10 bp = 1 turn). This means that the two strands of DNA are more tightly wound around each other, creating tension.

A stretch of **underwound** DNA has fewer base pairs per turn than the usual average (10 bp = 1 turn). This means that the two strands of DNA are less tightly wound around each other; ultimately this can lead to strand separation.

#### Key Concepts

- The B-form of DNA is a double helix consisting of two polynucleotide chains that run antiparallel.
- The nitrogenous bases of each chain are flat purine or pyrimidine rings that face inwards and pair with one another by hydrogen bonding to form A-T or G-C pairs only.
- The diameter of the double helix is 20 Å, and there is a complete turn every 34 Å, with 10 base pairs per turn.
- The double helix forms a major (wide) groove and a minor (narrow) groove.

---

The observation that the bases are present in different amounts in the DNAs of different species led to the concept that the *sequence of bases is the form in which genetic information is carried*. By the 1950s, the concept of genetic information was common: the twin problems it posed were working out the structure of the nucleic acid, and explaining how a sequence of bases in DNA could represent the sequence of amino acids in a protein.

Three notions converged in the construction of the double helix model for DNA by Watson and Crick in 1953:

- X-ray diffraction data showed that DNA has the form of a regular helix, making a complete turn every  $34 \text{ \AA}$  (3.4 nm), with a diameter of  $\sim 20 \text{ \AA}$  (2 nm). Since the distance between adjacent nucleotides is  $3.4 \text{ \AA}$ , there must be 10 nucleotides per turn.
- The density of DNA suggests that the helix must contain two polynucleotide chains. The constant diameter of the helix can be explained if the bases in each chain face inward and are restricted so that a purine is always opposite a pyrimidine, avoiding partnerships of purine-purine (too wide) or pyrimidine-pyrimidine (too narrow).
- Irrespective of the absolute amounts of each base, the proportion of G is always the same as the proportion of C in DNA, and the proportion of A is always the same as that of T. So the composition of any DNA can be described by the proportion of its bases that is G + C. This ranges from 26% to 74% for different species.

Watson and Crick proposed that the two polynucleotide chains in the double helix associate by *hydrogen bonding between the nitrogenous bases*. G can hydrogen bond specifically only with C, while A can bond specifically only with T. These reactions are described as **base pairing**, and the paired bases (G with C, or A with T) are said to be **complementary**.

The model proposed that the two polynucleotide chains to run in opposite directions (**antiparallel**), as illustrated in **Figure 1.8**. Looking along the helix, one strand runs in the  $5' \rightarrow 3'$  direction, while its partner runs  $3' \rightarrow 5'$  (374; 376; 375).

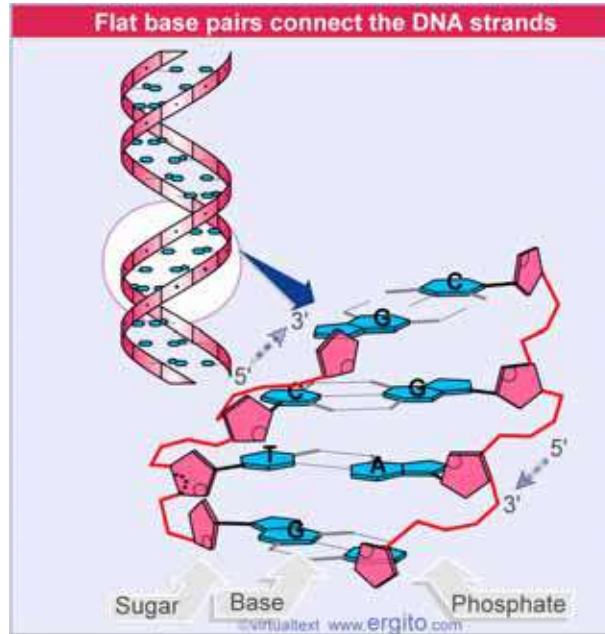

**Figure 1.8** The double helix maintains a constant width because purines always face pyrimidines in the complementary A-T and G-C base pairs. The sequence in the figure is T-A, C-G, A-T, G-C.

The sugar-phosphate backbone is on the outside and carries negative charges on the phosphate groups. When DNA is in solution *in vitro*, the charges are neutralized by the binding of metal ions, typically by  $\text{Na}^+$ . In the cell, positively charged proteins provide some of the neutralizing force. These proteins play an important role in determining the organization of DNA in the cell.

The bases lie on the inside. They are flat structures, lying in pairs perpendicular to the axis of the helix. Consider the double helix in terms of a spiral staircase: the base pairs form the treads, as illustrated schematically in **Figure 1.9**. Proceeding along the helix, bases are stacked above one another, in a sense like a pile of plates.

**Figure 1.9** Flat base pairs lie perpendicular to the sugar-phosphate backbone.

Each base pair is rotated  $\sim 36^\circ$  around the axis of the helix relative to the next base pair. So  $\sim 10$  base pairs make a complete turn of  $360^\circ$ . The twisting of the two strands around one another forms a double helix with a **minor groove** ( $\sim 12 \text{ \AA}$  across) and a **major groove** ( $\sim 22 \text{ \AA}$  across), as can be seen from the scale model of **Figure 1.10**. The double helix is **right-handed**; the turns run clockwise looking along the helical axis. These features represent the accepted model for what is known as the **B-form** of DNA.

**Figure 1.10** The two strands of DNA form a double helix.

It is important to realize that the B-form represents an *average*, not a precisely specified structure. DNA structure can change locally. If it has more base pairs per turn it is said to be **overwound**; if it has fewer base pairs per turn it is **underwound**. Local winding can be affected by the overall conformation of the DNA double helix in space or by the binding of proteins to specific sites.

## GENES ARE DNA

### 1.1.7 DNA replication is semiconservative

---

#### Key Terms

A **parental** strand or duplex of DNA refers to the DNA that will be replicated.

The **antisense strand (Template strand)** of DNA is complementary to the sense strand, and is the one that acts as the template for synthesis of mRNA.

A **daughter** strand or duplex of DNA refers to the newly synthesized DNA.

**Semiconservative replication** is accomplished by separation of the strands of a parental duplex, each then acting as a template for synthesis of a complementary strand.

#### Key Concepts

- The Meselson-Stahl experiment used density labeling to prove that the single polynucleotide strand is the unit of DNA that is conserved during replication.
  - Each strand of a DNA duplex acts as a template to synthesize a daughter strand.
  - The sequences of the daughter strands are determined by complementary base pairing with the separated parental strands.
- 

It is crucial that the genetic material is reproduced accurately. Because the two polynucleotide strands are joined only by hydrogen bonds, they are able to separate without requiring breakage of covalent bonds. The specificity of base pairing suggests that each of the separated **parental** strands could act as a **template strand** for the synthesis of a complementary **daughter** strand. **Figure 1.11** shows the principle that a new daughter strand is assembled on each parental strand. The sequence of the daughter strand is dictated by the parental strand; an *A* in the parental strand causes a *T* to be placed in the daughter strand, a parental *G* directs incorporation of a daughter *C*, and so on.

**Figure 1.11** Base pairing provides the mechanism for replicating DNA.

The top part of the figure shows a parental (unreplicated) duplex that consists of the original two parental strands. The lower part shows the two daughter duplexes that are being produced by complementary base pairing. Each of the daughter duplexes is identical in sequence with the original parent, and contains one parental strand and one newly synthesized strand. *The structure of DNA carries the information needed to perpetuate its sequence.*

The consequences of this mode of replication are illustrated in **Figure 1.12**. The parental duplex is replicated to form two daughter duplexes, each of which consists of one parental strand and one (newly synthesized) daughter strand. *The unit conserved from one generation to the next is one of the two individual strands comprising the parental duplex.* This behavior is called **semiconservative replication**.

**Figure 1.12** Replication of DNA is semiconservative.

The figure illustrates a prediction of this model. If the parental DNA carries a "heavy" density label because the organism has been grown in medium containing a suitable isotope (such as  $^{15}\text{N}$ ), its strands can be distinguished from those that are synthesized when the organism is transferred to a medium containing normal "light" isotopes.

The parental DNA consists of a duplex of two heavy strands (red). After one generation of growth in light medium, the duplex DNA is "hybrid" in density – it consists of one heavy parental strand (red) and one light daughter strand (blue). After a second generation, the two strands of each hybrid duplex have separated; each gains a light partner, so that now half of the duplex DNA remains hybrid while half is entirely light (both strands are blue).

*The individual strands of these duplexes are entirely heavy or entirely light. This pattern was confirmed experimentally in the Meselson-Stahl experiment of 1958, which followed the semiconservative replication of DNA through three generations of growth of *E. coli*. When DNA was extracted from bacteria and its density measured by centrifugation, the DNA formed bands corresponding to its density – heavy for parental, hybrid for the first generation, and half hybrid and half light in the second generation (377; for review see 2524).*

---

## GENES ARE DNA

### 1.1.8 DNA strands separate at the replication fork

---

#### Key Terms

A **replication fork (Growing point)** is the point at which strands of parental duplex DNA are separated so that replication can proceed. A complex of proteins including DNA polymerase is found at the fork.

A **DNA polymerase** is an enzyme that synthesizes a daughter strand(s) of DNA (under direction from a DNA template). Any particular enzyme may be involved in repair or replication (or both).

**RNA polymerases** are enzymes that synthesize RNA using a DNA template (formally described as DNA-dependent RNA polymerases).

A **deoxyribonuclease (DNAase)** is an enzyme that attacks bonds in DNA. It may cut only one strand or both strands.

**Ribonucleases (RNAase)** are enzymes that cleave RNA. They may be specific for single-stranded or for double-stranded RNA, and may be either endonucleases or exonucleases.

**Exonucleases** cleave nucleotides one at a time from the end of a polynucleotide chain; they may be specific for either the 5' or 3' end of DNA or RNA.

**Endonucleases** cleave bonds within a nucleic acid chain; they may be specific for RNA or for single-stranded or double-stranded DNA.

#### Key Concepts

- Replication of DNA is undertaken by a complex of enzymes that separate the parental strands and synthesize the daughter strands.
- The replication fork is the point at which the parental strands are separated.
- The enzymes that synthesize DNA are called DNA polymerases; the enzymes that synthesize RNA are RNA polymerases.
- Nucleases are enzymes that degrade nucleic acids; they include DNAases and RNAases, and can be divided into endonucleases and exonucleases.

---

Replication requires the two strands of the parental duplex to separate. However, the disruption of structure is only transient and is reversed as the daughter duplex is formed. Only a small stretch of the duplex DNA is separated into single strands at any moment.

The helical structure of a molecule of DNA engaged in replication is illustrated in **Figure 1.10**. The nonreplicated region consists of the parental duplex, opening into the replicated region where the two daughter duplexes have formed. The double helical structure is disrupted at the junction between the two regions, which is called the **replication fork**. Replication involves movement of the replication fork along the parental DNA, so there is a continuous unwinding of the parental strands and

rewinding into daughter duplexes.

**Figure 1.10** The replication fork is the region of DNA in which there is a transition from the unwound parental duplex to the newly replicated daughter duplexes.

The synthesis of nucleic acids is catalyzed by specific enzymes, which recognize the template and undertake the task of catalyzing the addition of subunits to the polynucleotide chain that is being synthesized. The enzymes are named according to the type of chain that is synthesized: **DNA polymerases** synthesize DNA, and **RNA polymerases** synthesize RNA.

Degradation of nucleic acids also requires specific enzymes: **deoxyribonucleases (DNAases)** degrade DNA, and **ribonucleases (RNAases)** degrade RNA. The nucleases fall into the general classes of **exonucleases** and **endonucleases**:

- Endonucleases cut individual bonds *within* RNA or DNA molecules, generating discrete fragments. Some DNAases cleave both strands of a duplex DNA at the target site, while others cleave only one of the two strands. Endonucleases are involved in cutting reactions, as shown in **Figure 1.11**.
- Exonucleases remove residues one at a time from the end of the molecule, generating mononucleotides. They always function on a single nucleic acid strand, and each exonuclease proceeds in a specific direction, that is, starting at either a 5' or at a 3' end and proceeding toward the other end. They are involved in trimming reactions, as shown in **Figure 1.12**.

**Figure 1.11** An endonuclease cleaves a bond within a nucleic acid. This example shows an enzyme that attacks one strand of a DNA duplex.

**Figure 1.12** An exonuclease removes bases one at a time by cleaving the last bond in a polynucleotide chain.

## GENES ARE DNA

### 1.1.9 Nucleic acids hybridize by base pairing

---

#### Key Terms

**Denaturation** of protein describes its conversion from the physiological conformation to some other (inactive) conformation.

**Renaturation** describes the reassociation of denatured complementary single strands of a DNA double helix.

**Annealing** of DNA describes the renaturation of a duplex structure from single strands that were obtained by denaturing duplex DNA.

**Hybridization** describes the pairing of complementary RNA and DNA strands to give an RNA-DNA hybrid.

#### Key Concepts

- Heating causes the two strands of a DNA duplex to separate.
- The  $T_m$  is the midpoint of the temperature range for denaturation.
- Complementary single strands can renature when the temperature is reduced.
- Denaturation and renaturation/hybridization can occur with DNA-DNA, DNA-RNA, or RNA-RNA combinations, and can be intermolecular or intramolecular.
- The ability of two single-stranded nucleic acid preparations to hybridize is a measure of their complementarity.

---

A crucial property of the double helix is the ability to separate the two strands without disrupting covalent bonds. This makes it possible for the strands to separate and reform under physiological conditions at the (very rapid) rates needed to sustain genetic functions. The specificity of the process is determined by complementary base pairing.

*The concept of base pairing is central to all processes involving nucleic acids. Disruption of the base pairs is a crucial aspect of the function of a double-stranded molecule, while the ability to form base pairs is essential for the activity of a single-stranded nucleic acid.* **Figure 1.16** shows that base pairing enables complementary single-stranded nucleic acids to form a duplex structure.

**Figure 1.16** Base pairing occurs in duplex DNA and also in intra- and inter-molecular interactions in single-stranded RNA (or DNA).

- An intramolecular duplex region can form by base pairing between two complementary sequences that are part of a single-stranded molecule.
- A single-stranded molecule may base pair with an independent, complementary single-stranded molecule to form an intermolecular duplex.

Formation of duplex regions from single-stranded nucleic acids is most important for RNA, but single-stranded DNA also exists (in the form of viral genomes). Base pairing between independent complementary single strands is not restricted to DNA-DNA or RNA-RNA, but can also occur between a DNA molecule and an RNA molecule.

The lack of covalent links between complementary strands makes it possible to manipulate DNA *in vitro*. The noncovalent forces that stabilize the double helix are disrupted by heating or by exposure to low salt concentration. The two strands of a double helix separate entirely when all the hydrogen bonds between them are broken.

The process of strand separation is called **denaturation** or (more colloquially) *melting*. ("Denaturation" is also used to describe loss of authentic protein structure; it is a general term implying that the natural conformation of a macromolecule has been converted to some other form.)

Denaturation of DNA occurs over a narrow temperature range and results in striking changes in many of its physical properties. The midpoint of the temperature range over which the strands of DNA separate is called the *melting temperature* ( $T_m$ ). It depends on the proportion of G·C base pairs. Because each G·C base pair has three hydrogen bonds, it is more stable than an A·T base pair, which has only two hydrogen bonds. The more G·C base pairs are contained in a DNA, the greater the energy that is needed to separate the two strands. In solution under physiological conditions, a DNA that is 40% G·C – a value typical of mammalian genomes – denatures with a  $T_m$  of about 87°C. So duplex DNA is stable at the temperature prevailing in the cell.

The denaturation of DNA is reversible under appropriate conditions. The ability of the two separated complementary strands to reform into a double helix is called **renaturation**. Renaturation depends on specific base pairing between the complementary strands. **Figure 1.17** shows that the reaction takes place in two stages. First, single strands of DNA in the solution encounter one another by chance; if their sequences are complementary, the two strands base pair to generate a short double-helical region. Then the region of base pairing extends along the molecule by a zipper-like effect to form a lengthy duplex molecule. Renaturation of the double helix restores the original properties that were lost when the DNA was denatured.

**Figure 1.17** Denatured single strands of DNA can renature to give the duplex form.

Renaturation describes the reaction between two complementary sequences that were separated by denaturation. However, the technique can be extended to allow any two complementary nucleic acid sequences to react with each other to form a duplex structure. This is sometimes called **annealing**, but the reaction is more generally described as **hybridization** whenever nucleic acids of different sources are involved, as in the case when one preparation consists of DNA and the other consists of RNA. *The ability of two nucleic acid preparations to hybridize constitutes a precise test for their complementarity since only complementary sequences can form a duplex structure.*

The principle of the hybridization reaction is to expose two single-stranded nucleic acid preparations to each other and then to measure the amount of double-stranded material that forms. **Figure 1.18** illustrates a procedure in which a DNA preparation is denatured and the single strands are adsorbed to a filter. Then a second denatured DNA (or RNA) preparation is added. The filter is treated so that the second preparation can adsorb to it only if it is able to base pair with the DNA that was originally adsorbed. Usually the second preparation is radioactively labeled, so that the reaction can be measured as the amount of radioactive label retained by the filter.

**Figure 1.18** Filter hybridization establishes whether a solution of denatured DNA (or RNA) contains sequences complementary to the strands immobilized on the filter.

The extent of hybridization between two single-stranded nucleic acids is determined by their complementarity. Two sequences need not be *perfectly* complementary to hybridize. If they are closely related but not identical, an imperfect duplex is formed in which base pairing is interrupted at positions where the two single strands do not correspond.

## GENES ARE DNA

### 1.1.10 Mutations change the sequence of DNA

---

#### Key Terms

**Spontaneous mutations** occur in the absence of any added reagent to increase the mutation rate, as the result of errors in replication (or other events involved in the reproduction of DNA) or by environmental damage.

The **background level** of mutation describes the rate at which sequence changes accumulate in the genome of an organism. It reflects the balance between the occurrence of spontaneous mutations and their removal by repair systems, and is characteristic for any species.

**Mutagens** increase the rate of mutation by inducing changes in DNA sequence, directly or indirectly.

**Induced mutations** result from the action of a mutagen. The mutagen may act directly on the bases in DNA or it may act indirectly to trigger a pathway that leads to a change in DNA sequence.

#### Key Concepts

- All mutations consist of changes in the sequence of DNA.
- Mutations may occur spontaneously or may be induced by mutagens.

---

Mutations provide decisive evidence that DNA is the genetic material. When a change in the sequence of DNA causes an alteration in the sequence of a protein, we may conclude that the DNA codes for that protein. Furthermore, a change in the phenotype of the organism may allow us to identify the function of the protein. The existence of many mutations in a gene may allow many variant forms of a protein to be compared, and a detailed analysis can be used to identify regions of the protein responsible for individual enzymatic or other functions.

All organisms suffer a certain number of mutations as the result of normal cellular operations or random interactions with the environment. These are called **spontaneous mutations**; the rate at which they occur is characteristic for any particular organism and is sometimes called the **background level**. Mutations are rare events, and of course those that damage a gene are selected against during evolution. It is therefore difficult to obtain large numbers of spontaneous mutants to study from natural populations.

The occurrence of mutations can be increased by treatment with certain compounds. These are called **mutagens**, and the changes they cause are referred to as **induced mutations**. Most mutagens act directly by virtue of an ability either to modify a particular base of DNA or to become incorporated into the nucleic acid. The effectiveness of a mutagen is judged by how much it increases the rate of mutation above background. By using mutagens, it becomes possible to induce many changes in any gene (for review see 3).

Spontaneous mutations that inactivate gene function occur in bacteriophages and bacteria at a relatively constant rate of  $3-4 \times 10^{-3}$  per genome per generation (2221). Given the large variation in genome sizes between bacteriophages and bacteria, this corresponds to wide differences in the mutation rate per base pair. This suggests that the overall rate of mutation has been subject to selective forces that have balanced the deleterious effects of most mutations against the advantageous effects of some mutations. This conclusion is strengthened by the observation that an archaeal microbe that lives under harsh conditions of high temperature and acidity (which are expected to damage DNA) does not show an elevated mutation rate, but in fact has an overall mutation rate just below the average range (2203).

**Figure 1.19** shows that in bacteria, the mutation rate corresponds to  $\sim 10^{-6}$  events per locus per generation or to an average rate of change per base pair of  $10^{-9}$ - $10^{-10}$  per generation. The rate at individual base pairs varies very widely, over a 10,000 fold range. We have no accurate measurement of the rate of mutation in eukaryotes, although usually it is thought to be somewhat similar to that of bacteria on a per-locus per-generation basis (2487).

**Figure 1.19** A base pair is mutated at a rate of  $10^{-9} - 10^{-10}$  per generation, a gene of 1000 bp is mutated at  $\sim 10^{-6}$  per generation, and a bacterial genome is mutated at  $3 \times 10^{-3}$  per generation.

## GENES ARE DNA

### 1.1.11 Mutations may affect single base pairs or longer sequences

---

#### Key Terms

A **point mutation** is a change in the sequence of DNA involving a single base pair.

A **transition** is a mutation in which one pyrimidine is replaced by the other and/or in which one purine is replaced by the other.

A **transversion** is a mutation in which a purine is replaced by a pyrimidine or vice versa.

**Base mispairing** is a coupling between two bases that does not conform to the Watson-Crick rule, e.g., adenine with cytosine, thymine with guanine.

An **insertion** is the addition of a stretch of base pairs in DNA. Duplications are a special class of insertions.

A **transposon (transposable element)** is a DNA sequence able to insert itself (or a copy of itself) at a new location in the genome, without having any sequence relationship with the target locus.

A **deletion** is the removal of a sequence of DNA, the regions on either side being joined together except in the case of a terminal deletion at the end of a chromosome.

#### Key Concepts

- A point mutation changes a single base pair.
- Point mutations can be caused by the chemical conversion of one base into another or by mistakes that occur during replication.
- A transition replaces a G·C base pair with an A·T base pair or vice-versa.
- A transversion replaces a purine with a pyrimidine, such as changing A·T to T·A.
- Insertions are the most common type of mutation, and result from the movement of transposable elements.

---

*Any base pair of DNA can be mutated. A **point mutation** changes only a single base pair, and can be caused by either of two types of event (for review see 3238):*

- Chemical modification of DNA directly changes one base into a different base.
- A malfunction during the replication of DNA causes the wrong base to be inserted into a polynucleotide chain during DNA synthesis.

Point mutations can be divided into two types, depending on the nature of the change when one base is substituted for another:

- The most common class is the **transition**, comprising the substitution of one pyrimidine by the other, or of one purine by the other. This replaces a G·C pair with an A·T pair or vice versa.
- The less common class is the **transversion**, in which a purine is replaced by a pyrimidine or vice versa, so that an A·T pair becomes a T·A or C·G pair.

The effects of nitrous acid provide a classic example of a transition caused by the chemical conversion of one base into another. **Figure 1.20** shows that nitrous acid performs an oxidative deamination that converts cytosine into uracil. In the replication cycle following the transition, the U pairs with an A, instead of with the G with which the original C would have paired. So the C·G pair is replaced by a T·A pair when the A pairs with the T in the next replication cycle. (Nitrous acid also deaminates adenine, causing the reverse transition from A·T to G·C.)

**Figure 1.20** Mutations can be induced by chemical modification of a base.

Transitions are also caused by **base mispairing**, when unusual partners pair in defiance of the usual restriction to Watson-Crick pairs. Base mispairing usually occurs as an aberration resulting from the incorporation into DNA of an abnormal base that has ambiguous pairing properties. **Figure 1.21** shows the example of bromouracil (BrdU), an analog of thymine that contains a bromine atom in place of the methyl group of thymine. BrdU is incorporated into DNA in place of thymine. But it has ambiguous pairing properties, because the presence of the bromine atom allows a shift to occur in which the base changes structure from a keto (=O) form to an enol (-OH) form. The enol form can base pair with guanine, which leads to substitution of the original A·T pair by a G·C pair.

**Figure 1.21** Mutations can be induced by the incorporation of base analogs into DNA.

The mistaken pairing can occur either during the original incorporation of the base or in a subsequent replication cycle. The transition is induced with a certain probability in each replication cycle, so the incorporation of BrdU has continuing effects on the sequence of DNA.

Point mutations were thought for a long time to be the principal means of change in individual genes. However, we now know that **insertions** of stretches of additional material are quite frequent. The source of the inserted material lies with **transposable elements**, sequences of DNA with the ability to move from one site to another (see *Molecular Biology 4.16 Transposons* and *Molecular Biology 4.17 Retroviruses and retroposons*.) An insertion usually abolishes the activity of a gene. Where such insertions have occurred, **deletions** of part or all of the inserted material, and sometimes of the adjacent regions, may subsequently occur.

A significant difference between point mutations and the insertions/deletions is that the frequency of point mutation can be increased by mutagens, whereas the occurrence of changes caused by transposable elements is not affected. However, insertions and deletions can also occur by other mechanisms – for example, involving mistakes made during replication or recombination – although probably

these are less common. And a class of mutagens called the acridines introduce (very small) insertions and deletions.

## GENES ARE DNA

### 1.1.12 The effects of mutations can be reversed

---

#### Key Terms

**Revertants** are derived by reversion of a mutant cell or organism to the wild-type phenotype.

**Forward mutations** inactivate a wild-type gene.

A **back mutation** reverses the effect of a mutation that had inactivated a gene; thus it restores wild type.

A **true reversion** is a mutation that restores the original sequence of the DNA.

**Second-site reversion** occurs when a second mutation suppresses the effect of a first mutation.

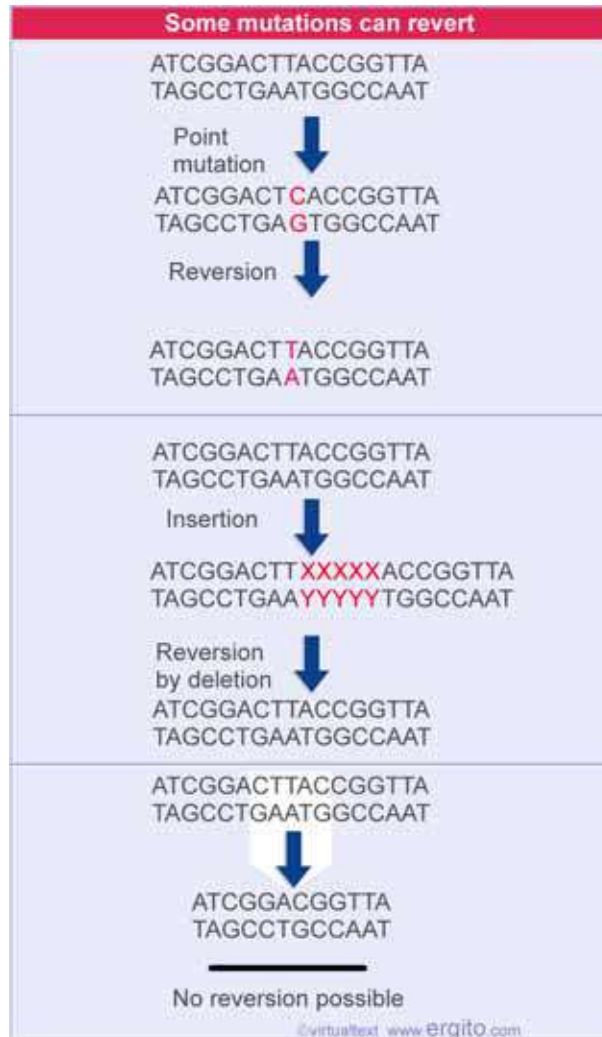

**Suppression** occurs when a second event eliminates the effects of a mutation without reversing the original change in DNA.

A **suppressor** is a second mutation that compensates for or alters the effects of a primary mutation.

#### Key Concepts

- Forward mutations inactivate a gene, and back mutations (or revertants) reverse their effects.
  - Insertions can revert by deletion of the inserted material, but deletions cannot revert.
  - Suppression occurs when a mutation in a second gene bypasses the effect of mutation in the first gene.
- 

**Figure 1.22** shows that the isolation of **revertants** is an important characteristic that distinguishes point mutations and insertions from deletions:

**Figure 1.22** Point mutations and insertions can revert, but deletions cannot revert.

- A point mutation can revert by restoring the original sequence or by gaining a compensatory mutation elsewhere in the gene.
- An insertion of additional material can revert by deletion of the inserted material.
- A deletion of part of a gene cannot revert.

Mutations that inactivate a gene are called **forward mutations**. Their effects are reversed by **back mutations**, which are of two types.

An exact reversal of the original mutation is called **true reversion**. So if an A-T pair has been replaced by a G-C pair, another mutation to restore the A-T pair will exactly regenerate the wild-type sequence.

Alternatively, another mutation may occur elsewhere in the gene, and its effects

compensate for the first mutation. This is called **second-site reversion**. For example, one amino acid change in a protein may abolish gene function, but a second alteration may compensate for the first and restore protein activity.

A forward mutation results from any change that inactivates a gene, whereas a back mutation must restore function to a protein damaged by a particular forward mutation. So the demands for back mutation are much more specific than those for forward mutation. The rate of back mutation is correspondingly lower than that of forward mutation, typically by a factor of ~10.

Mutations can also occur in other genes to circumvent the effects of mutation in the original gene. This effect is called **suppression**. A locus in which a mutation suppresses the effect of a mutation in another locus is called a **suppressor**.

*This content is available online at <http://www.ergito.com/main.jsp?bcs=MBIO.1.1.12>*

---

## GENES ARE DNA

### 1.1.13 Mutations are concentrated at hotspots

---

#### Key Terms

A **hotspot** is a site in the genome at which the frequency of mutation (or recombination) is very much increased, usually by at least an order of magnitude relative to neighboring sites.

#### Key Concepts

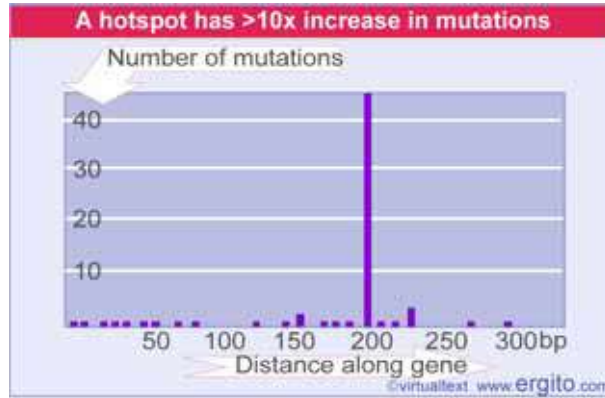

- The frequency of mutation at any particular base pair is determined by statistical fluctuation, except for hotspots, where the frequency is increased by at least an order of magnitude.

---

So far we have dealt with mutations in terms of individual changes in the sequence of DNA that influence the activity of the genetic unit in which they occur. When we consider mutations in terms of the inactivation of the gene, most genes within a species show more or less similar rates of mutation relative to their size. This suggests that the gene can be regarded as a target for mutation, and that damage to any part of it can abolish its function. As a result, susceptibility to mutation is roughly proportional to the size of the gene. But consider the sites of mutation within the sequence of DNA; are all base pairs in a gene equally susceptible or are some more likely to be mutated than others?

What happens when we isolate a large number of independent mutations in the same gene? Many mutants are obtained. Each is the result of an individual mutational event. Then the site of each mutation is determined. Most mutations will lie at different sites, but some will lie at the same position. Two independently isolated mutations at the same site may constitute exactly the same change in DNA (in which case the same mutational event has happened on more than one occasion), or they may constitute different changes (three different point mutations are possible at each base pair).

The histogram of **Figure 1.23** shows the frequency with which mutations are found at each base pair in the *lacI* gene of *E. coli*. The statistical probability that more than one mutation occurs at a particular site is given by random-hit kinetics (as seen in the Poisson distribution). So some sites will gain one, two, or three mutations, while others will not gain any. But some sites gain far more than the number of mutations expected from a random distribution; they may have 10× or even 100× more mutations than predicted by random hits. These sites are called **hotspots**. Spontaneous mutations may occur at hotspots; and different mutagens may have different hotspots.

**Figure 1.23** Spontaneous mutations occur throughout the *lacI* gene of *E. coli*, but are concentrated at a hotspot.

This content is available online at <http://www.ergito.com/main.jsp?bcs=MBIO.1.1.13>

---

## GENES ARE DNA

### 1.1.14 Many hotspots result from modified bases

---

#### Key Terms

**Modified bases** are all those except the usual four from which DNA (T, C, A, G) or RNA (U, C, A, G) are synthesized; they result from postsynthetic changes in the nucleic acid.

A **mismatch** describes a site in DNA where the pair of bases does not conform to the usual G-C or A-T pairs. It may be caused by incorporation of the wrong base during replication or by mutation of a base.

#### Key Concepts

- A common cause of hotspots is the modified base 5-methylcytosine, which is spontaneously deaminated to thymine.

---

A major cause of spontaneous mutation results from the presence of an unusual base in the DNA. In addition to the four bases that are inserted into DNA when it is synthesized, **modified bases** are sometimes found. The name reflects their origin; they are produced by chemically modifying one of the four bases already present in DNA. The most common modified base is 5-methylcytosine, generated by a methylase enzyme that adds a methyl group to certain cytosine residues at specific sites in the DNA.

Sites containing 5-methylcytosine provide hotspots for spontaneous point mutation in *E. coli*. In each case, the mutation takes the form of a G·C to A·T transition. The hotspots are not found in strains of *E. coli* that cannot methylate cytosine.

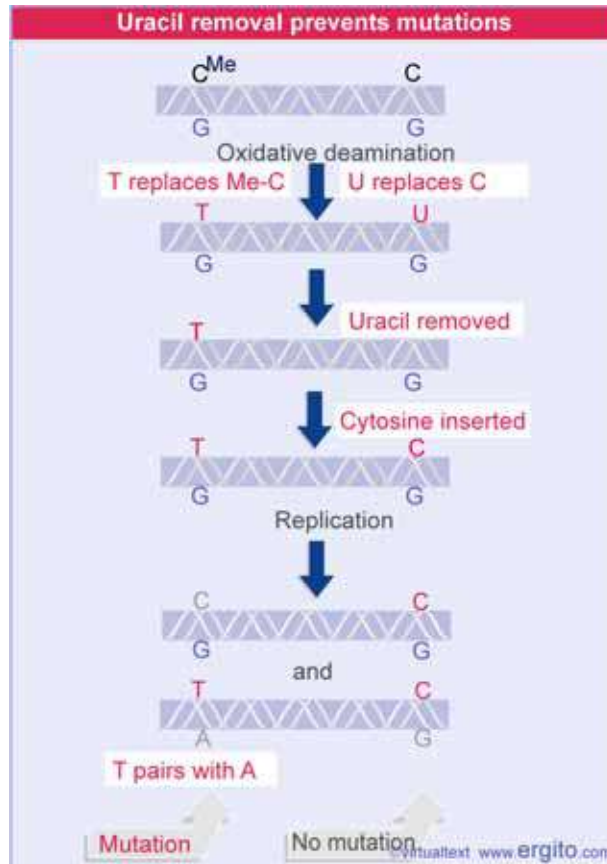

The reason for the existence of the hotspots is that cytosine bases suffer spontaneous deamination at an appreciable frequency. In this reaction, the amino group is replaced by a keto group. Recall that deamination of cytosine generates uracil (see **Figure 1.20**). **Figure 1.24** compares this reaction with the deamination of 5-methylcytosine where deamination generates thymine. The effect in DNA is to generate the base pairs G·U and G·T, respectively, where there is a **mismatch** between the partners.

**Figure 1.24** Deamination of cytosine produces uracil, whereas deamination of 5-methyl-cytosine produces thymine.

All organisms have repair systems that correct mismatched base pairs by removing and replacing one of the bases. The operation of these systems determines whether mismatched pairs such as G·U and G·T result in mutations.

**Figure 1.25** shows that the consequences of deamination are different for 5-methylcytosine and cytosine. Deaminating the (rare) 5-methylcytosine causes a mutation, whereas deamination of the more common cytosine does not have this effect (382). This happens because the repair systems are much more effective in recognizing G·U than G·T.

**Figure 1.25** The deamination of 5-methylcytosine produces thymine (by C-G to T-A transitions), while the deamination of cytosine produces uracil (which usually is removed and then replaced by cytosine).

*E. coli* contains an enzyme, uracil-DNA-glycosidase, that removes uracil residues from DNA (see *Molecular Biology 4.15.22 Base flipping is used by methylases and glycosylases*). This action leaves an unpaired G residue, and a "repair system" then inserts a C base to partner it. The net result of these reactions is to restore the original sequence of the DNA. This system protects DNA against the consequences of spontaneous deamination of cytosine (although it is not active enough to prevent the effects of the increased level of deamination caused by nitrous acid; see **Figure 1.20**).

But the deamination of 5-methylcytosine leaves thymine. This creates a mismatched base pair, G-T. If the mismatch is not corrected before the next replication cycle, a mutation results. At the next replication, the bases in the mispaired G-T partnership separate, and then they pair with new partners to produce one wild-type G-C pair and one mutant A-T pair.

Deamination of 5-methylcytosine is the most common cause of production of G-T mismatched pairs in DNA. Repair systems that act on G-T mismatches have a bias toward replacing the T with a C (rather than the alternative of replacing the G with an A), which helps to reduce the rate of mutation (see *Molecular Biology 4.15.24 Controlling the direction of mismatch repair*). However, these

systems are not as effective as the removal of U from G·U mismatches. As a result, deamination of 5-methylcytosine leads to mutation much more often than does deamination of cytosine.

5-methylcytosine also creates hotspots in eukaryotic DNA. It is common at CpG dinucleotides that are concentrated in regions called CpG islands (see *Molecular Biology 5.21.19 CpG islands are regulatory targets*). Although 5-methylcytosine accounts for ~1% of the bases in human DNA, sites containing the modified base account for ~30% of all point mutations. This makes the state of 5-methylcytosine a particularly important determinant of mutation in animal cells.

The importance of repair systems in reducing the rate of mutation is emphasized by the effects of eliminating the mouse enzyme MBD4, a glycosylase that can remove T (or U) from mismatches with G. The result is to increase the mutation rate at CpG sites by a factor of  $3\times$  (2845). (The reason the effect is not greater is that MBD4 is only one of several systems that act on G·T mismatches; we can imagine that elimination of all the systems would increase the mutation rate much more.)

The operation of these systems casts an interesting light on the use of T in DNA compared with U in RNA. Perhaps it relates to the need of DNA for stability of sequence; the use of T means that any deaminations of C are immediately recognized, because they generate a base (U) not usually present in the DNA. This greatly increases the efficiency with which repair systems can function (compared with the situation when they have to recognize G·T mismatches, which can be produced also by situations where removing the T would not be the appropriate response). Also, the phosphodiester bond of the backbone is more labile when the base is U.

## GENES ARE DNA

### 1.1.15 A gene codes for a single polypeptide

---

#### Key Terms

A **homomultimer** is a protein composed of identical subunits.

A **heteromultimer** is a protein that is composed of nonidentical subunits (coded by different genes).

#### Key Concepts

- The one gene : one enzyme hypothesis summarizes the basis of modern genetics: that a gene is a stretch of DNA coding for a single polypeptide chain.
  - Most mutations damage gene function.
- 

The first systematic attempt to associate genes with enzymes showed that each stage in a metabolic pathway is catalyzed by a single enzyme and can be blocked by mutation in a different gene. This led to the *one gene : one enzyme hypothesis*. Each metabolic step is catalyzed by a particular enzyme, whose production is the responsibility of a single gene. A mutation in the gene alters the activity of the protein for which it is responsible.

A modification in the hypothesis is needed to accommodate proteins that consist of more than one subunit. If the subunits are all the same, the protein is a **homomultimer**, represented by a single gene. If the subunits are different, the protein is a **heteromultimer**. Stated as a more general rule applicable to any heteromultimeric protein, the one gene : one enzyme hypothesis becomes more precisely expressed as *one gene : one polypeptide chain*.

Identifying which protein represents a particular gene can be a protracted task. The mutation responsible for creating Mendel's wrinkled-pea mutant was identified only in 1990 as an alteration that inactivates the gene for a starch branching enzyme!

It is important to remember that a gene does not directly generate a protein. As shown previously in **Figure 1.2**, a gene codes for an RNA, which may in turn code for a protein. Most genes code for proteins, but some genes code for RNAs that do not give rise to proteins. These RNAs may be structural components of the apparatus responsible for synthesizing proteins or may have roles in regulating gene expression. The basic principle is that the gene is a sequence of DNA that specifies the sequence of an independent product. The process of gene expression may terminate in a product that is either RNA or protein.

A mutation is a random event with regard to the structure of the gene, so the greatest probability is that it will damage or even abolish gene function. Most mutations that affect gene function are recessive: *they represent an absence of function, because the mutant gene has been prevented from producing its usual protein.* **Figure 1.26** illustrates the relationship between recessive and wild-type alleles. When a

heterozygote contains one wild-type allele and one mutant allele, the wild-type allele is able to direct production of the enzyme. The wild-type allele is therefore dominant. (This assumes that an adequate *amount* of protein is made by the single wild-type allele. When this is not true, the smaller amount made by one allele as compared to two alleles results in the intermediate phenotype of a partially dominant allele in a heterozygote.)

**Figure 1.26** Genes code for proteins; dominance is explained by the properties of mutant proteins. A recessive allele does not contribute to the phenotype because it produces no protein (or protein that is nonfunctional).

## GENES ARE DNA

### 1.1.16 Mutations in the same gene cannot complement

---

#### Key Terms

A **complementation test** determines whether two mutations are alleles of the same gene. It is accomplished by crossing two different recessive mutations that have the same phenotype and determining whether the wild-type phenotype can be produced. If so, the mutations are said to complement each other and are probably not mutations in the same gene.

Two mutants are said to **complement** each other when a diploid that is heterozygous for each mutation produces the wild type phenotype.

A **complementation group** is a series of mutations unable to complement when tested in pairwise combinations in *trans*; defines a genetic unit (the cistron).

A **cistron** is the genetic unit defined by the complementation test; it is equivalent to the gene.

A **gene (cistron)** is the segment of DNA specifying production of a polypeptide chain; it includes regions preceding and following the coding region (leader and trailer) as well as intervening sequences (introns) between individual coding segments (exons).

#### Key Concepts

- A mutation in a gene affects only the protein coded by the mutant copy of the gene, and does not affect the protein coded by any other allele.
- Failure of two mutations to complement (produce wild-phenotype) when they are present in *trans* configuration in a heterozygote means that they are part of the same gene.

---

How do we determine whether two mutations that cause a similar phenotype lie in the same gene? If they map close together, they may be alleles. However, they could also represent mutations in two *different* genes whose proteins are involved in the same function. The **complementation test** is used to determine whether two mutations lie in the same gene or in different genes. The test consists of making a heterozygote for the two mutations (by mating parents homozygous for each mutation).

If the mutations lie in the same gene, the parental genotypes can be represented as:

$$\frac{m_1}{m_1} \quad \text{and} \quad \frac{m_2}{m_2}$$

The first parent provides an  $m_1$  mutant allele and the second parent provides an  $m_2$

allele, so that the heterozygote has the constitution:

$$\frac{m_1}{m_2}$$

No wild-type gene is present, so the heterozygote has mutant phenotype.

If the mutations lie in different genes, the parental genotypes can be represented as:

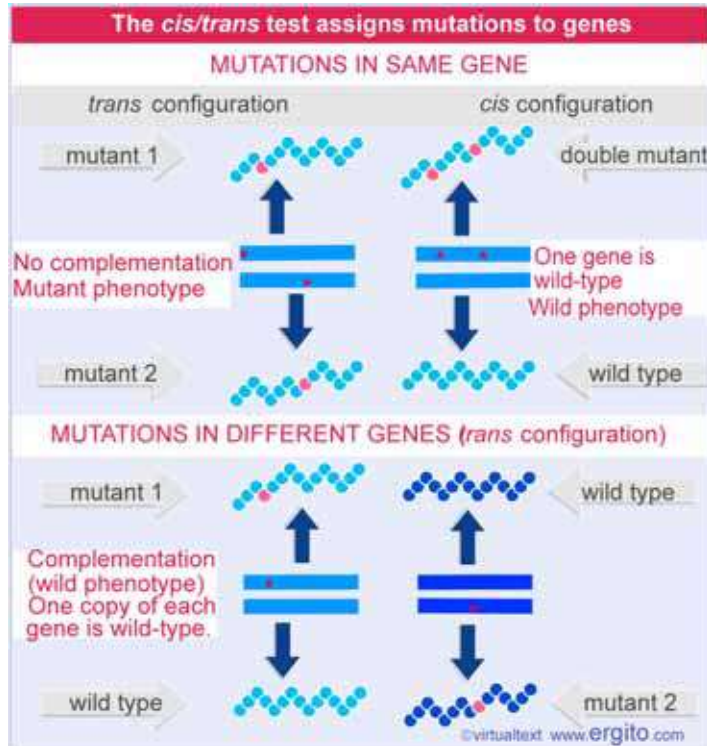

$$\frac{m_1 +}{m_1 +} \text{ and } \frac{+ m_2}{+ m_2}$$

Each chromosome has a wild-type copy of one gene (represented by the plus sign) and a mutant copy of the other. Then the heterozygote has the constitution:

$$\frac{m_1 +}{+ m_2}$$

in which the two parents between them have provided a wild-type copy of each gene. The heterozygote has wild phenotype; the two genes are said to **complement**.

The complementation test is shown in more detail in **Figure 1.27**. The basic test consists of the comparison shown in the top part of the figure. If two mutations lie in the same gene, we see a difference in the phenotypes of the *trans* configuration and the *cis* configuration. The *trans* configuration is mutant, because each allele has a (different) mutation. But the *cis* configuration is wild-type, because one allele has two mutations but the other allele has no mutations. The lower part of the figure shows that if the two mutations lie in different genes, we always see a wild phenotype. There is always one wild-type and one mutant allele of each gene, and the configuration is irrelevant. The basic test and some exceptions to it are discussed in *Molecular Biology Supplement 32.9 Complementation*.

**Figure 1.27** The cistron is defined by the complementation test. Genes are represented by bars; red stars identify sites of mutation.

Failure to complement means that two mutations are part of the *same* genetic unit. Mutations that do not complement one another are said to comprise part of the **same complementation group**. Another term that is used to describe the unit defined by the complementation test is the **cistron**. This is the same as the **gene**. Basically these three terms all describe a stretch of DNA that functions as a unit to give rise to an RNA or protein product. The properties of the gene with regards to complementation are explained by the fact that this product is a single molecule that behaves as a functional unit.

## GENES ARE DNA

### 1.1.17 Mutations may cause loss-of-function or gain-of-function

---

#### Key Terms

A **null mutation** completely eliminates the function of a gene.

**Leaky mutations** leave some residual function, for instance when the mutant protein is partially active (in the case of a missense mutation), or when read-through produces a small amount of wild-type protein (in the case of a nonsense mutation).

A **loss-of-function** mutation eliminates or reduces the activity of a gene. It is often, but not always, recessive.

A **gain-of-function** mutation usually refers to a mutation that causes an increase in the normal gene activity. It sometimes represents acquisition of certain abnormal properties. It is often, but not always, dominant.

**Silent mutations** do not change the sequence of a protein because they produce synonymous codons.

**Neutral substitutions** in a protein cause changes in amino acids that do not affect activity.

#### Key Concepts

- Recessive mutations are due to loss-of-function by the protein product.
  - Dominant mutations result from a gain-of-function.
  - Testing whether a gene is essential requires a null mutation (one that completely eliminates its function).
  - Silent mutations have no effect, either because the base change does not change the sequence or amount of protein, or because the change in protein sequence has no effect.
  - Leaky mutations do affect the function of the gene product, but are not revealed in the phenotype because sufficient activity remains.
- 

The various possible effects of mutation in a gene are summarized in **Figure 1.28**.

**Figure 1.28** Mutations that do not affect protein sequence or function are silent. Mutations that abolish all protein activity are null. Point mutations that cause loss-of-function are recessive; those that cause gain-of-function are dominant.

When a gene has been identified, insight into its function in principle can be gained by generating a mutant organism that entirely lacks the gene. A mutation that completely eliminates gene function, usually because the gene has been deleted, is called a **null mutation**. If a gene is essential, a null mutation is lethal.

To determine what effect a gene has upon the phenotype, it is essential to characterize a null mutant. When a mutation fails to affect the phenotype, it is always possible that this is because it is a **leaky mutation** – enough active product is made to fulfill its function, even though the activity is quantitatively reduced or qualitatively different from the wild type. But if a null mutant fails to affect a phenotype, we may safely conclude that the gene function is not necessary.

Null mutations, or other mutations that impede gene function (but do not necessarily abolish it entirely) are called **loss-of-function** mutations. A loss-of-function mutation is recessive (as in the example of **Figure 1.26**). Sometimes a mutation has the opposite effect and causes a protein to acquire a new function; such a change is called a **gain-of-function** mutation. A gain-of-function mutation is dominant.

Not all mutations in DNA lead to a detectable change in the phenotype. Mutations without apparent effect are called **silent mutations**. They fall into two types. Some involve base changes in DNA that do not cause any change in the amino acid present in the corresponding protein. Others change the amino acid, but the replacement in

the protein does not affect its activity; these are called **neutral substitutions**.

## GENES ARE DNA

### 1.1.18 A locus may have many different mutant alleles

---

#### Key Terms

A locus is said to have **multiple alleles** when more than two allelic forms have been found. Each allele may cause a different phenotype.

#### Key Concepts

- The existence of multiple alleles allows heterozygotes to occur representing any pairwise combination of alleles.

---

If a recessive mutation is produced by every change in a gene that prevents the production of an active protein, there should be a large number of such mutations in any one gene. Many amino acid replacements may change the structure of the protein sufficiently to impede its function.

Different variants of the same gene are called **multiple alleles**, and their existence makes it possible to create a heterozygote between mutant alleles. The relationship between these multiple alleles takes various forms.

In the simplest case, a wild-type gene codes for a protein product that is functional. Mutant allele(s) code for proteins that are nonfunctional.

But there are often cases in which a series of mutant alleles have different phenotypes. For example, wild-type function of the *white* locus of *D. melanogaster* is required for development of the normal red color of the eye. The locus is named for the effect of extreme (null) mutations, which cause the fly to have a white eye in mutant homozygotes.

To describe wild-type and mutant alleles, wild genotype is indicated by a plus superscript after the name of the locus ( $w^+$  is the wild-type allele for [red] eye color in *D. melanogaster*). Sometimes + is used by itself to describe the wild-type allele, and only the mutant alleles are indicated by the name of the locus.

An entirely defective form of the gene (or absence of phenotype) may be indicated by a minus superscript. To distinguish among a variety of mutant alleles with different effects, other superscripts may be introduced, such as  $w^i$  or  $w^a$ .

The  $w^+$  allele is dominant over any other allele in heterozygotes. There are many different mutant alleles. **Figure 1.29** shows a (small) sample. Although some alleles have no eye color, many alleles produce some color. Each of these mutant alleles must therefore represent a different mutation of the gene, which does not eliminate its function entirely, but leaves a residual activity that produces a characteristic phenotype. These alleles are named for the color of the eye in a homozygote. (Most

$w$  alleles affect the quantity of pigment in the eye, and the examples in the Figure are arranged in [roughly] declining amount of color, but others, such as  $w^{sp}$ , affect the pattern in which it is deposited.)

Each allele has a different phenotype	
Allele	Phenotype of homozygote
$w^+$	red eye (wild type)
$w^{bl}$	blood
$w^{ch}$	cherry
$w^{bf}$	buff
$w^h$	honey
$w^a$	apricot
$w^e$	eosin
$w^l$	ivory
$w^z$	zeste (lemon-yellow)
$w^{sp}$	mottled, color varies
$w^1$	white (no color)

©virtualtext www.ergito.com

**Figure 1.29** The  $w$  locus has an extensive series of alleles, whose phenotypes extend from wild-type (red) color to complete lack of pigment.

When multiple alleles exist, an animal may be a heterozygote that carries two different mutant alleles. The phenotype of such a heterozygote depends on the nature of the residual activity of each allele. The relationship between two mutant alleles is in principle no different from that between wild-type and mutant alleles: one allele may be dominant, there may be partial dominance, or there may be codominance.

*This content is available online at <http://www.ergito.com/main.jsp?bcs=MBIO.1.1.18>*

## GENES ARE DNA

### 1.1.19 A locus may have more than one wild-type allele

---

#### Key Terms

**Polymorphism** (more fully genetic polymorphism) refers to the simultaneous occurrence in the population of genomes showing variations at a given position. The original definition applied to alleles producing different phenotypes. Now it is also used to describe changes in DNA affecting the restriction pattern or even the sequence. For practical purposes, to be considered as an example of a polymorphism, an allele should be found at a frequency > 1% in the population.

#### Key Concepts

- A locus may have a polymorphic distribution of alleles, with no individual allele that can be considered to be the sole wild-type.

---

There is not necessarily a unique wild-type allele at any particular locus. Control of the human blood group system provides an example. Lack of function is represented by the null type, *O* group. But the functional alleles *A* and *B* provide activities that are codominant with one another and dominant over *O* group. The basis for this relationship is illustrated in **Figure 1.30**.

**Figure 1.30** The ABO blood group locus codes for a galactosyltransferase whose specificity determines the blood group.

The O (or H) antigen is generated in all individuals, and consists of a particular carbohydrate group that is added to proteins. The *ABO* locus codes for a galactosyltransferase enzyme that adds a further sugar group to the O antigen. The specificity of this enzyme determines the blood group. The *A* allele produces an enzyme that uses the cofactor UDP-N-acetylgalactose, creating the A antigen. The *B* allele produces an enzyme that uses the cofactor UDP-galactose, creating the B antigen. The A and B versions of the transferase protein differ in 4 amino acids that presumably affect its recognition of the type of cofactor. The *O* allele has a mutation (a small deletion) that eliminates activity, so no modification of the O antigen occurs.

This explains why *A* and *B* alleles are dominant in the *AO* and *BO* heterozygotes: the corresponding transferase activity creates the A or B antigen. The *A* and *B* alleles are codominant in *AB* heterozygotes, because both transferase activities are expressed. The *OO* homozygote is a null that has neither activity, and therefore lacks both antigens.

Neither *A* nor *B* can be regarded as uniquely wild type, since they represent alternative activities rather than loss or gain of function. A situation such as this, in which there are multiple functional alleles in a population, is described as a **polymorphism** (see *Molecular Biology 1.3.3 Individual genomes show extensive*

*variation).*

## GENES ARE DNA

### 1.1.20 Recombination occurs by physical exchange of DNA

---

#### Key Terms

**Crossing-over** describes the reciprocal exchange of material between chromosomes that occurs during prophase I of meiosis and is responsible for genetic recombination.

A **bivalent** is the structure containing all four chromatids (two representing each homologue) at the start of meiosis.

**Chromatids** are the copies of a chromosome produced by replication. The name is usually used to describe the copies in the period before they separate at the subsequent cell division.

A **chiasma** (*pl.* chiasmata) is a site at which two homologous chromosomes appear to have exchanged material during meiosis.

**Breakage and reunion** describes the mode of genetic recombination, in which two DNA duplex molecules are broken at corresponding points and then rejoined crosswise (involving formation of a length of heteroduplex DNA around the site of joining).

**Heteroduplex DNA (Hybrid DNA)** is generated by base pairing between complementary single strands derived from the different parental duplex molecules; it occurs during genetic recombination.

#### Key Concepts

- Recombination is the result of crossing-over that occurs at chiasmata and involves two of the four chromatids.
  - Recombination occurs by a breakage and reunion that proceeds via an intermediate of hybrid DNA.
- 

Genetic recombination describes the generation of new combinations of alleles that occurs at each generation in diploid organisms. The two copies of each chromosome may have different alleles at some loci. By exchanging corresponding parts between the chromosomes, recombinant chromosomes can be generated that are different from the parental chromosomes.

Recombination results from a physical exchange of chromosomal material. This is visible in the form of the **crossing-over** that occurs during meiosis (the specialized division that produces haploid germ cells). Meiosis starts with a cell that has duplicated its chromosomes, so that it has four copies of each chromosome. Early in meiosis, all four copies are closely associated (synapsed) in a structure called a **bivalent**. Each individual chromosomal unit is called a **chromatid** at this stage. Pairwise exchanges of material occur between the chromatids.

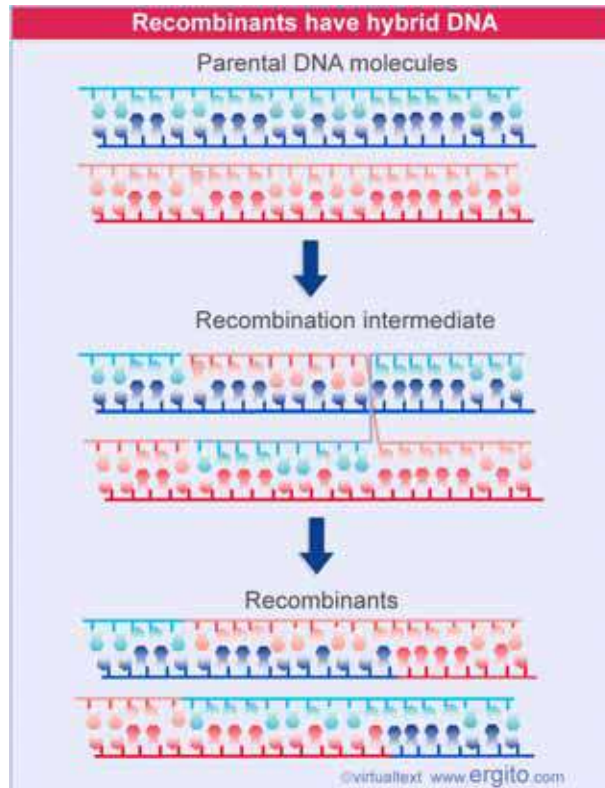

The visible result of a crossing-over event is called a **chiasma**, and is illustrated diagrammatically in **Figure 1.31**. A chiasma represents a site at which two of the chromatids in a bivalent have been broken at corresponding points. The broken ends have been rejoined crosswise, generating new chromatids. Each new chromatid consists of material derived from one chromatid on one side of the junction point, with material from the other chromatid on the opposite side. The two recombinant chromatids have reciprocal structures. The event is described as a **breakage and reunion**. Its nature explains why a single recombination event can produce only 50% recombinants: each individual recombination event involves only two of the four associated chromatids.

**Figure 1.31** Chiasma formation is responsible for generating recombinants.

The complementarity of the two strands of DNA is essential for the recombination process. Each of the chromatids shown in **Figure 1.31** consists of a very long duplex of DNA. For them to be broken and reconnected without any loss of material requires a mechanism to recognize exactly corresponding positions. This is provided by complementary base pairing.

Recombination involves a process in which the single strands in the region of the crossover exchange their partners. **Figure 1.32** shows that this creates a stretch of **hybrid DNA** in which the single strand of one duplex is paired with its complement from the other duplex. The mechanism of course involves other stages (strands must be broken and resealed), and we discuss this in more detail in *Molecular Biology 4.15 Recombination and repair*, but the crucial feature that makes precise recombination possible is the complementarity of DNA strands. The figure shows only some stages of the reaction, but we see that a stretch of hybrid DNA forms in the recombination intermediate when a single strand crosses over from one duplex to the other. Each recombinant consists of one parental duplex DNA at the left, connected by a stretch of hybrid DNA to the other parental duplex at the right. Each duplex DNA corresponds to one of the chromatids involved in recombination in **Figure 1.31**.

**Figure 1.32** Recombination involves pairing between complementary strands of the two parental duplex DNAs.

The formation of hybrid DNA requires the sequences of the two recombining duplexes to be close enough to allow pairing between the complementary strands. If there are no differences between the two parental genomes in this region, formation of hybrid DNA will be perfect. But the reaction can be tolerated even when there are small differences. In this case, the hybrid DNA has points of mismatch, at which a base in one strand faces a base in the other strand that is not complementary to it. The correction of such mismatches is another feature of genetic recombination (see *Molecular Biology 4.15 Recombination and repair*).

## GENES ARE DNA

### 1.1.21 The genetic code is triplet

---

#### Key Terms

The **genetic code** is the correspondence between triplets in DNA (or RNA) and amino acids in protein.

A **codon** is a triplet of nucleotides that represents an amino acid or a termination signal.

**Frameshift** mutations arise by deletions or insertions that are not a multiple of 3 base pairs and change the frame in which triplets are translated into protein. The term is inappropriate outside of coding sequences.

**Acridines** are mutagens that act on DNA to cause the insertion or deletion of a single base pair. They were useful in defining the triplet nature of the genetic code.

A **suppressor** is a second mutation that compensates for or alters the effects of a primary mutation.

A frameshift **suppressor** is an insertion or deletion of a base that restores the original reading frame in a gene that has had a base deletion or insertion.

#### Key Concepts

- The genetic code is read in triplet nucleotides called codons.
  - The triplets are nonoverlapping and are read from a fixed starting point.
  - Mutations that insert or delete individual bases cause a shift in the triplet sets after the site of mutation.
  - Combinations of mutations that together insert or delete 3 bases (or multiples of three) insert or delete amino acids but do not change the reading of the triplets beyond the last site of mutation.
- 

Each gene represents a particular protein chain. The concept that each protein consists of a particular series of amino acids dates from Sanger's characterization of insulin in the 1950s. The discovery that a gene consists of DNA faces us with the issue of how a sequence of nucleotides in DNA represents a sequence of amino acids in protein.

A crucial feature of the general structure of DNA is that *it is independent of the particular sequence of its component nucleotides*. The sequence of nucleotides in DNA is important not because of its structure *per se*, but because it *codes* for the sequence of amino acids that constitutes the corresponding polypeptide. The relationship between a sequence of DNA and the sequence of the corresponding protein is called the **genetic code**.

The structure and/or enzymatic activity of each protein follows from its primary sequence of amino acids. By determining the sequence of amino acids in each

protein, the gene is able to carry all the information needed to specify an active polypeptide chain. In this way, a single type of structure – the gene – is able to represent itself in innumerable polypeptide forms.

Together the various protein products of a cell undertake the catalytic and structural activities that are responsible for establishing its phenotype. Of course, in addition to sequences that code for proteins, DNA also contains certain sequences whose function is to be recognized by regulator molecules, usually proteins. Here the function of the DNA is determined by its sequence directly, not via any intermediary code. Both types of region, genes expressed as proteins and sequences recognized as such, constitute genetic information.

The genetic code is deciphered by a complex apparatus that interprets the nucleic acid sequence. This apparatus is essential if the information carried in DNA is to have meaning. In any given region, only one of the two strands of DNA codes for protein, so we write the genetic code as a sequence of bases (rather than base pairs).

The genetic code is read in groups of three nucleotides, each group representing one amino acid. Each trinucleotide sequence is called a **codon**. A gene includes a series of codons that is read sequentially from a starting point at one end to a termination point at the other end. Written in the conventional 5' → 3' direction, the nucleotide sequence of the DNA strand that codes for protein corresponds to the amino acid sequence of the protein written in the direction from N-terminus to C-terminus.

The genetic code is read in *nonoverlapping triplets from a fixed starting point*:

- Nonoverlapping implies that each codon consists of three nucleotides and that successive codons are represented by successive trinucleotides.
- The use of a *fixed starting point* means that assembly of a protein must start at one end and work to the other, so that different parts of the coding sequence cannot be read independently.

The nature of the code predicts that two types of mutations will have different effects. If a particular sequence is read sequentially, such as:

UUU AAA GGG CCC (codons)

aa1 aa2 aa3 aa4 (amino acids)

then a point mutation will affect only one amino acid. For example, the substitution of an A by some other base (X) causes aa2 to be replaced by aa5:

UUU AAX GGG CCC

aa1 aa5 aa3 aa4

because only the second codon has been changed.

*But a mutation that inserts or deletes a single base will change the triplet sets for the entire subsequent sequence. A change of this sort is called a **frameshift**. An insertion might take the form:*

UUU AAX AGG GCC C

aa1 aa5 aa6 aa7

Because the new sequence of triplets is completely different from the old one, the entire amino acid sequence of the protein is altered beyond the site of mutation. So the function of the protein is likely to be lost completely.

Frameshift mutations are induced by the **acridines**, compounds that bind to DNA and distort the structure of the double helix, causing additional bases to be incorporated or omitted during replication. Each mutagenic event sponsored by an acridine results in the addition or removal of a single base pair (for review see 4).

If an acridine mutant is produced by, say, addition of a nucleotide, it should revert to wild type by deletion of the nucleotide. But reversion can also be caused by deletion of a different base, at a site close to the first. Combinations of such mutations provided revealing evidence about the nature of the genetic code.

**Figure 1.33** illustrates the properties of frameshift mutations. An insertion or a deletion changes the entire protein sequence following the site of mutation. But the combination of an insertion and a deletion causes the code to be read incorrectly only between the two sites of mutation; correct reading resumes after the second site.

**Figure 1.33** Frameshift mutations show that the genetic code is read in triplets from a fixed starting point.

Genetic analysis of acridine mutations in the *rII* region of the phage T6 in 1961 showed that all the mutations could be classified into one of two sets, described as (+) and (−). Either type of mutation by itself causes a frameshift, the (+) type by virtue of a base addition, the (−) type by virtue of a base deletion. Double mutant combinations of the types (+ +) and (− −) continue to show mutant behavior. But combinations of the types (+ −) or (− +) suppress one another, giving rise to a description in which one mutation is described as a **suppressor** of the other. (In the context of this work, "suppressor" is used in an unusual sense, because the second mutation is in the same gene as the first.)

These results show that the genetic code must be read as a sequence that is fixed by the starting point, so additions or deletions compensate for each other, whereas double additions or double deletions remain mutant. But this does not reveal how many nucleotides make up each codon.

When triple mutants are constructed, only (+ + +) and (− − −) combinations show the wild phenotype, while other combinations remain mutant. If we take three additions or three deletions to correspond respectively to the addition or omission overall of a single amino acid, this implies that the code is read in triplets. An incorrect amino acid sequence is found between the two outside sites of mutation, and the sequence on either side remains wild type, as indicated in **Figure 1.33** (378; 379).

## GENES ARE DNA

### 1.1.22 Every sequence has three possible reading frames

---

#### Key Terms

A **reading frame** is one of the three possible ways of reading a nucleotide sequence. Each reading frame divides the sequence into a series of successive triplets. There are three possible reading frames in any sequence, depending on the starting point. If the first frame starts at position 1, the second frame starts at position 2, and the third frame starts at position 3.

An **open reading frame (ORF)** is a sequence of DNA consisting of triplets that can be translated into amino acids starting with an initiation codon and ending with a termination codon.

The **initiation codon** is a special codon (usually AUG) used to start synthesis of a protein.

A **stop codon (Termination codon)** is one of three triplets (UAG, UAA, UGA) that causes protein synthesis to terminate. They are also known historically as *nonsense codons*. The UAA codon is called ochre, and the UAG codon is called amber, after the names of the nonsense mutations by which they were originally identified.

A **blocked** reading frame cannot be translated into protein because of the occurrence of termination codons.

#### Key Concepts

- Usually only one reading frame is translated and the other two are blocked by frequent termination signals.

---

If the genetic code is read in nonoverlapping triplets, there are three possible ways of translating any nucleotide sequence into protein, depending on the starting point. These are called **reading frames**. For the sequence

A C G A C G A C G A C G A C G A C G

the three possible reading frames are

ACG ACG ACG ACG ACG ACG ACG

CGA CGA CGA CGA CGA CGA CGA

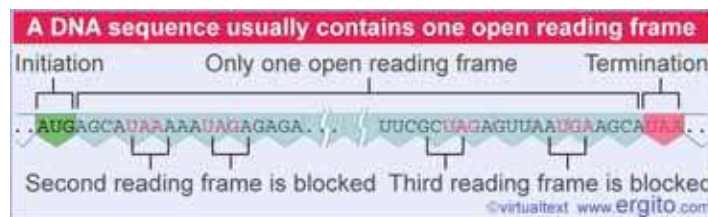

GAC GAC GAC GAC GAC GAC GAC

A reading frame that consists exclusively of triplets representing amino acids is called an **open reading frame** or **ORF**. A sequence that is translated into protein has

a reading frame that starts with a special **initiation codon** (AUG) and that extends through a series of triplets representing amino acids until it ends at one of three types of **termination codon** (see *Molecular Biology 2.5 Messenger RNA*).

A reading frame that cannot be read into protein because termination codons occur frequently is said to be **blocked**. If a sequence is blocked in all three reading frames, it cannot have the function of coding for protein.

When the sequence of a DNA region of unknown function is obtained, each possible reading frame is analyzed to determine whether it is open or blocked. Usually no more than one of the three possible frames of reading is open in any single stretch of DNA. **Figure 1.34** shows an example of a sequence that can be read in only one reading frame, because the alternative reading frames are blocked by frequent termination codons. A long open reading frame is unlikely to exist by chance; if it were not translated into protein, there would have been no selective pressure to prevent the accumulation of termination codons. So the identification of a lengthy open reading frame is taken to be *prima facie* evidence that the sequence is translated into protein in that frame. An open reading frame (ORF) for which no protein product has been identified is sometimes called an unidentified reading frame (URF).

**Figure 1.34** An open reading frame starts with AUG and continues in triplets to a termination codon. Blocked reading frames may be interrupted frequently by termination codons.

This content is available online at <http://www.ergito.com/main.jsp?bcs=MBIO.1.1.22>

---

## GENES ARE DNA

### 1.1.23 Prokaryotic genes are colinear with their proteins

---

#### Key Terms

A **colinear** relationship describes the 1:1 representation of a sequence of triplet nucleotides in a sequence of amino acids.

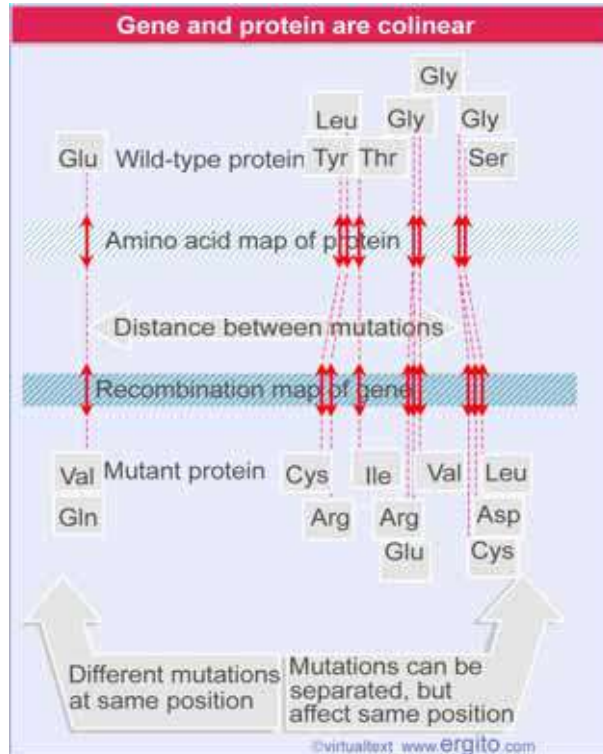

#### Key Concepts

- A prokaryotic gene consists of a continuous length of  $3N$  nucleotides that codes for  $N$  amino acids.
  - The gene, mRNA, and protein are all colinear.
- 

By comparing the nucleotide sequence of a gene with the amino acid sequence of a protein, we can determine directly whether the gene and the protein are **colinear**: whether the sequence of nucleotides in the gene corresponds exactly with the sequence of amino acids in the protein. In bacteria and their viruses, there is an exact equivalence. Each gene contains a continuous stretch of DNA whose length is directly related to the number of amino acids in the protein that it represents. A gene of  $3N$  bp is required to code for a protein of  $N$  amino acids, according to the genetic code.

The equivalence of the bacterial gene and its product means that a physical map of DNA will exactly match an amino acid map of the protein. How well do these maps fit with the recombination map?

The colinearity of gene and protein was originally investigated in the tryptophan synthetase gene of *E. coli* (see *Great Experiments 1.2 Gene-protein colinearity*). Genetic distance was measured by the percent recombination between mutations; protein distance was measured by the number of amino acids separating sites of replacement. **Figure 1.35** compares the two maps. The order of seven sites of mutation is the same as the order of the corresponding sites of amino acid replacement. And the recombination distances are relatively similar to the actual distances in the protein. The recombination map expands the distances between some mutations, but otherwise there is little distortion of the recombination map relative to the physical map (380; 1225).

**Figure 1.35** The recombination map of the tryptophan synthetase gene corresponds with the amino acid sequence of the protein.

The recombination map makes two further general points about the organization of the gene. Different mutations may cause a wild-type amino acid to be replaced with different substituents. If two such mutations cannot recombine, they must involve different point mutations at the same position in DNA. If the mutations can be separated on the genetic map, but affect the same amino acid on the upper map (the connecting lines converge in the figure), they must involve point mutations at different positions that affect the same amino acid. This happens because the unit of genetic recombination (actually 1 bp) is smaller than the unit coding for the amino acid (actually 3 bp).

## GENES ARE DNA

### 1.1.24 Several processes are required to express the protein product of a gene

---

#### Key Terms

**Messenger RNA (mRNA)** is the intermediate that represents one strand of a gene coding for protein. Its coding region is related to the protein sequence by the triplet genetic code.

**Transcription** describes synthesis of RNA on a DNA template.

**Translation** is synthesis of protein on the mRNA template.

A **coding region** is a part of the gene that represents a protein sequence.

The **leader** of a protein is a short N-terminal sequence responsible for initiating passage into or through a membrane.

A **trailer (3' UTR)** is a nontranslated sequence at the 3' end of an mRNA following the termination codon.

**Pre-mRNA** is used to describe the nuclear transcript that is processed by modification and splicing to give an mRNA.

**Processing** of RNA describes changes that occur after its transcription, including modification of the 5' and 3' ends, internal methylation, splicing, or cleavage.

**RNA splicing** is the process of excising the sequences in RNA that correspond to introns, so that the sequences corresponding to exons are connected into a continuous mRNA.

#### Key Concepts

- A prokaryotic gene is expressed by transcription into mRNA and then by translation of the mRNA into protein.
- In eukaryotes, a gene may contain internal regions that are not represented in protein.
- Internal regions are removed from the RNA transcript by RNA splicing to give an mRNA that is colinear with the protein product.
- Each mRNA consists of a nontranslated 5' leader, a coding region, and a nontranslated 3' trailer.

---

In comparing gene and protein, we are restricted to dealing with the sequence of DNA stretching between the points corresponding to the ends of the protein. However, a gene is not directly translated into protein, but is expressed via the production of a **messenger RNA** (abbreviated to **mRNA**), a nucleic acid intermediate actually used to synthesize a protein (as we see in detail in *Molecular Biology 2.5 Messenger RNA*).

Messenger RNA is synthesized by the same process of complementary base pairing used to replicate DNA, with the important difference that it corresponds to only one strand of the DNA double helix. **Figure 1.36** shows that the sequence of messenger RNA is complementary with the sequence of one strand of DNA and is identical (apart from the replacement of T with U) with the other strand of DNA. The convention for writing DNA sequences is that the top strand runs 5' → 3', with the sequence that is the same as RNA.

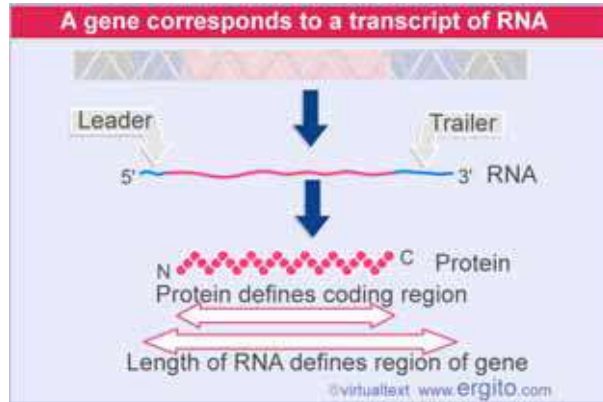

**Figure 1.36** RNA is synthesized by using one strand of DNA as a template for complementary base pairing.

The process by which a gene gives rise to a protein is called gene expression. In bacteria, it consists of two stages. The first stage is **transcription**, when an mRNA copy of one strand of the DNA is produced. The second stage is **translation** of the mRNA into protein. This is the process by which the sequence of an mRNA is read in triplets to give the series of amino acids that make the corresponding protein.

A messenger RNA includes a sequence of nucleotides that corresponds with the sequence of amino acids in the protein. This part of the nucleic acid is called the **coding region**. But the messenger RNA includes additional sequences on either end; these sequences do not directly represent protein. The 5' nontranslated region is called the **leader**, and the 3' nontranslated region is called the **trailer**.

The *gene* includes the entire sequence represented in messenger RNA. Sometimes mutations impeding gene function are found in the additional, noncoding regions, confirming the view that these comprise a legitimate part of the genetic unit.

**Figure 1.37** illustrates this situation, in which the gene is considered to comprise a continuous stretch of DNA, needed to produce a particular protein. It includes the sequence coding for that protein, but also includes sequences on either side of the coding region.

**Figure 1.37** The gene may be longer than the sequence coding for protein.

A bacterium consists of only a single compartment, so transcription and translation occur in the same place, as illustrated in **Figure 1.38**.

**Figure 1.38** Transcription and translation take place in the same compartment in bacteria.

In eukaryotes transcription occurs in the nucleus, but the RNA product must be *transported* to the cytoplasm in order to be translated. For the simplest eukaryotic genes (just like in bacteria) the transcript RNA is in fact the mRNA. But for more complex genes, the immediate transcript of the gene is a **pre-mRNA** that requires **processing** to generate the mature mRNA. The basic stages of gene expression in a eukaryote are outlined in **Figure 1.39**. This results in a spatial separation between transcription (in the nucleus) and translation (in the cytoplasm).

**Figure 1.39** Gene expression is a multistage process.

The most important stage in processing is **RNA splicing**. Many genes in eukaryotes (and a majority in higher eukaryotes) contain internal regions that do not code for protein. The process of splicing removes these regions from the pre-mRNA to generate an RNA that has a continuous open reading frame (see **Figure 2.1**). Other processing events that occur at this stage involve the modification of the 5' and 3' ends of the pre-mRNA (see **Figure 5.16**).

Translation is accomplished by a complex apparatus that includes both protein and RNA components. The actual "machine" that undertakes the process is the *ribosome*, a large complex that includes some large RNAs (*ribosomal RNAs*, abbreviated to *rRNAs*) and many small proteins. The process of recognizing which amino acid corresponds to a particular nucleotide triplet requires an intermediate *transfer RNA* (abbreviated to *tRNA*); there is at least one tRNA species for every amino acid. Many ancillary proteins are involved. We describe translation in *Molecular Biology 2.5 Messenger RNA*, but note for now that the ribosomes are the large structures in **Figure 1.38** that move along the mRNA.

The important point to note at this stage is that the process of gene expression involves RNA not only as the essential substrate, but also in providing components of the apparatus. The rRNA and tRNA components are coded by genes and are generated by the process of transcription (just like mRNA, except that there is no subsequent stage of translation).

## GENES ARE DNA

### 1.1.25 Proteins are *trans*-acting but sites on DNA are *cis*-acting

---

#### Key Terms

*cis* configuration describes two sites on the same molecule of DNA.

*trans* configuration of two sites refers to their presence on two different molecules of DNA (chromosomes).

A *cis-acting* site affects the activity only of sequences on its own molecule of DNA (or RNA); this property usually implies that the site does not code for protein.

#### Key Concepts

- All gene products (RNA or proteins) are *trans*-acting. They can act on any copy of a gene in the cell.
- *cis*-acting mutations identify sequences of DNA that are targets for recognition by *trans*-acting products. They are not expressed as RNA or protein and affect only the contiguous stretch of DNA.

---

A crucial step in the definition of the gene was the realization that all its parts must be present on one contiguous stretch of DNA. In genetic terminology, sites that are located on the same DNA are said to be in *cis*. Sites that are located on two different molecules of DNA are described as being in *trans*. So two mutations may be in *cis* (on the same DNA) or in *trans* (on different DNAs). The complementation test uses this concept to determine whether two mutations are in the same gene (see **Figure 1.27** in *Molecular Biology 1.1.16 Mutations in the same gene cannot complement*). We may now extend the concept of the difference between *cis* and *trans* effects from defining the coding region of a gene to describing the interaction between regulatory elements and a gene.

Suppose that the ability of a gene to be expressed is controlled by a protein that binds to the DNA close to the coding region. In the example depicted in **Figure 1.40**, messenger RNA can be synthesized only when the protein is bound to the DNA. Now suppose that a mutation occurs in the DNA sequence to which this protein binds, so that the protein can no longer recognize the DNA. As a result, the DNA can no longer be expressed.

**Figure 1.40** Control sites in DNA provide binding sites for proteins; coding regions are expressed via the synthesis of RNA.

*So a gene can be inactivated either by a mutation in a control site or by a mutation in a coding region.* The mutations cannot be distinguished genetically, because both have the property of acting only on the DNA sequence of the single allele in which they occur. They have identical properties in the complementation test, and a mutation in a control region is therefore defined as comprising part of the gene in the same way as a mutation in the coding region.

**Figure 1.41** shows that a deficiency in the control site *affects only the coding region to which it is connected; it does not affect the ability of the other allele to be expressed.* A mutation that acts solely by affecting the properties of the contiguous sequence of DNA is called **cis-acting**.

**Figure 1.41** A *cis*-acting site controls the adjacent DNA but does not influence the other allele.

We may contrast the behavior of the *cis*-acting mutation shown in **Figure 1.41** with the result of a mutation in the gene coding for the regulator protein. **Figure 1.42** shows that the absence of regulator protein would prevent *both* alleles from being expressed. A mutation of this sort is said to be *trans*-acting.

**Figure 1.42** A *trans*-acting mutation in a protein affects both alleles of a gene that it controls.

Reversing the argument, if a mutation is *trans*-acting, we know that its effects must be exerted through some diffusible product (typically a protein) that acts on multiple targets within a cell. But if a mutation is *cis*-acting, it must function via affecting directly the properties of the contiguous DNA, which means that it is *not expressed in the form of RNA or protein*.

## GENES ARE DNA

### 1.1.26 Genetic information can be provided by DNA or RNA

---

#### Key Terms

The **central dogma** describes the basic nature of genetic information: sequences of nucleic acid can be perpetuated and interconverted by replication, transcription, and reverse transcription, but translation from nucleic acid to protein is unidirectional, because nucleic acid sequences cannot be retrieved from protein sequences.

A **retrovirus** is an RNA virus with the ability to convert its sequence into DNA by reverse transcription.

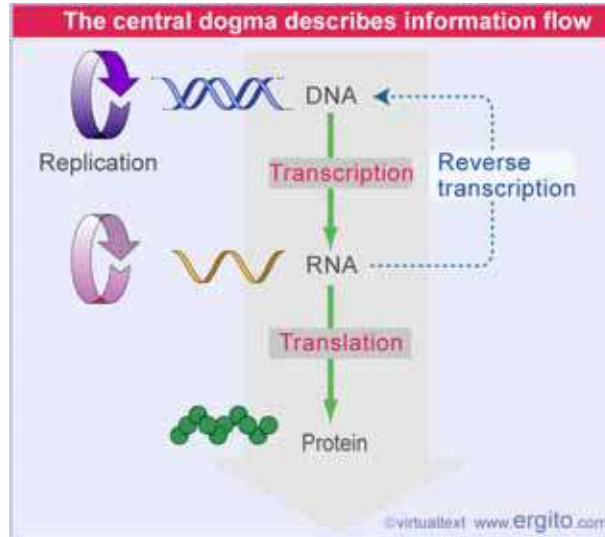

**Reverse transcription** is synthesis of DNA on a template of RNA. It is accomplished by the enzyme reverse transcriptase.

#### Key Concepts

- Cellular genes are DNA, but viruses and viroids may have genes of RNA.
  - DNA is converted into RNA by transcription, and RNA may be converted into DNA by reverse transcription.
  - The translation of RNA into protein is unidirectional.
- 

The **central dogma** defines the paradigm of molecular biology. Genes are perpetuated as sequences of nucleic acid, but function by being expressed in the form of proteins. Replication is responsible for the inheritance of genetic information. Transcription and translation are responsible for its conversion from one form to another.

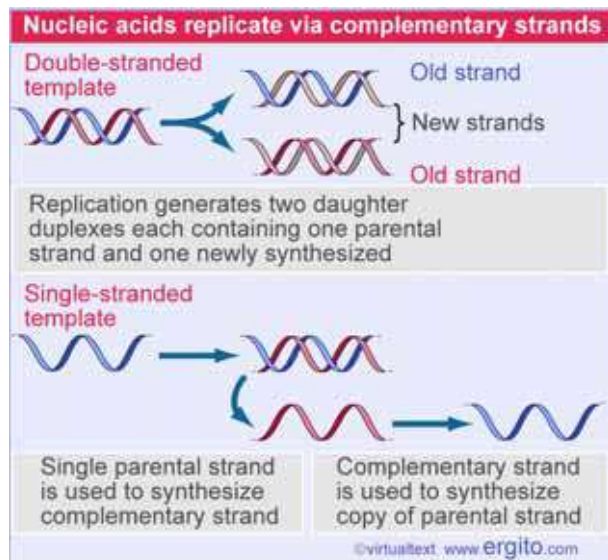

**Figure 1.43** illustrates the roles of replication, transcription, and translation, viewed from the perspective of the central dogma:

**Figure 1.43** The central dogma states that information in nucleic acid can be perpetuated or transferred, but the transfer of information into protein is irreversible.

- *The perpetuation of nucleic acid may involve either DNA or RNA as the genetic material.* Cells use only DNA. Some viruses use RNA, and replication of viral RNA occurs in the infected cell.
- *The expression of cellular genetic information usually is unidirectional.* Transcription of DNA generates RNA molecules that can be used further *only* to generate protein sequences; generally they cannot be retrieved for use as genetic information. Translation of RNA into protein is always irreversible.

These mechanisms are equally effective for the cellular genetic information of prokaryotes or eukaryotes, and for the information carried by viruses. The genomes of all living organisms consist of duplex DNA. Viruses have genomes that consist of DNA or RNA; and there are examples of each type that are double-stranded (ds) or single-stranded (ss). Details of the mechanism used to replicate the nucleic acid vary among the viral systems, but the principle of replication via synthesis of complementary strands remains the same, as illustrated in **Figure 1.44**.

**Figure 1.44** Double-stranded and single-stranded nucleic acids both replicate by synthesis of complementary strands governed by the rules of base pairing.

Cellular genomes reproduce DNA by the mechanism of semi-conservative replication. Double-stranded virus genomes, whether DNA or RNA, also replicate by using the individual strands of the duplex as templates to synthesize partner strands.

Viruses with single-stranded genomes use the single strand as template to synthesize a complementary strand; and this complementary strand in turn is used to synthesize its complement, which is, of course, identical with the original starting strand. Replication may involve the formation of stable double-stranded intermediates or use double-stranded nucleic acid only as a transient stage.

The restriction to unidirectional transfer from DNA to RNA is not absolute. It is overcome by the **retroviruses**, whose genomes consist of single-stranded RNA molecules. During the infective cycle, the RNA is converted by the process of **reverse transcription** into a single-stranded DNA, which in turn is converted into a double-stranded DNA. This duplex DNA becomes part of the genome of the cell, and is inherited like any other gene. *So reverse transcription allows a sequence of RNA to be retrieved and used as genetic information.*

The existence of RNA replication and reverse transcription establishes the general principle that *information in the form of either type of nucleic acid sequence can be converted into the other type*. In the usual course of events, however, the cell relies on the processes of DNA replication, transcription, and translation. But on rare occasions (possibly mediated by an RNA virus), information from a cellular RNA is converted into DNA and inserted into the genome. Although reverse transcription plays no role in the regular operations of the cell, it becomes a mechanism of potential importance when we consider the evolution of the genome.

The same principles are followed to perpetuate genetic information from the massive genomes of plants or amphibians to the tiny genomes of mycoplasma and the yet smaller genetic information of DNA or RNA viruses. **Figure 1.45** summarizes some

examples that illustrate the range of genome types and sizes.

Genomes have nucleic acids		
Genome	Gene Number	Base Pairs
<b>Organisms</b>		
Plants	<50,000	<10 <sup>11</sup>
Mammals	30,000	~3 x 10 <sup>9</sup>
Worms	14,000	~10 <sup>8</sup>
Flies	12,000	1.6 x 10 <sup>8</sup>
Fungi	6,000	1.3 x 10 <sup>7</sup>
Bacteria	2-4,000	<10 <sup>7</sup>
Mycoplasma	500	<10 <sup>6</sup>
<b>dsDNA Viruses</b>		
Vaccinia	<300	187,000
Papova (SV40)	~6	5,226
Phage T4	~200	165,000
<b>ssDNA Viruses</b>		
Parvovirus	5	5,000
Phage φX174	11	5,387
<b>dsRNA Viruses</b>		
Reovirus	22	23,000
<b>ssRNA Viruses</b>		
Coronavirus	7	20,000
Influenza	12	13,500
TMV	4	6,400
Phage MS2	4	3,569
STNV	1	1,300
<b>Viroids</b>		
PSTV RNA	0	359

**Figure 1.45** The amount of nucleic acid in the genome varies over an enormous range.

Throughout the range of organisms, with genomes varying in total content over a 100,000 fold range, a common principle prevails. *The DNA codes for all the proteins that the cell(s) of the organism must synthesize; and the proteins in turn (directly or indirectly) provide the functions needed for survival.* A similar principle describes the function of the genetic information of viruses, whether DNA or RNA. *The nucleic acid codes for the protein(s) needed to package the genome and also for any functions additional to those provided by the host cell that are needed to reproduce the virus during its infective cycle.* (The smallest virus, the satellite tobacco necrosis virus [STNV], cannot replicate independently, but requires the simultaneous presence of a "helper" virus [tobacco necrosis virus, TNV], which is itself a normally infectious virus.)

## GENES ARE DNA

### 1.1.27 Some hereditary agents are extremely small

#### Key Terms

A **viroid** is a small infectious nucleic acid that does not have a protein coat.

**Virion** is the physical virus particle (irrespective of its ability to infect cells and reproduce).

A **subviral pathogen** is an infectious agent that is smaller than a virus, such as a virusoid.

**Scrapie** is an infective agent made of protein.

A **prion** is a proteinaceous infectious agent, which behaves as an inheritable trait, although it contains no nucleic acid. Examples are PrP<sup>Sc</sup>, the agent of scrapie in sheep and bovine spongiform encephalopathy, and Psi, which confers an inherited state in yeast.

**PrP** is the protein that is the active component of the prion that causes scrapie and related diseases. The form involved in the disease is called PrP<sup>Sc</sup>.

#### Key Concepts

- Some very small hereditary agents do not code for protein but consist of RNA or of protein that has hereditary properties.

**Viroids** are infectious agents that cause diseases in higher plants (for review see 2525). They are very small circular molecules of RNA. Unlike viruses, where the infectious agent consists of a **virion**, a genome encapsulated in a protein coat, *the viroid RNA is itself the infectious agent*. The viroid consists solely of the RNA, which is extensively but imperfectly base paired, forming a characteristic rod like the example shown in **Figure 1.46**. Mutations that interfere with the structure of the rod reduce infectivity.

**Figure 1.46** PSTV RNA is a circular molecule that forms an extensive double-stranded structure, interrupted by many interior loops. The severe and mild forms differ at three sites.

A viroid RNA consists of a single molecular species that is replicated autonomously

in infected cells. Its sequence is faithfully perpetuated in its descendants. Viroids fall into several groups. A given viroid is identified with a group by its similarity of sequence with other members of the group. For example, four viroids related to PSTV (potato spindle tuber viroid) have 70-83% similarity of sequence with it. Different isolates of a particular viroid strain vary from one another, and the change may affect the phenotype of infected cells. For example, the *mild* and *severe* strains of PSTV differ by three nucleotide substitutions.

Viroids resemble viruses in having heritable nucleic acid genomes. They fulfill the criteria for genetic information. Yet viroids differ from viruses in both structure and function. They are sometimes called **subviral pathogens**. Viroid RNA does not appear to be translated into protein. So it cannot itself code for the functions needed for its survival. This situation poses two questions. How does viroid RNA replicate? And how does it affect the phenotype of the infected plant cell?

Replication must be carried out by enzymes of the host cell, subverted from their normal function. The heritability of the viroid sequence indicates that viroid RNA provides the template.

Viroids are presumably pathogenic because they interfere with normal cellular processes. They might do this in a relatively random way, for example, by sequestering an essential enzyme for their own replication or by interfering with the production of necessary cellular RNAs. Alternatively, they might behave as abnormal regulatory molecules, with particular effects upon the expression of individual genes (for review see 12).

An even more unusual agent is **scrapie**, the cause of a degenerative neurological disease of sheep and goats. The disease is related to the human diseases of kuru and Creutzfeldt-Jakob syndrome, which affect brain function.

*The infectious agent of scrapie does not contain nucleic acid.* This extraordinary agent is called a **prion** (proteinaceous infectious agent) (for review see 2523). It is a 28 kD hydrophobic glycoprotein, **PrP**. PrP is coded by a cellular gene (conserved among the mammals) that is expressed in normal brain. The protein exists in two forms. The product found in normal brain is called PrP<sup>c</sup>. It is entirely degraded by proteases. The protein found in infected brains is called PrP<sup>sc</sup>. It is extremely resistant to degradation by proteases. PrP<sup>c</sup> is converted to PrP<sup>sc</sup> by a modification or conformational change that confers protease-resistance, and which has yet to be fully defined (383).

As the infectious agent of scrapie, PrP<sup>sc</sup> must in some way modify the synthesis of its normal cellular counterpart so that it becomes infectious instead of harmless (see *Molecular Biology 5.23.24 Prions cause diseases in mammals*). Mice that lack a PrP gene cannot be infected to develop scrapie, which demonstrates that PrP is essential for development of the disease (386).

## GENES ARE DNA

### 1.1.28 Summary

---

Two classic experiments proved that DNA is the genetic material. DNA isolated from one strain of *Pneumococcus* bacteria can confer properties of that strain upon another strain. And DNA is the only component that is inherited by progeny phages from the parental phages. DNA can be used to transfect new properties into eukaryotic cells.

DNA is a double helix consisting of antiparallel strands in which the nucleotide units are linked by 5'–3' phosphodiester bonds. The backbone provides the exterior; purine and pyrimidine bases are stacked in the interior in pairs in which A is complementary to T while G is complementary to C. The strands separate and use complementary base pairing to assemble daughter strands in semiconservative replication. Complementary base pairing is also used to transcribe an RNA representing one strand of a DNA duplex.

A stretch of DNA may code for protein. The genetic code describes the relationship between the sequence of DNA and the sequence of the protein. Only one of the two strands of DNA codes for protein. A codon consists of three nucleotides that represent a single amino acid. A coding sequence of DNA consists of a series of codons, read from a fixed starting point. Usually only one of the three possible reading frames can be translated into protein.

A chromosome consists of an uninterrupted length of duplex DNA that contains many genes. Each gene (or cistron) is transcribed into an RNA product, which in turn is translated into a polypeptide sequence if the gene codes for protein. An RNA or protein product of a gene is said to be *trans*-acting. A gene is defined as a unit on a single stretch of DNA by the complementation test. A site on DNA that regulates the activity of an adjacent gene is said to be *cis*-acting.

A gene may have multiple alleles. Recessive alleles are caused by a loss-of-function. A null allele has total loss-of-function. Dominant alleles are caused by gain-of-function.

A mutation consists of a change in the sequence of A·T and G·C base pairs in DNA. A mutation in a coding sequence may change the sequence of amino acids in the corresponding protein. A frameshift mutation alters the subsequent reading frame by inserting or deleting a base; this causes an entirely new series of amino acids to be coded after the site of mutation. A point mutation changes only the amino acid represented by the codon in which the mutation occurs. Point mutations may be reverted by back mutation of the original mutation. Insertions may revert by loss of the inserted material, but deletions cannot revert. Mutations may also be suppressed indirectly when a mutation in a different gene counters the original defect.

The natural incidence of mutations is increased by mutagens. Mutations may be concentrated at hotspots. A type of hotspot responsible for some point mutations is caused by deamination of the modified base 5-methylcytosine.

Forward mutations occur at a rate of  $\sim 10^{-6}$  per locus per generation; back mutations are rarer. Not all mutations have an effect on the phenotype.

Although all genetic information in cells is carried by DNA, viruses have genomes of double-stranded or single-stranded DNA or RNA. Viroids are subviral pathogens that consist solely of small circular molecules of RNA, with no protective packaging. The RNA does not code for protein and its mode of perpetuation and of pathogenesis is unknown. Scrapie consists of a proteinaceous infectious agent.

## THE INTERRUPTED GENE

### 1.2.1 Introduction

---

#### Key Terms

An **exon** is any segment of an interrupted gene that is represented in the mature RNA product.

An **intron (Intervening sequence)** is a segment of DNA that is transcribed, but removed from within the transcript by splicing together the sequences (exons) on either side of it.

A **transcript** is the RNA product produced by copying one strand of DNA. It may require processing to generate a mature RNA.

**RNA splicing** is the process of excising the sequences in RNA that correspond to introns, so that the sequences corresponding to exons are connected into a continuous mRNA.

A **structural gene** codes for any RNA or protein product other than a regulator.

#### Key Concepts

- Eukaryotic genomes contain interrupted genes in which exons (represented in the final RNA product) alternate with introns (removed from the initial transcript).
- The exon sequences occur in the same order in the gene and in the RNA, but an interrupted gene is longer than its final RNA product because of the presence of the introns.

---

Until eukaryotic genes were characterized by molecular mapping, we assumed that they would have the same organization as prokaryotic genes. We expected the gene to consist of a length of DNA that is colinear with the protein. But a comparison between the structure of DNA and the corresponding mRNA shows a discrepancy in many cases. The mRNA always includes a nucleotide sequence that corresponds exactly with the protein product according to the rules of the genetic code. *But the gene includes additional sequences that lie within the coding region, interrupting the sequence that represents the protein.* (For a description of the discovery see *Great Experiments 4.1 The discovery of RNA splicing* and *Great Experiments 4.2 The discovery of split genes and RNA splicing.*)

The sequences of DNA comprising an interrupted gene are divided into the two categories depicted in **Figure 2.1**:

**Figure 2.1** Interrupted genes are expressed via a precursor RNA. Introns are removed when the exons are spliced together. The mRNA has only the sequences of the exons.

- The **exons** are the sequences represented in the mature RNA. By definition, a gene starts and ends with exons, corresponding to the 5' and 3' ends of the RNA.
- The **introns** are the intervening sequences that are removed when the primary transcript is processed to give the mature RNA.

The expression of interrupted genes requires an additional step that does not occur for uninterrupted genes. The DNA gives rise to an RNA copy (a **transcript**) that exactly represents the genome sequence. But this RNA is only a precursor; it cannot be used for producing protein. First the introns must be removed from the RNA to give a messenger RNA that consists only of the series of exons. This process is called **RNA splicing**. It involves a precise deletion of an intron from the primary transcript; the ends of the RNA on either side are joined to form a covalently intact molecule (see *Molecular Biology 5.24 RNA splicing and processing*).

The **structural gene** comprises the region in the genome between points corresponding to the 5' and 3' terminal bases of mature mRNA. We know that transcription starts at the 5' end of the mRNA, but usually it extends beyond the 3' end, which is generated by cleavage of the RNA (see *Molecular Biology 5.24.19 The 3' ends of mRNAs are generated by cleavage and polyadenylation*). The gene is considered to include the regulatory regions on both sides of the gene that are required for initiating and (sometimes) terminating gene expression.

This content is available online at <http://www.ergito.com/main.jsp?bcs=MBIO.1.2.1>

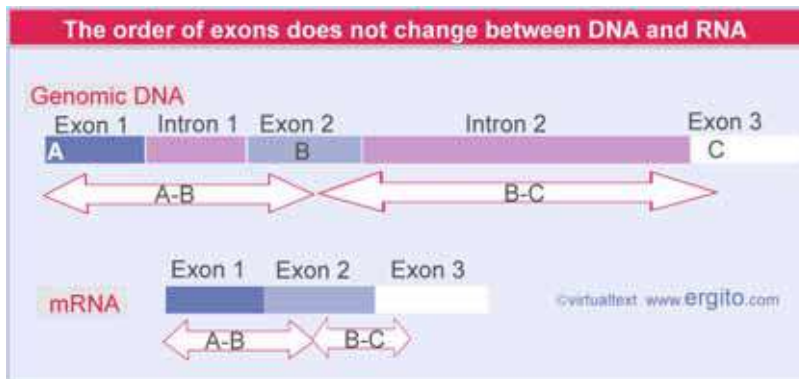

## THE INTERRUPTED GENE

### 1.2.2 An interrupted gene consists of exons and introns

#### Key Concepts

- Introns are removed by the process of RNA splicing, which occurs only *in cis* on an individual RNA molecule.
- Only mutations in exons can affect protein sequence, but mutations in introns can affect processing of the RNA and therefore prevent production of protein.

How does the existence of introns change our view of the gene? Following splicing, the exons are always joined together in the same order in which they lie in DNA. So the colinearity of gene and protein is maintained between the individual exons and the corresponding parts of the protein chain. **Figure 2.2** shows that the *order* of mutations in the gene remains the same as the order of amino acid replacements in the protein. But the *distances* in the gene do not correspond at all with the distances in the protein. Genetic distances, as seen on a recombination map, have no relationship to the distances between the corresponding points in the protein. The length of the gene is defined by the length of the initial (precursor) RNA instead of by the length of the messenger RNA.

**Figure 2.2** Exons remain in the same order in mRNA as in DNA, but distances along the gene do not correspond to distances along the mRNA or protein products. The distance from A-B in the gene is smaller than the distance from B-C; but the distance from A-B in the mRNA (and protein) is greater than the distance from B-C.

All the exons are represented on the same molecule of RNA, and their splicing together occurs only as an *intramolecular* reaction. There is usually no joining of exons carried by *different* RNA molecules, so the mechanism excludes any splicing together of sequences representing different alleles. Mutations located in different exons of a gene cannot complement one another; thus they continue to be defined as members of the same complementation group.

Mutations that directly affect the sequence of a protein must lie in exons. What are

the effects of mutations in the introns? Since the introns are not part of the messenger RNA, mutations in them cannot directly affect protein structure. However, they can prevent the production of the messenger RNA – for example, by inhibiting the splicing together of exons. A mutation of this sort acts only on the allele that carries it. So it fails to complement any other mutation in that allele, and constitutes part of the same complementation group as the exons.

Mutations that affect splicing are usually deleterious. The majority are single base substitutions at the junctions between introns and exons. They may cause an exon to be left out of the product, cause an intron to be included, or make splicing occur at an aberrant site. The most common result is to introduce a termination codon that results in truncation of the protein sequence. About 15% of the point mutations that cause human diseases are caused by disruption of splicing (for review see 3645).

Eukaryotic genes are not necessarily interrupted. Some correspond directly with the protein product in the same manner as prokaryotic genes. In yeast, most genes are uninterrupted. In higher eukaryotes, most genes are interrupted; and the introns are usually much longer than exons, creating genes that are very much larger than their coding regions (for review see 8).

## THE INTERRUPTED GENE

### 1.2.3 Restriction endonucleases are a key tool in mapping DNA

---

#### Key Terms

**Restriction endonucleases** recognize specific short sequences of DNA and cleave the duplex (sometimes at target site, sometimes elsewhere, depending on type).

A **restriction map** is a linear array of sites on DNA cleaved by various restriction enzymes.

A **kilobase (kb)** is a measure of length and may be used to refer to DNA (1000 base pairs) or to RNA (1000 bases).

A **megabase (Mb)** is 1 million base pairs of DNA.

#### Key Concepts

- Restriction endonucleases can be used to cleave DNA into defined fragments.
- A map can be generated by using the overlaps between the fragments generated by different restriction enzymes.

---

The characterization of eukaryotic genes was made possible by the development of techniques for physically mapping DNA. The techniques can be extended to (single-stranded) RNA by making a (double-stranded) DNA copy of the RNA. A physical map of any DNA molecule can be obtained by breaking it at defined points whose distance apart can be accurately determined. Specific breaks are made possible by the ability of **restriction endonucleases** to recognize rather short sequences of double-stranded DNA as targets for cleavage.

Each restriction enzyme has a particular target in duplex DNA, usually a specific sequence of 4-6 base pairs. The enzyme cuts the DNA at every point at which its target sequence occurs. Different restriction enzymes have different target sequences, and a large range of these activities (obtained from a wide variety of bacteria) now is available.

A **restriction map** represents a linear sequence of the sites at which particular restriction enzymes find their targets. Distance along such maps is measured directly in base pairs (abbreviated *bp*) for short distances; longer distances are given in **kb**, corresponding to kilobase ( $10^3$ ) pairs in DNA or to kilobases in RNA. At the level of the chromosome, a map is described in megabase pairs ( $1 \text{ Mb} = 10^6 \text{ bp}$ ).

When a DNA molecule is cut with a suitable restriction enzyme, it is cleaved into distinct fragments. These fragments can be separated on the basis of their size by gel electrophoresis, as shown in **Figure 2.3**. The cleaved DNA is placed on top of a gel made of agarose or polyacrylamide. When an electric current is passed through the gel, each fragment moves down at a rate that is inversely related to the log of its molecular weight. This movement produces a series of bands. Each band corresponds

to a fragment of particular size, decreasing down the gel.

**Figure 2.3** Fragments generated by cleaving DNA with a restriction endonuclease can be separated according to their sizes.

By analyzing the restriction fragments of DNA, we can generate a map of the original molecule in the form shown in **Figure 2.4**. The method is explained in detail in *Molecular Biology Supplement 32.11 Restriction mapping*. The map shows the positions at which particular restriction enzymes cut DNA; the distances between the sites of cutting are measured in base pairs. So the DNA is divided into a series of regions of defined lengths that lie between sites recognized by the restriction enzymes. An important feature is that a restriction map can be obtained for any sequence of DNA, *irrespective of whether mutations have been identified in it*, or, indeed, whether we have any knowledge of its function (392) (for review see 6; 10).

**Figure 2.4** A restriction map is a linear sequence of sites separated by defined distances on DNA. The map identifies the sites cleaved by enzymes A and B, as defined by the individual fragments produced by the single and double digests.

## THE INTERRUPTED GENE

### 1.2.4 Organization of interrupted genes may be conserved

#### Key Concepts

- Introns can be detected by the presence of additional regions when genes are compared with their RNA products by restriction mapping or electron microscopy, but the ultimate definition is based on comparison of sequences.
- The positions of introns are usually conserved when homologous genes are compared between different organisms, but the lengths of the corresponding introns may vary greatly.
- Introns usually do not code for proteins.

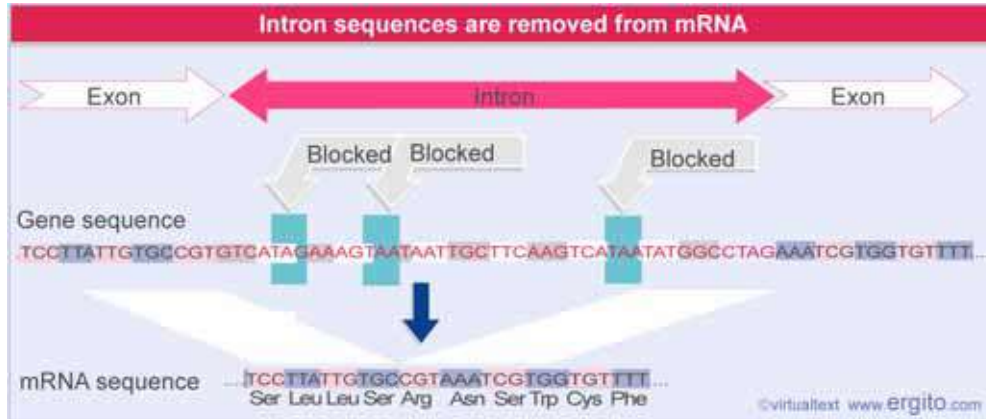

When a gene is uninterrupted, the restriction map of its DNA corresponds exactly with the map of its mRNA.

When a gene possesses an intron, the map at each end of the gene corresponds with the map at each end of the message sequence. But within the gene, the maps diverge, because additional regions are found in the gene, but are not represented in the message. Each such region corresponds to an intron. The example of **Figure 2.5** compares the restriction maps of a  $\beta$ -globin gene and mRNA. There are two introns. Each intron contains a series of restriction sites that are absent from the cDNA. But the pattern of restriction sites in the exons is the same in both the cDNA and the gene (387; 388; 389; 390; 391).

**Figure 2.5** Comparison of the restriction maps of cDNA and genomic DNA for mouse  $\beta$ -globin shows that the gene has two introns that are not present in the cDNA. The exons can be aligned exactly between cDNA and gene.

Ultimately a comparison of the nucleotide sequences of the genomic and mRNA sequences precisely defines the introns. As indicated in **Figure 2.6**, an intron usually has no open reading frame. An intact reading frame is created in the mRNA sequence by the removal of the introns.

**Figure 2.6** An intron is a sequence present in the gene but absent from the mRNA (here shown in terms of the cDNA sequence). The reading frame is indicated by the alternating open and shaded blocks; note that all three possible reading frames are blocked by termination codons in the intron.

The structures of eukaryotic genes show extensive variation. Some genes are uninterrupted, so that the genomic sequence is colinear with that of the mRNA. Most higher eukaryotic genes are interrupted, but the introns vary enormously in both number and size.

All classes of genes may be interrupted: nuclear genes coding for proteins, nucleolar genes coding for rRNA, and genes coding for tRNA. Interruptions also are found in mitochondrial genes in lower eukaryotes, and in chloroplast genes. Interrupted genes do not appear to be excluded from any class of eukaryotes, and have been found in bacteria and bacteriophages, although they are extremely rare in prokaryotic genomes.

Some interrupted genes possess only one or a few introns. The globin genes provide an extensively studied example (see *Molecular Biology 1.2.11 The members of a gene family have a common organization*). The two general types of globin gene,  $\alpha$  and  $\beta$ , share a common type of structure. The consistency of the organization of mammalian globin genes is evident from the structure of the "generic" globin gene summarized in **Figure 2.7**.

**Figure 2.7** All functional globin genes have an interrupted structure with three exons. The lengths indicated in the figure apply to the mammalian  $\beta$ -globin genes.

Interruptions occur at homologous positions (relative to the coding sequence) in all known active globin genes, including those of mammals, birds, and frogs. The first intron is always fairly short, and the second usually is longer, but the actual lengths

can vary. Most of the variation in overall lengths between different globin genes results from the variation in the second intron. In the mouse, the second intron in the  $\alpha$ -globin gene is only 150 bp long, so the overall length of the gene is 850 bp, compared with the major  $\beta$ -globin gene where the intron length of 585 bp gives the gene a total length of 1382 bp. The variation in length of the genes is much greater than the range of lengths of the mRNAs ( $\alpha$ -globin mRNA = 585 bases,  $\beta$ -globin mRNA = 620 bases).

The example of DHFR, a somewhat larger gene, is shown in **Figure 2.8**. The mammalian DHFR (dihydrofolate reductase) gene is organized into 6 exons that correspond to the 2000 base mRNA. But they extend over a much greater length of DNA because the introns are very long. In three mammals the exons remain essentially the same, and the relative positions of the introns are unaltered, but the lengths of individual introns vary extensively, resulting in a variation in the length of the gene from 25-31 kb.

**Figure 2.8** Mammalian genes for DHFR have the same relative organization of rather short exons and very long introns, but vary extensively in the lengths of corresponding introns.

The globin and DHFR genes present examples of a general phenomenon: *genes that are related by evolution have related organizations, with conservation of the positions of (at least some) of the introns. Variations in the lengths of the genes are primarily determined by the lengths of the introns.*

## THE INTERRUPTED GENE

### 1.2.5 Exon sequences are conserved but introns vary

---

#### Key Concepts

- Comparisons of related genes in different species show that the sequences of the corresponding exons are usually conserved but the sequences of the introns are much less well related.
- Introns evolve much more rapidly than exons because of the lack of selective pressure to produce a protein with a useful sequence.

---

Is a structural gene unique in its genome? The answer can be ambiguous. The entire length of the gene is unique as such, but its exons often are related to those of other genes. As a general rule, when two genes are related, the relationship between their exons is closer than the relationship between the introns. In an extreme case, the exons of two genes may code for the same protein sequence, but the introns may be different. This implies that the two genes originated by a duplication of some common ancestral gene. Then differences accumulated between the copies, but they were restricted in the exons by the need to code for protein functions.

As we see later when we consider the evolution of the gene, exons can be considered as basic building blocks that are assembled in various combinations. A gene may have some exons that are related to exons of another gene, but the other exons may be unrelated. Usually the introns are not related at all in such cases. Such genes may arise by duplication and translocation of individual exons.

The relationship between two genes can be plotted in the form of the dot matrix comparison of **Figure 2.9**. A dot is placed to indicate each position at which the same sequence is found in each gene. The dots form a line at an angle of  $45^\circ$  if two sequences are identical. The line is broken by regions that lack similarity, and it is displaced laterally or vertically by deletions or insertions in one sequence relative to the other.

**Figure 2.9** The sequences of the mouse  $\alpha^{\text{maj}}$  and  $\alpha^{\text{min}}$  globin genes are closely related in coding regions, but differ in the flanking regions and large intron. Data kindly provided by Philip Leder.

When the two  $\beta$ -globin genes of the mouse are compared, such a line extends through the three exons and through the small intron. The line tapers out in the flanking regions and in the large intron. This is a typical pattern, in which coding sequences are well related, the relationship can extend beyond the boundaries of the exons, but it is lost in longer introns and the regions on either side of the gene.

The overall degree of divergence between two exons is related to the differences between the proteins. It is caused mostly by base substitutions. In the translated regions, the exons are under the constraint of needing to code for amino acid sequences, so they are limited in their potential to change sequence. Many of the changes do not affect codon meanings, because they change one codon into another that represents the same amino acid. Changes occur more freely in nontranslated regions (corresponding to the 5' leader and 3' trailer of the mRNA).

In corresponding introns, the pattern of divergence involves both changes in size (due to deletions and insertions) and base substitutions. Introns evolve much more rapidly than exons. When a gene is compared in different species, sometimes the exons are homologous, while the introns have diverged so much that corresponding sequences cannot be recognized.

Mutations occur at the same rate in both exons and introns, but are removed more effectively from the exons by adverse selection. However, in the absence of the constraints imposed by a coding function, an intron is able quite freely to accumulate point substitutions and other changes. These changes imply that the intron does not have a sequence-specific function. Whether its presence is at all necessary for gene function is not clear.

## THE INTERRUPTED GENE

### 1.2.6 Genes can be isolated by the conservation of exons

---

#### Key Terms

A **zoo blot** describes the use of Southern blotting to test the ability of a DNA probe from one species to hybridize with the DNA from the genomes of a variety of other species.

**Exon trapping** inserts a genomic fragment into a vector whose function depends on the provision of splicing junctions by the fragment.

#### Key Concepts

- Conservation of exons can be used as the basis for identifying coding regions by identifying fragments whose sequences are present in multiple organisms.

---

Some major approaches to identifying genes are based on the contrast between the conservation of exons and the variation of introns. In a region containing a gene whose function has been conserved among a range of species, the sequence representing the protein should have two distinctive properties:

- it must have an open reading frame;
- and it is likely to have a related sequence in other species.

These features can be used to isolate genes.

Suppose we know by genetic data that a particular genetic trait is located in a given chromosomal region. If we lack knowledge about the nature of the gene product, how are we to identify the gene in a region that may be (for example) >1 Mb?

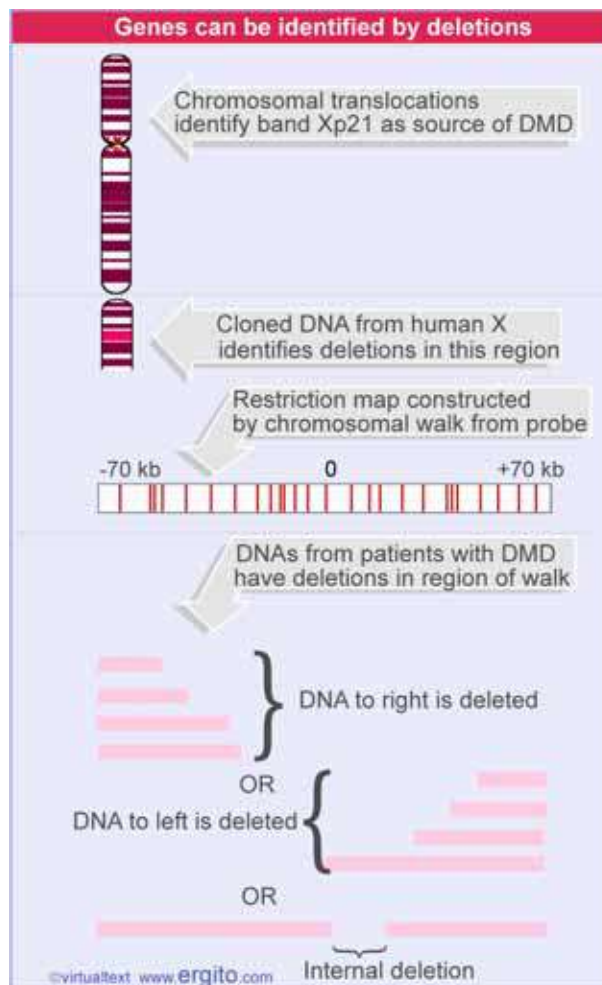

A heroic approach that has proved successful with some genes of medical importance is to screen relatively short fragments from the region for the two properties expected of a conserved gene. First we seek to identify fragments that cross-hybridize with the genomes of other species. Then we examine these fragments for open reading frames.

The first criterion is applied by performing a **zoo blot**. We use short fragments from the region as (radioactive) probes to test for related DNA from a variety of species by Southern blotting. If we find hybridizing fragments in several species related to that of the probe – the probe is usually human – the probe becomes a candidate for an exon of the gene.

The candidates are sequenced, and if they contain open reading frames, are used to isolate surrounding genomic regions. If these appear to be part of an exon, we may

then use them to identify the entire gene, to isolate the corresponding cDNA or mRNA, and ultimately to identify the protein.

This approach is especially important when the target gene is spread out because it has many large introns. This proved to be the case with Duchenne muscular dystrophy (DMD), a degenerative disorder of muscle, which is X-linked and affects 1 in 3500 of human male births. The steps in identifying the gene are summarized in **Figure 2.10**.

**Figure 2.10** The gene involved in Duchenne muscular dystrophy was tracked down by chromosome mapping and walking to a region in which deletions can be identified with the occurrence of the disease.

Linkage analysis localized the DMD locus to chromosomal band Xp21. Patients with the disease often have chromosomal rearrangements involving this band. By comparing the ability of X-linked DNA probes to hybridize with DNA from patients and with normal DNA, cloned fragments were obtained that correspond to the region that was rearranged or deleted in patients' DNA.

Once some DNA in the general vicinity of the target gene has been obtained, it is

possible to "walk" along the chromosome until the gene is reached (see *Molecular Biology Supplement 32.12 Genome mapping*). A chromosomal walk was used to construct a restriction map of the region on either side of the probe, covering a region of >100 kb. Analysis of the DNA from a series of patients identified large deletions in this region, extending in either direction. The most telling deletion is one contained entirely within the region, since this delineates a segment that must be important in gene function and indicates that the gene, or at least part of it, lies in this region (3032; 3033).

Having now come into the region of the gene, we need to identify its exons and introns. A zoo blot identified fragments that cross-hybridize with the mouse X chromosome and with other mammalian DNAs. As summarized in **Figure 2.11**, these were scrutinized for open reading frames and the sequences typical of exon-intron junctions. Fragments that met these criteria were used as probes to identify homologous sequences in a cDNA library prepared from muscle mRNA.

**Figure 2.11** The Duchenne muscular dystrophy gene was characterized by zoo blotting, cDNA hybridization, genomic hybridization, and identification of the protein.

The cDNA corresponding to the gene identifies an unusually large mRNA, ~14 kb. Hybridization back to the genome shows that the mRNA is represented in >60 exons, which are spread over ~2000 kb of DNA. This makes DMD the longest gene identified; in fact, it is 10× longer than any other known gene (3034; 3035).

The gene codes for a protein of ~500 kD, called dystrophin, which is a component of muscle, present in rather low amounts. All patients with the disease have deletions at this locus, and lack (or have defective) dystrophin.

Muscle also has the distinction of having the largest known protein, titin, with almost 27,000 amino acids. Its gene has the largest number of exons (178) and the longest single exon in the human genome (17,000 bp).

Another technique that allows genomic fragments to be scanned rapidly for the presence of exons is called **exon trapping** (3030). **Figure 2.12** shows that it starts with a vector that contains a strong promoter, and has a single intron between two exons. When this vector is transfected into cells, its transcription generates large amounts of an RNA containing the sequences of the two exons. A restriction cloning site lies within the intron, and is used to insert genomic fragments from a region of interest. If a fragment does not contain an exon, there is no change in the splicing pattern, and the RNA contains only the same sequences as the parental vector. But if the genomic fragment contains an exon flanked by two partial intron sequences, the splicing sites on either side of this exon are recognized, and the sequence of the exon is inserted into the RNA between the two exons of the vector. This can be detected readily by reverse transcribing the cytoplasmic RNA into cDNA, and using PCR to amplify the sequences between the two exons of the vector. So the appearance in the amplified population of sequences from the genomic fragment indicates that an exon has been trapped. Because introns are usually large and exons are small in animal cells, there is a high probability that a random piece of genomic DNA will contain the required structure of an exon surrounded by partial introns. In fact, exon trapping may mimic the events that have occurred naturally during evolution of genes (see *Molecular Biology 1.2.9 How did interrupted genes evolve?*).

**Figure 2.12** A special splicing vector is used for exon trapping. If an exon is present in the genomic fragment, its sequence will be recovered in the cytoplasmic RNA, but if the genomic fragment consists solely of sequences from within intron, splicing does not occur, and the mRNA is not exported to the cytoplasm.

## THE INTERRUPTED GENE

### 1.2.7 Genes show a wide distribution of sizes

#### Key Concepts

- Most genes are uninterrupted in yeasts, but are interrupted in higher eukaryotes.
- Exons are usually short, typically coding for <100 amino acids.
- Introns are short in lower eukaryotes, but range up to several 10s of kb in length in higher eukaryotes.
- The overall length of a gene is determined largely by its introns.

**Figure 2.13** shows the overall organization of genes in yeasts, insects, and mammals. In *S. cerevisiae*, the great majority of genes (>96%) are not interrupted, and those that have exons usually remain reasonably compact. There are virtually no *S. cerevisiae* genes with more than 4 exons.

**Figure 2.13** Most genes are uninterrupted in yeast, but most genes are interrupted in flies and mammals. (Uninterrupted genes have only 1 exon, and are totaled in the leftmost column.)

In insects and mammals, the situation is reversed. Only a few genes have uninterrupted coding sequences (6% in mammals). Insect genes tend to have a fairly small number of exons, typically fewer than 10. Mammalian genes are split into more pieces, and some have several 10s of exons. ~50% of mammalian genes have >10 introns.

Examining the consequences of this type of organization for the overall size of the gene, we see in **Figure 2.14** that there is a striking difference between yeast and the higher eukaryotes. The average yeast gene is 1.4 kb long, and very few are longer than 5 kb. The predominance of interrupted genes in high eukaryotes, however, means that the gene can be much larger than the unit that codes for protein. Relatively few genes in flies or mammals are shorter than 2 kb, and many have lengths between 5 kb and 100 kb. The average human gene is 27 kb long (see **Figure 3.22**).

**Figure 2.14** Yeast genes are small, but genes in flies and mammals have a dispersed distribution extending to very large sizes.

The switch from largely uninterrupted to largely interrupted genes occurs in the lower eukaryotes. In fungi (excepting the yeasts), the majority of genes are interrupted, but they have a relatively small number of exons (<6) and are fairly short (<5 kb). The switch to long genes occurs within the higher eukaryotes, and genes become significantly larger in the insects. With this increase in the length of the gene, the relationship between genome complexity and organism complexity is lost (see **Figure 3.5**).

As genome size increases, the tendency is for introns to become rather large, while exons remain quite small.

**Figure 2.15** shows that the exons coding for stretches of protein tend to be fairly small. In higher eukaryotes, the average exon codes for ~50 amino acids, and the general distribution fits well with the idea that genes have evolved by the slow addition of units that code for small, individual domains of proteins (see *Molecular Biology 1.2.9 How did interrupted genes evolve?*). There is no very significant difference in the sizes of exons in different types of higher eukaryotes, although the distribution is more compact in vertebrates where there are few exons longer than 200 bp. In yeast, there are some longer exons that represent uninterrupted genes where the coding sequence is intact. There is a tendency for exons coding for untranslated 5' and 3' regions to be longer than those that code for proteins.

**Figure 2.15** Exons coding for proteins are usually short.

**Figure 2.16** shows that introns vary widely in size. In worms and flies, the average intron is not much longer than the exons. There are no very long introns in worms, but flies contain a significant proportion. In vertebrates, the size distribution is much wider, extending from approximately the same length as the exons (<200 bp) to lengths measured in 10s of kbs, and extending up to 50-60 kb in extreme cases.

**Figure 2.16** Introns range from very short to very long.

Very long genes are the result of very long introns, not the result of coding for longer products. There is no correlation between gene size and mRNA size in higher eukaryotes; nor is there a good correlation between gene size and the number of exons. The size of a gene therefore depends primarily on the lengths of its individual introns. In mammals, insects, and birds, the "average" gene is approximately 5× the length of its mRNA.

## THE INTERRUPTED GENE

### 1.2.8 Some DNA sequences code for more than one protein

---

#### Key Concepts

- The use of alternative initiation or termination codons allows two proteins to be generated where one is equivalent to a fragment of the other.
  - Nonhomologous protein sequences can be produced from the same sequence of DNA when it is read in different reading frames by two (overlapping) genes.
  - Homologous proteins that differ by the presence or absence of certain regions can be generated by differential (alternative) splicing, when certain exons are included or excluded. This may take the form of including or excluding individual exons or of choosing between alternative exons.
- 

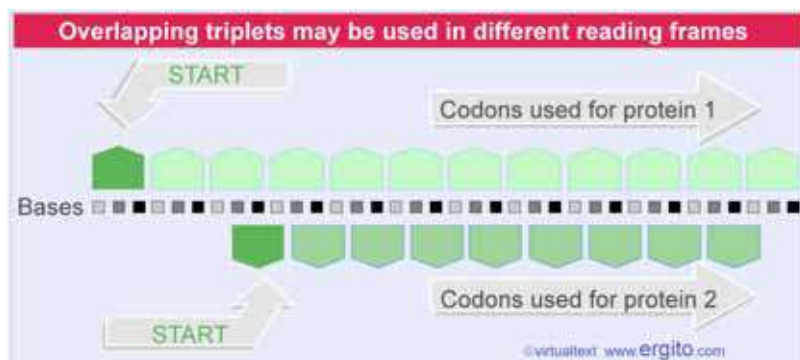

Most genes consist of a sequence of DNA that is devoted solely to the purpose of coding for one protein (although the gene may include noncoding regions at either end and introns within the coding region). However, there are some cases in which a single sequence of DNA codes for more than one protein.

*Overlapping genes* occur in the relatively simple situation in which one gene is part of the other. The first half (or second half) of a gene is used independently to specify a protein that represents the first (or second) half of the protein specified by the full gene. This relationship is illustrated in **Figure 2.17**. The end result is much the same as though a partial cleavage took place in the protein product to generate part-length as well as full-length forms.

**Figure 2.17** Two proteins can be generated from a single gene by starting (or terminating) expression at different points.

Two genes overlap in a more subtle manner when the same sequence of DNA is shared between two *nonhomologous* proteins. This situation arises when the same sequence of DNA is translated in more than one reading frame. In cellular genes, a DNA sequence usually is read in only one of the three potential reading frames, but in some viral and mitochondrial genes, there is an overlap between two adjacent genes that are read in different reading frames. This situation is illustrated in **Figure 2.18**. The distance of overlap is usually relatively short, so that most of the sequence representing the protein retains a unique coding function.

**Figure 2.18** Two genes may share the same sequence by reading the DNA in different frames.

In some genes, *alternative* patterns of gene expression create switches in the pathway for connecting the exons. A single gene may generate a variety of mRNA products that differ in their content of exons. The difference may be that certain exons are optional – they may be included or spliced out. Or there may be exons that are treated as mutually exclusive – one or the other is included, but not both. The alternative forms produce proteins in which one part is common while the other part

is different.

In some cases, the alternative means of expression do not affect the sequence of the protein; for example, changes that affect the 5' nontranslated leader or the 3' nontranslated trailer may have regulatory consequences, but the same protein is made. In other cases, one exon is substituted for another, as indicated in **Figure 2.19**.

**Figure 2.19** Alternative splicing generates the  $\alpha$  and  $\beta$  variants of troponin T.

In this example, the proteins produced by the two mRNAs contain sequences that overlap extensively, but that are different within the alternatively spliced region. The 3' half of the troponin T gene of rat muscle contains 5 exons, but only 4 are used to construct an individual mRNA. Three exons, WXZ, are the same in both expression patterns. However, in one pattern the  $\alpha$  exon is spliced between X and Z; in the other pattern, the  $\beta$  exon is used. The  $\alpha$  and  $\beta$  forms of troponin T therefore differ in the sequence of the amino acids present between sequences W and Z, depending on which of the alternative exons,  $\alpha$  or  $\beta$ , is used. Either one of the  $\alpha$  and  $\beta$  exons can be used to form an individual mRNA, but both cannot be used in the same mRNA.

**Figure 2.20** illustrates an example in which alternative splicing leads to the inclusion of an exon in some mRNAs, while it is left out of others. A single type of transcript is made from the gene, but it can be spliced in either of two ways. In the first pathway, two introns are spliced out, and the three exons are joined together. In the second pathway, the second exon is not recognized. As a result, a single large intron is spliced out. This intron consists of intron 1 + exon 2 + intron 2. In effect, exon 2 has been treated in this pathway as part of the single intron. The pathways produce two proteins that are the same at their ends, but one of which has an additional sequence in the middle. So the region of DNA codes for more than one protein. (Other types of combinations that are produced by alternative splicing are discussed in *Molecular Biology 5.24.12 Alternative splicing involves differential use of splice junctions*).

**Figure 2.20** Alternative splicing uses the same pre-mRNA to generate mRNAs that have different combinations of exons.

Sometimes two pathways operate simultaneously, a certain proportion of the RNA being spliced in each way; sometimes the pathways are alternatives that are expressed under different conditions, one in one cell type and one in another cell type.

So alternative (or differential) splicing can generate proteins with overlapping sequences from a single stretch of DNA. It is curious that the higher eukaryotic genome is extremely spacious in having large genes that are often quite dispersed, but at the same time it may make multiple products from an individual locus. Alternative splicing expands the number of proteins relative to the number of genes by ~15% in flies and worms, but has much bigger effects in man, where ~60% of genes may have alternative modes of expression (see *Molecular Biology 1.3.11 The human genome has fewer genes than expected*). About 80% of the alternative splicing events result in a change in the protein sequence.

## THE INTERRUPTED GENE

### 1.2.9 How did interrupted genes evolve?

---

#### Key Concepts

- The major evolutionary question is whether genes originated as sequences interrupted by exons or whether they were originally uninterrupted.
- Most protein-coding genes probably originated in an interrupted form, but interrupted genes that code for RNA may have originally been uninterrupted.
- A special class of introns is mobile and can insert itself into genes.

---

The highly interrupted structure of eukaryotic genes suggests a picture of the eukaryotic genome as a sea of introns (mostly but not exclusively unique in sequence), in which islands of exons (sometimes very short) are strung out in individual archipelagoes that constitute genes.

What was the original form of genes that today are interrupted?

- The "introns early" model supposes that introns have always been an integral part of the gene. Genes originated as interrupted structures, and those without introns have lost them in the course of evolution.
- The "introns late" model supposes that the ancestral protein-coding units consisted of uninterrupted sequences of DNA. Introns were subsequently inserted into them.

A test of the models is to ask whether the difference between eukaryotic and prokaryotic genes can be accounted for by the acquisition of introns in the eukaryotes or by the loss of introns from the prokaryotes.

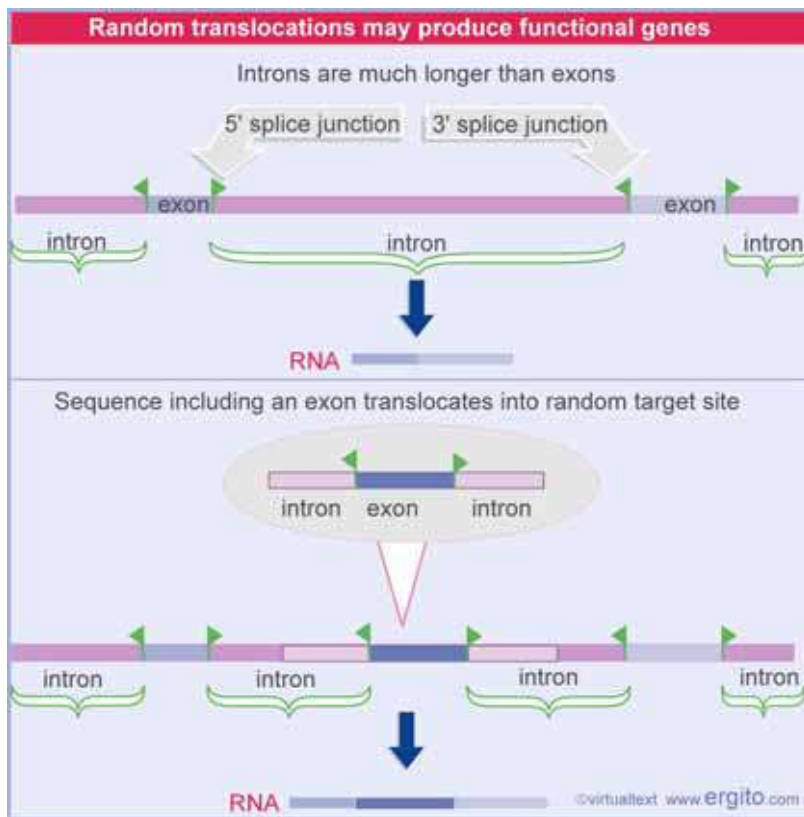

The introns early model suggests that the mosaic structure of genes is a remnant of an ancient approach to the reconstruction of genes to make novel proteins. Suppose that an early cell had a number of separate protein-coding sequences. One aspect of its evolution is likely to have been the reorganization and juxtaposition of different polypeptide units to build up new proteins.

If the protein-coding unit must be a continuous series of codons, every such reconstruction would require a precise recombination of DNA to place the two protein-coding units in register, end to end in the same reading frame. Furthermore, if this combination is not successful, the cell has been damaged, because it has lost the original protein-coding units.

But if an approximate recombination of DNA could place the two protein-coding units within the same transcription unit, splicing patterns could be tried out at the level of RNA to combine the two proteins into a single polypeptide chain. And if

these combinations are not successful, the original protein-coding units remain available for further trials. Such an approach essentially allows the cell to try out controlled deletions in RNA without suffering the damaging instability that could occur from applying this procedure to DNA. This argument is supported by the fact that we can find related exons in different genes, as though the gene had been assembled by mixing and matching exons (see *Molecular Biology 1.2.10 Some exons can be equated with protein functions*).

**Figure 2.21** illustrates the outcome when a random sequence that includes an exon is translocated to a new position in the genome. Exons are very small relative to introns, so it is likely that the exon will find itself within an intron. Because only the sequences at the exon-intron junctions are required for splicing, the exon is likely to be flanked by functional 3' and 5' splice junctions, respectively. Because splicing junctions are recognized in pairs, the 5' splicing junction of the original intron is likely to interact with the 3' splicing junction introduced by the new exon, instead of with its original partner. Similarly, the 5' splicing junction of the new exon will interact with the 3' splicing junction of the original intron. The result is to insert the new exon into the RNA product between the original two exons. So long as the new exon is in the same coding frame as the original exons, a new protein sequence will be produced. This type of event could have been responsible for generating new combinations of exons during evolution. Note that the principle of this type of event is mimicked by the technique of exon trapping that is used to screen for functional exons (see **Figure 2.12**).

**Figure 2.21** An exon surrounded by flanking sequences that is translocated into an intron may be spliced into the RNA product.

Alternative forms of genes for rRNA and tRNA are sometimes found, with and without introns. In the case of the tRNAs, where all the molecules conform to the same general structure, it seems unlikely that evolution brought together the two regions of the gene. After all, the different regions are involved in the base pairing that gives significance to the structure. So here it must be that the introns were inserted into continuous genes.

Organelle genomes provide some striking connections between the prokaryotic and eukaryotic worlds. Because of many general similarities between mitochondria or chloroplasts and bacteria, it seems likely that the organelles originated by an *endosymbiosis* in which an early bacterial prototype was inserted into eukaryotic cytoplasm. Yet in contrast with the resemblances with bacteria – for example, as seen in protein or RNA synthesis – some organelle genes possess introns, and therefore resemble eukaryotic nuclear genes.

Introns are found in several chloroplast genes, including some that have homologies with genes of *E. coli*. This suggests that the endosymbiotic event occurred before introns were lost from the prokaryotic line. If a suitable gene can be found, it may therefore be possible to trace gene lineage back to the period when endosymbiosis occurred.

The mitochondrial genome presents a particularly striking case. The genes of yeast and mammalian mitochondria code for virtually identical mitochondrial proteins, in spite of a considerable difference in gene organization. Vertebrate mitochondrial genomes are very small, with an extremely compact organization of continuous genes, whereas yeast mitochondrial genomes are larger and have some complex interrupted genes. Which is the ancestral form? The yeast mitochondrial introns (and certain other introns) can have the property of mobility – they are self-contained sequences that can splice out of the RNA and insert DNA copies elsewhere – which suggests that they may have arisen by insertions into the genome (see *Molecular Biology 5.26.5 Some group I introns code for endonucleases that sponsor mobility* and *Molecular Biology 5.26.6 Some group II introns code for reverse transcriptases*).

## THE INTERRUPTED GENE

### 1.2.10 Some exons can be equated with protein functions

---

#### Key Concepts

- Facts suggesting that exons were the building blocks of evolution and the first genes were interrupted are:
    - Gene structure is conserved between genes in very distant species.
    - Many exons can be equated with coding for protein sequences that have particular functions.
    - Related exons are found in different genes.
- 

If current proteins evolved by combining ancestral proteins that were originally separate, the accretion of units is likely to have occurred sequentially over some period of time, with one exon added at a time (for review see 9). Can the different functions from which these genes were pieced together be seen in their present structures? In other words, can we equate particular functions of current proteins with individual exons ?

In some cases, there is a clear relationship between the structures of the gene and protein. The example *par excellence* is provided by the immunoglobulin proteins, which are coded by genes in which every exon corresponds exactly with a known functional domain of the protein. **Figure 2.22** compares the structure of an immunoglobulin with its gene.

**Figure 2.22** Immunoglobulin light chains and heavy chains are coded by genes whose structures (in their expressed forms) correspond with the distinct domains in the protein. Each protein domain corresponds to an exon; introns are numbered 1-5.

An immunoglobulin is a tetramer of two light chains and two heavy chains, which aggregate to generate a protein with several distinct domains. Light chains and heavy chains differ in structure, and there are several types of heavy chain. Each type of chain is expressed from a gene that has a series of exons corresponding with the structural domains of the protein.

In many instances, some of the exons of a gene can be identified with particular functions. In secretory proteins, the first exon, coding for the N-terminal region of the polypeptide, often specifies the signal sequence involved in membrane secretion. An example is insulin.

The view that exons are the functional building blocks of genes is supported by cases in which two genes may have some exons that are related to one another, while other exons are found only in one of the genes. **Figure 2.23** summarizes the relationship between the receptor for human LDL (plasma low density lipoprotein) and other proteins. In the center of the LDL receptor gene is a series of exons related to the exons of the gene for the precursor for EGF (epidermal growth factor). In the N-terminal part of the protein, a series of exons codes for a sequence related to the blood protein complement factor C9. So the LDL receptor gene was created by assembling *modules* for its various functions. These modules are also used in different combinations in other proteins.

**Figure 2.23** The LDL receptor gene consists of 18 exons, some of which are related to EGF precursor and some to the C9 blood complement gene. Triangles mark the positions of introns. Only some of the introns in the region related to EGF precursor are identical in position to those in the EGF gene.

Exons tend to be fairly small (see **Figure 2.12**), around the size of the smallest polypeptide that can assume a stable folded structure, ~20-40 residues. Perhaps proteins were originally assembled from rather small modules. Each module need not necessarily correspond to a current function; several modules could have combined to generate a function. The number of exons in a gene tends to increase with the length of its protein, which is consistent with the view that proteins acquire multiple functions by successively adding appropriate modules.

This idea might explain another feature of protein structure: it seems that the sites represented at exon-intron boundaries often are located at the surface of a protein. As modules are added to a protein, the connections, at least of the most recently added modules, could tend to lie at the surface.

## THE INTERRUPTED GENE

### 1.2.11 The members of a gene family have a common organization

---

#### Key Terms

A **superfamily** is a set of genes all related by presumed descent from a common ancestor, but now showing considerable variation.

#### Key Concepts

- A common feature in a set of genes is assumed to identify a property that preceded their separation in evolution.
- All globin genes have a common form of organization with 3 exons and 2 introns, suggesting that they are descended from a single ancestral gene.

---

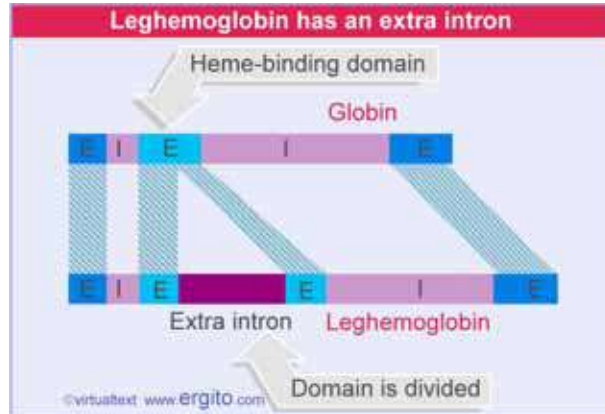

A fascinating case of evolutionary conservation is presented by the  $\alpha$ - and  $\beta$ -globins and two other proteins related to them. Myoglobin is a monomeric oxygen-binding protein of animals, whose amino acid sequence suggests a common (though ancient) origin with the globin subunits. Leghemoglobins are oxygen-binding proteins present in the legume class of plants; like myoglobin, they are monomeric. They too share a common origin with the other heme-binding proteins. Together, the globins, myoglobin, and leghemoglobin constitute the globin **superfamily**, a set of gene families all descended from some (distant) common ancestor.

Both  $\alpha$ - and  $\beta$ -globin genes have three exons (see **Figure 2.7**). The two introns are located at constant positions relative to the coding sequence. The central exon represents the heme-binding domain of the globin chain.

Myoglobin is represented by a single gene in the human genome, whose structure is essentially the same as that of the globin genes. The three-exon structure therefore predates the evolution of separate myoglobin and globin functions.

Leghemoglobin genes contain three introns, the first and last of which occur at points in the coding sequence that are homologous to the locations of the two introns in the globin genes. This remarkable similarity suggests an exceedingly ancient origin for the heme-binding proteins in the form of a split gene, as illustrated in **Figure 2.24**.

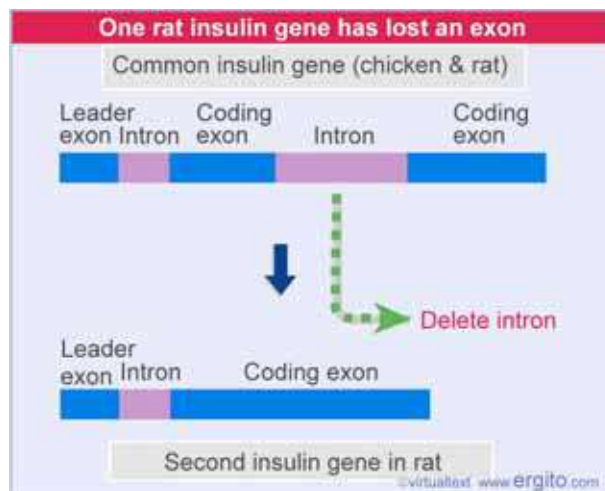

**Figure 2.24** The exon structure of globin genes corresponds with protein function, but leghemoglobin has an extra intron in the central domain.

The central intron of leghemoglobin separates two exons that together code for the sequence corresponding to the single central exon in globin. Could the central exon of the globin gene have been derived by a fusion of two central exons in the ancestral gene? Or is the single central exon the ancestral form; in this case, an intron must have been inserted into it at the start of plant evolution?

Cases in which homologous genes differ in structure may provide information about their evolution. An example is insulin. Mammals and birds have only one gene for insulin, except for the rodents, which have two genes. **Figure 2.25** illustrates the structures of these genes.

**Figure 2.25** The rat insulin gene with one intron evolved by losing an intron from an ancestor with two interruptions.

The principle we use in comparing the organization of related genes in different species is that *a common feature identifies a structure that predated the evolutionary separation of the two species*. In chicken, the single insulin gene has two introns; one of the two rat genes has the same structure. The common structure implies that the ancestral insulin gene had two introns. However, the second rat gene has only one

intron. It must have evolved by a gene duplication in rodents that was followed by the precise removal of one intron from one of the copies.

The organization of some genes shows extensive discrepancies between species. In these cases, there must have been extensive removal or insertion of introns during evolution.

A well characterized case is represented by the actin genes. The typical actin gene has a nontranslated leader of <100 bases, a coding region of ~1200 bases, and a trailer of ~200 bases. Most actin genes are interrupted; the positions of the introns can be aligned with regard to the coding sequence (except for a single intron sometimes found in the leader).

**Figure 2.26** shows that almost every actin gene is different in its pattern of interruptions. Taking all the genes together, introns occur at 12 different sites. However, no individual gene has more than 6 introns; some genes have only one intron, and one is uninterrupted altogether. How did this situation arise? If we suppose that the primordial actin gene was interrupted, and all current actin genes are related to it by loss of introns, different introns have been lost in each evolutionary branch. Probably some introns have been lost entirely, so the primordial gene could well have had 20 or more. The alternative is to suppose that a process of intron insertion continued independently in the different lines of evolution. The relationships between the intron locations found in different species may be used ultimately to construct a tree for the evolution of the gene.

**Figure 2.26** Actin genes vary widely in their organization. The sites of introns are indicated in purple.

The relationship between exons and protein domains is somewhat erratic. In some cases there is a clear 1:1 relationship; in others no pattern is to be discerned. One possibility is that removal of introns has fused the adjacent exons. This means that the intron must have been precisely removed, without changing the integrity of the coding region. An alternative is that some introns arose by insertion into a coherent domain. Together with the variations that we see in exon placement in cases such as the actin genes, this argues that intron positions can be adjusted in the course of

evolution.

The equation of at least some exons with protein domains, and the appearance of related exons in different proteins, leaves no doubt that the duplication and juxtaposition of exons has played an important role in evolution. It is possible that the number of ancestral exons, from which all proteins have been derived by duplication, variation, and recombination, could be relatively small (a few thousands or tens of thousands). By taking exons as the building blocks of evolution, this view implicitly accepts the introns early model for the origin of genes coding for proteins.

## THE INTERRUPTED GENE

### 1.2.12 Is all genetic information contained in DNA?

---

#### Key Terms

**Positional information** describes the localization of macromolecules at particular places in an embryo. The localization may itself be a form of information that is inherited.

#### Key Concepts

- The definition of the gene has reversed from "one gene : one protein" to "one protein : one gene".
- Positional information is also important in development.

---

The concept of the gene has evolved significantly in the past few years. The question of what's in a name is especially appropriate for the gene. We can no longer say that a gene is a sequence of DNA that continuously and uniquely codes for a particular protein. In situations in which a stretch of DNA is responsible for production of one particular protein, current usage regards the entire sequence of DNA, from the first point represented in the messenger RNA to the last point corresponding to its end, as comprising the "gene," exons, introns, and all.

When the sequences representing proteins overlap or have alternative forms of expression, we may reverse the usual description of the gene. Instead of saying "one gene-one polypeptide," we may describe the relationship as "one polypeptide-one gene." So we regard the sequence actually responsible for production of the polypeptide (including introns as well as exons) as constituting the gene, while recognizing that from the perspective of another protein, part of this same sequence also belongs to *its* gene. This allows the use of descriptions such as "overlapping" or "alternative" genes.

We can now see how far we have come from the original one gene : one enzyme hypothesis. Up to that time, the driving question was the nature of the gene. Once it was discovered that genes represent proteins, the paradigm became fixed in the form of the concept that every genetic unit functions through the synthesis of a particular protein.

This view remains the central paradigm of molecular biology: a sequence of DNA functions either by directly coding for a particular protein or by being necessary for the use of an adjacent segment that actually codes for the protein. How far does this paradigm take us beyond explaining the basic relationship between genes and proteins?

The development of multicellular organisms rests on the use of different genes to generate the different cell phenotypes of each tissue. The expression of genes is determined by a regulatory network that takes the form of a cascade. Expression of

the first set of genes at the start of embryonic development leads to expression of the genes involved in the next stage of development, which in turn leads to a further stage, and so on until all the tissues of the adult are functioning. The molecular nature of this regulatory network is largely unknown, but we assume that it consists of genes that code for products (probably protein, perhaps sometimes RNA) that act on other genes.

While such a series of interactions is almost certainly the means by which the developmental program is executed, we can ask whether it is entirely sufficient. One specific question concerns the nature and role of **positional information**. We know that all parts of a fertilized egg are not equal; one of the features responsible for development of different tissue parts from different regions of the egg is location of information (presumably specific macromolecules) within the cell.

We do not know how these particular regions are formed. But we may speculate that the existence of positional information in the egg leads to the differential expression of genes in the cells subsequently formed in these regions, which leads to the development of the adult organism, which leads to the development of an egg with the appropriate positional information#

This possibility prompts us to ask whether some information needed for development of the organism is contained in a form that we cannot directly attribute to a sequence of DNA (although the expression of particular sequences may be needed to perpetuate the positional information). Put in a more general way, we might ask: when we read out the entire sequence of DNA comprising the genome of some organism and interpret it in terms of proteins and regulatory regions, could we in principle construct an organism (or even a single living cell) by controlled expression of the proper genes?

---

## THE INTERRUPTED GENE

### 1.2.13 Summary

---

All types of eukaryotic genomes contain interrupted genes. The proportion of interrupted genes is low in yeasts and increases in the lower eukaryotes; few genes are uninterrupted in higher eukaryotes.

Introns are found in all classes of eukaryotic genes. The structure of the interrupted gene is the same in all tissues, exons are joined together in RNA in the same order as their organization in DNA, and the introns usually have no coding function. Introns are removed from RNA by splicing. Some genes are expressed by alternative splicing patterns, in which a particular sequence is removed as an intron in some situations, but retained as an exon in others.

Positions of introns are often conserved when the organization of homologous genes is compared between species. Intron sequences vary, and may even be unrelated, although exon sequences remain well related. The conservation of exons can be used to isolate related genes in different species.

The size of a gene is determined primarily by the lengths of its introns. Introns become larger early in the higher eukaryotes, when gene sizes therefore increase significantly. The range of gene sizes in mammals is generally from 1-100 kb, but it is possible to have even larger genes; the longest known case is dystrophin at 2000 kb.

Some genes share only some of their exons with other genes, suggesting that they have been assembled by addition of exons representing individual modules of the protein. Such modules may have been incorporated into a variety of different proteins. The idea that genes have been assembled by accretion of exons implies that introns were present in genes of primitive organisms. Some of the relationships between homologous genes can be explained by loss of introns from the primordial genes, with different introns being lost in different lines of descent.

---

## THE CONTENT OF THE GENOME

### 1.3.1 Introduction

---

#### Key Terms

The **genome** is the complete set of sequences in the genetic material of an organism. It includes the sequence of each chromosome plus any DNA in organelles.

The **transcriptome** is the complete set of RNAs present in a cell, tissue, or organism. Its complexity is due mostly to mRNAs, but it also includes noncoding RNAs.

The **proteome** is the complete set of proteins that is expressed by the entire genome. Because some genes code for multiple proteins, the size of the proteome is greater than the number of genes. Sometimes the term is used to describe complement of proteins expressed by a cell at any one time.

---

The key question about the genome is how many genes it contains. We can think about the total number of genes at four levels, corresponding to successive stages in gene expression:

- The **genome** is the complete set of genes of an organism. Ultimately it is defined by the complete DNA sequence, although as a practical matter it may not be possible to identify every gene unequivocally solely on the basis of sequence.
- The **transcriptome** is the complete set of genes expressed under particular conditions. It is defined in terms of the set of RNA molecules that is present, and can refer to a single cell type or to any more complex assembly of cells up to the complete organism. Because some genes generate multiple mRNAs, the transcriptome is likely to be larger than the number of genes defined directly in the genome. The transcriptome includes noncoding RNAs as well as mRNAs.
- The **proteome** is the complete set of proteins. It should correspond to the mRNAs in the transcriptome, although there can be differences of detail reflecting changes in the relative abundance or stabilities of mRNAs and proteins. It can be used to refer to the set of proteins coded by the whole genome or produced in any particular cell or tissue.
- Proteins may function independently or as part of multiprotein assemblies. If we could identify all protein-protein interactions, we could define the total number of independent assemblies of proteins.

The number of genes in the genome can be identified directly by defining open reading frames. Large scale mapping of this nature is complicated by the fact that interrupted genes may consist of many separated open reading frames. Since we do not necessarily have information about the functions of the protein products, or indeed proof that they are expressed at all, this approach is restricted to defining the *potential* of the genome. However, a strong presumption exists that any conserved open reading frame is likely to be expressed.

Another approach is to define the number of genes directly in terms of the transcriptome (by directly identifying all the mRNAs) or proteome (by directly identifying all the proteins). This gives an assurance that we are dealing with *bona fide* genes that are expressed under known circumstances. It allows us to ask how many genes are expressed in a particular tissue or cell type, what variation exists in the relative levels of expression, and how many of the genes expressed in one particular cell are unique to that cell or are also expressed elsewhere.

Concerning the types of genes, we may ask whether a particular gene is essential: what happens to a null mutant? If a null mutation is lethal, or the organism has a visible defect, we may conclude that the gene is essential or at least conveys a selective advantage. But some genes can be deleted without apparent effect on the phenotype. Are these genes really dispensable, or does a selective disadvantage result from the absence of the gene, perhaps in other circumstances, or over longer periods of time?

*This content is available online at <http://www.ergito.com/main.jsp?bcs=MBIO.1.3.1>*

---

## THE CONTENT OF THE GENOME

### 1.3.2 Genomes can be mapped by linkage, restriction cleavage, or DNA sequence

---

Defining the contents of a genome essentially means making a map. We can think about mapping genes and genomes at several levels of resolution:

- A genetic (or linkage) map identifies the distance between mutations in terms of recombination frequencies. It is limited by its reliance on the occurrence of mutations that affect the phenotype. Because recombination frequencies can be distorted relative to the physical distance between sites, it does not accurately represent physical distances along the genetic material.
- A linkage map can also be constructed by measuring recombination between sites in genomic DNA. These sites have sequence variations that generate differences in the susceptibility to cleavage by certain (restriction) enzymes. Because such variations are common, such a map can be prepared for any organism irrespective of the occurrence of mutants. It has the same disadvantage as any linkage map that the relative distances are based on recombination.
- A restriction map is constructed by cleaving DNA into fragments with restriction enzymes and measuring the distances between the sites of cleavage. This represents distances in terms of the length of DNA, so it provides a physical map of the genetic material. A restriction map does not intrinsically identify sites of genetic interest. For it to be related to the genetic map, mutations have to be characterized in terms of their effects upon the restriction sites. Large changes in the genome can be recognized because they affect the sizes or numbers of restriction fragments. Point mutations are more difficult to detect.
- The ultimate map is to determine the sequence of the DNA. From the sequence, we can identify genes and the distances between them. By analyzing the protein-coding potential of a sequence of the DNA, we can deduce whether it represents a protein. The basic assumption here is that natural selection prevents the accumulation of damaging mutations in sequences that code for proteins. Reversing the argument, we may assume that an intact coding sequence is likely to be used to generate a protein.

By comparing the sequence of a wild-type DNA with that of a mutant allele, we can determine the nature of a mutation and its exact site of occurrence. This defines the relationship between the genetic map (based entirely on sites of mutation) and the physical map (based on or even comprising the sequence of DNA).

Similar techniques are used to identify and sequence genes and to map the genome, although there is of course a difference of scale. In each case, the principle is to obtain a series of overlapping fragments of DNA, which can be connected into a continuous map. The crucial feature is that each segment is related to the next segment on the map by characterizing the overlap between them, so that we can be sure no segments are missing. This principle is applied both at the level of ordering

large fragments into a map, and in connecting the sequences that make up the fragments.

*This content is available online at <http://www.ergito.com/main.jsp?bcs=MBIO.1.3.2>*

---

## THE CONTENT OF THE GENOME

### 1.3.3 Individual genomes show extensive variation

---

#### Key Terms

**Polymorphism** (more fully genetic polymorphism) refers to the simultaneous occurrence in the population of genomes showing variations at a given position. The original definition applied to alleles producing different phenotypes. Now it is also used to describe changes in DNA affecting the restriction pattern or even the sequence. For practical purposes, to be considered as an example of a polymorphism, an allele should be found at a frequency  $> 1\%$  in the population.

**Single nucleotide polymorphism (SNP)** describes a polymorphism (variation in sequence between individuals) caused by a change in a single nucleotide. This is responsible for most of the genetic variation between individuals.

**Restriction fragment length polymorphism (RFLP)** refers to inherited differences in sites for restriction enzymes (for example, caused by base changes in the target site) that result in differences in the lengths of the fragments produced by cleavage with the relevant restriction enzyme. RFLPs are used for genetic mapping to link the genome directly to a conventional genetic marker.

#### Key Concepts

- Polymorphism may be detected at the phenotypic level when a sequence affects gene function, at the restriction fragment level when it affects a restriction enzyme target site, and at the sequence level by direct analysis of DNA.
  - The alleles of a gene show extensive polymorphism at the sequence level, but many sequence changes do not affect function.
- 

The original Mendelian view of the genome classified alleles as either wild-type or mutant. Subsequently we recognized the existence of multiple alleles, each with a different effect on the phenotype. In some cases it may not even be appropriate to define any one allele as "wild-type".

The coexistence of multiple alleles at a locus is called genetic **polymorphism**. Any site at which multiple alleles exist as stable components of the population is by definition polymorphic. An allele is usually defined as polymorphic if it is present at a frequency of  $>1\%$  in the population.

What is the basis for the polymorphism among the mutant alleles? They possess different mutations that alter the protein function, thus producing changes in phenotype. If we compare the restriction maps or the DNA sequences of these alleles, they too will be polymorphic in the sense that each map or sequence will be different from the others.

Although not evident from the phenotype, the wild type may itself be polymorphic. Multiple versions of the wild-type allele may be distinguished by differences in sequence that do not affect their function, and which therefore do not produce

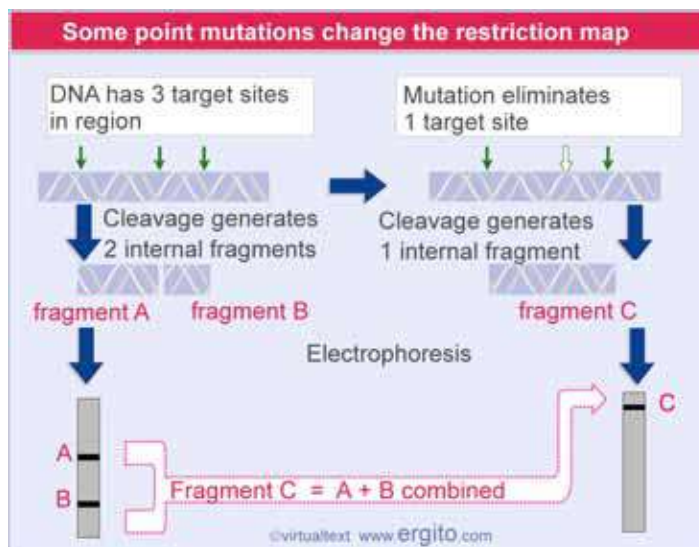

phenotypic variants. A population may have extensive polymorphism at the level of genotype. Many different sequence variants may exist at a given locus; some of them are evident because they affect the phenotype, but others are hidden because they have no visible effect.

So there may be a continuum of changes at a locus, including those that change DNA sequence but do not change protein sequence, those that change protein sequence without changing function, those that create proteins with different activities, and those that create mutant proteins that are nonfunctional.

A change in a single nucleotide when alleles are compared is called a **single nucleotide polymorphism (SNP)**. One occurs every ~1330 bases in the human genome. Defined by their SNPs, every human being is unique. SNPs can be detected by various means, ranging from direct comparisons of sequence to mass spectroscopy or biochemical methods that produce differences based on sequence variations in a defined region (for examples of SNP maps see 1187; 1188).

One aim of genetic mapping is to obtain a catalog of common variants. The observed frequency of SNPs per genome predicts that, over the human population as a whole (taking the sum of all human genomes of all living individuals), there should be >10 million SNPs that occur at a frequency of >1%. Already >1 million have been identified.

Some polymorphisms in the genome can be detected by comparing the restriction maps of different individuals. The criterion is a change in the pattern of fragments produced by cleavage with a restriction enzyme. **Figure 3.1** shows that when a target site is present in the genome of one individual and absent from another, the extra cleavage in the first genome will generate two fragments corresponding to the single fragment in the second genome.

**Figure 3.1** A point mutation that affects a restriction site is detected by a difference in restriction fragments.

Because the restriction map is independent of gene function, a polymorphism at this

level can be detected *irrespective of whether the sequence change affects the phenotype*. Probably very few of the restriction site polymorphisms in a genome actually affect the phenotype. Most involve sequence changes that have no effect on the production of proteins (for example, because they lie between genes).

A difference in restriction maps between two individuals is called a **restriction fragment length polymorphism (RFLP)**. Basically a RFLP is a SNP that is located in the target site for a restriction enzyme. It can be used as a genetic marker in exactly the same way as any other marker. Instead of examining some feature of the phenotype, we directly assess the genotype, as revealed by the restriction map. **Figure 3.2** shows a pedigree of a restriction polymorphism followed through three generations. It displays Mendelian segregation at the level of DNA marker fragments.

**Figure 3.2** Restriction site polymorphisms are inherited according to Mendelian rules. Four alleles for a restriction marker are found in all possible pairwise combinations, and segregate independently at each generation. Photograph kindly provided by Ray White.

## THE CONTENT OF THE GENOME

### 1.3.4 RFLPs and SNPs can be used for genetic mapping

---

#### Key Terms

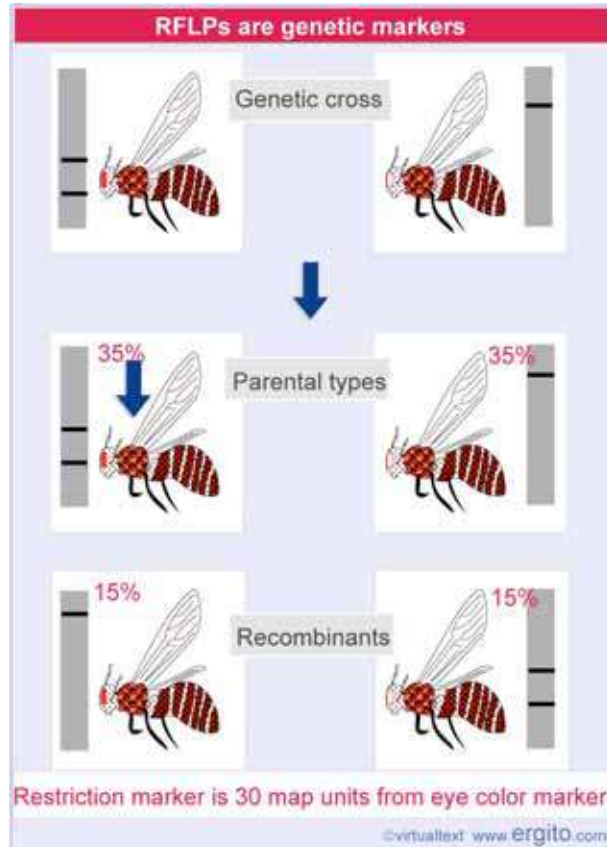

The **haplotype** is the particular combination of alleles in a defined region of some chromosome, in effect the genotype in miniature. Originally used to describe combinations of MHC alleles, it now may be used to describe particular combinations of RFLPs, SNPs, or other markers.

**DNA fingerprinting** analyzes the differences between individuals of the fragments generated by using restriction enzymes to cleave regions that contain short repeated sequences. Because these are unique to every individual, the presence of a particular subset in any two individuals can be used to define their common inheritance (e.g. a parent-child relationship).

#### Key Concepts

- RFLPs and SNPs can be the basis for linkage maps and are useful for establishing parent-progeny relationships.
- 

Recombination frequency can be measured between a restriction marker and a visible phenotypic marker as illustrated in **Figure 3.3**. So a genetic map can include both genotypic and phenotypic markers.

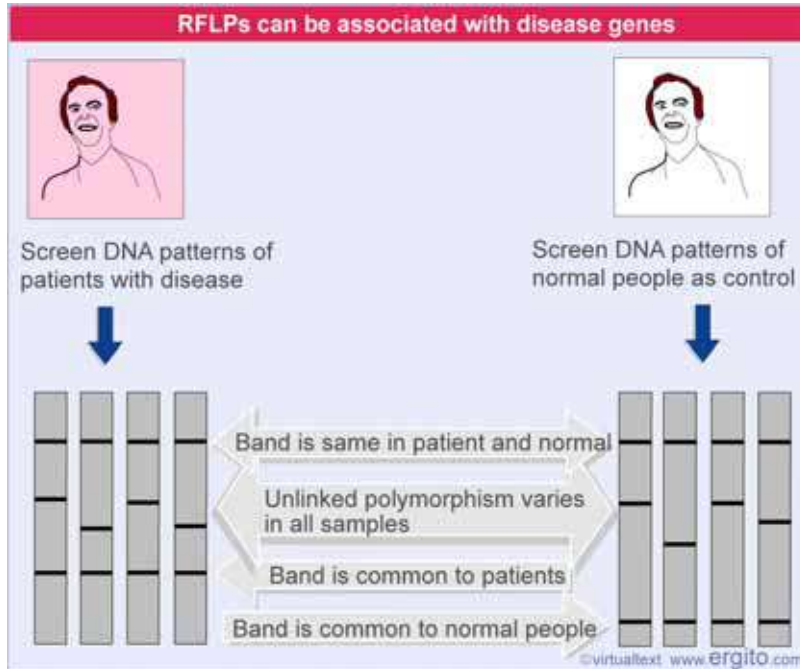

**Figure 3.3** A restriction polymorphism can be used as a genetic marker to measure recombination distance from a phenotypic marker (such as eye color). The figure simplifies the situation by showing only the DNA bands corresponding to the allele of one genome in a diploid.

Because restriction markers are not restricted to those genome changes that affect the phenotype, they provide the basis for an extremely powerful technique for identifying genetic loci at the molecular level. A typical problem concerns a mutation with known effects on the phenotype, where the relevant genetic locus can be placed on a genetic map, but for which we have no knowledge about the corresponding gene or protein. Many damaging or fatal human diseases fall into this category. For example cystic fibrosis shows Mendelian inheritance, but the molecular nature of the mutant function was unknown until it could be identified as a result of characterizing the gene.

If restriction polymorphisms occur at random in the genome, some should occur near any particular target gene. We can identify such restriction markers by virtue of their tight linkage to the mutant phenotype. If we compare the restriction map of DNA from patients suffering from a disease with the DNA of normal people, we may find that a particular restriction site is always present (or always absent) from the patients.

A hypothetical example is shown in **Figure 3.4**. This situation corresponds to finding 100% linkage between the restriction marker and the phenotype. It would imply that the restriction marker lies so close to the mutant gene that it is never separated from it by recombination.

**Figure 3.4** If a restriction marker is associated with a phenotypic characteristic, the restriction site must be located near the gene responsible for the phenotype. The mutation changing the band that is common in normal people into the band that is common in patients is very closely linked to the disease gene.

The identification of such a marker has two important consequences:

- It may offer a diagnostic procedure for detecting the disease. Some of the human diseases that are genetically well characterized but ill defined in molecular terms cannot be easily diagnosed. If a restriction marker is reliably linked to the phenotype, then its presence can be used to diagnose the disease.
- It may lead to isolation of the gene. The restriction marker must lie relatively near the gene on the genetic map if the two loci rarely or never recombine. Although "relatively near" in genetic terms can be a substantial distance in terms of base pairs of DNA, nonetheless it provides a starting point from which we can proceed along the DNA to the gene itself.

The frequent occurrence of SNPs in the human genome makes them useful for genetic mapping. From the  $1.4 \times 10^6$  SNPs that have already been identified, there is on average an SNP every 1-2 kb. This should allow rapid localization of new disease genes by locating them between the nearest SNPs (1442).

On the same principle, RFLP mapping has been in use for some time. Once an RFLP has been assigned to a linkage group, it can be placed on the genetic map. RFLP mapping in man and mouse has led to the construction of linkage maps for both genomes. Any unknown site can be tested for linkage to these sites and by this means rapidly placed on to the map (393; 394; 395). Because there are fewer RFLPs than SNPs, the resolution of the RFLP map is in principle more limited.

The frequency of polymorphism means that every individual has a unique constellation of SNPs or RFLPs. The particular combination of sites found in a specific region is called a **haplotype**, a genotype in miniature. Haplotype was originally introduced as a concept to describe the genetic constitution of the major histocompatibility locus, a region specifying proteins of importance in the immune system (see *Molecular Biology 5.25 Immune diversity*). The concept now has been extended to describe the particular combination of alleles or restriction sites (or any other genetic marker) present in some defined area of the genome.

The existence of RFLPs provides the basis for a technique to establish unequivocal parent-progeny relationships. In cases where parentage is in doubt, a comparison of the RFLP map in a suitable chromosome region between potential parents and child allows absolute assignment of the relationship. The use of DNA restriction analysis to identify individuals has been called **DNA fingerprinting**. Analysis of especially variable "minisatellite" sequences is used mapping in the human genome (for review see 11; 13) (see *Molecular Biology 1.4.14 Minisatellites are useful for genetic mapping*).

## THE CONTENT OF THE GENOME

### 1.3.5 Why are genomes so large?

---

#### Key Terms

The **C-value** is the total amount of DNA in the genome (per haploid set of chromosomes).

The **C-value paradox** describes the lack of relationship between the DNA content (C-value) of an organism and its coding potential.

#### Key Concepts

- There is no good correlation between genome size and genetic complexity.
  - There is an increase in the minimum genome size required to make organisms of increasing complexity.
  - There are wide variations in the genome sizes of organisms within many phyla.
- 

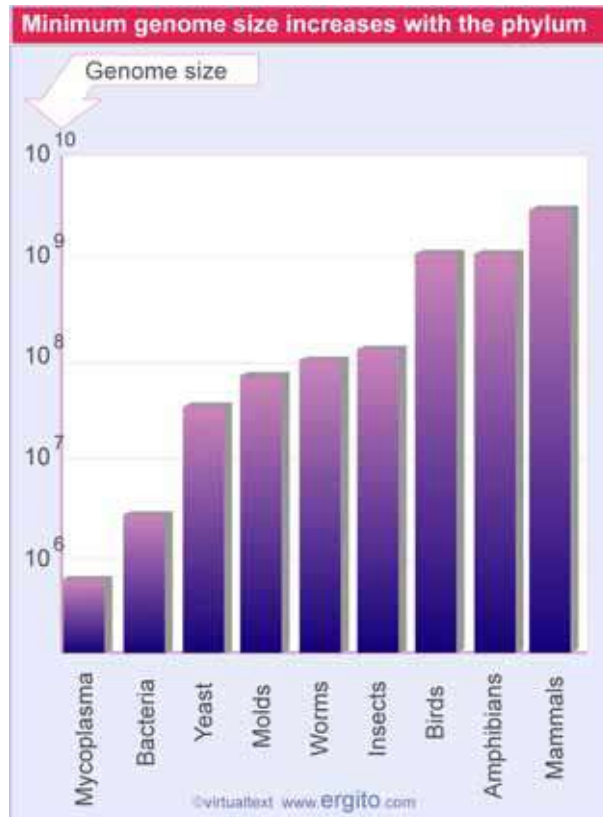

The total amount of DNA in the (haploid) genome is a characteristic of each living species known as its **C-value**. There is enormous variation in the range of C-values, from  $<10^6$  bp for a mycoplasma to  $>10^{11}$  bp for some plants and amphibians.

**Figure 3.5** summarizes the range of C-values found in different evolutionary phyla. There is an increase in the minimum genome size found in each group as the complexity increases. But as absolute amounts of DNA increase in the higher eukaryotes, we see some wide variations in the genome sizes within some phyla.

**Figure 3.5** DNA content of the haploid genome is related to the morphological complexity of lower eukaryotes, but varies extensively among the higher eukaryotes. The range of DNA values within a phylum is indicated by the shaded area.

Plotting the *minimum* amount of DNA required for a member of each group suggests in **Figure 3.6** that an increase in genome size is required to make more complex prokaryotes and lower eukaryotes.

**Figure 3.6** The minimum genome size found in each phylum increases from prokaryotes to mammals.

Mycoplasma are the smallest prokaryotes, and have genomes only  $\sim 3\times$  the size of a large bacteriophage. Bacteria start at  $\sim 2 \times 10^6$  bp. Unicellular eukaryotes (whose life-styles may resemble the prokaryotic) get by with genomes that are also small, although larger than those of the bacteria. Being eukaryotic *per se* does not imply a vast increase in genome size; a yeast may have a genome size of  $\sim 1.3 \times 10^7$  bp, only about twice the size of the largest bacterial genomes.

A further twofold increase in genome size is adequate to support the slime mold *D. discoideum*, able to live in either unicellular or multicellular modes. Another increase in complexity is necessary to produce the first fully multicellular organisms; the nematode worm *C. elegans* has a DNA content of  $8 \times 10^7$  bp.

We can also see the steady increase in genome size with complexity in the listing in **Figure 3.7** of some of the most commonly analyzed organisms. It is necessary to increase the genome size in order to make insects, birds or amphibians, and mammals. However, after this point there is no good relationship between genome size and morphological complexity of the organism.

Useful genome sizes		
Phylum	Species	Genome (bp)
Algae	<i>Pyrenomas salina</i>	$6.6 \times 10^5$
Mycoplasma	<i>M. pneumoniae</i>	$1.0 \times 10^6$
Bacterium	<i>E. coli</i>	$4.2 \times 10^6$
Yeast	<i>S. cerevisiae</i>	$1.3 \times 10^7$
Slime mold	<i>D. discoideum</i>	$5.4 \times 10^7$
Nematode	<i>C. elegans</i>	$8.0 \times 10^7$
Insect	<i>D. melanogaster</i>	$1.4 \times 10^8$
Bird	<i>G. domesticus</i>	$1.2 \times 10^9$
Amphibian	<i>X. laevis</i>	$3.1 \times 10^9$
Mammal	<i>H. sapiens</i>	$3.3 \times 10^9$

©virtualtext www.ergito.com

**Figure 3.7** The genome sizes of some common experimental animals.

We know that genes are much larger than the sequences needed to code for proteins, because exons (coding regions) may comprise only a small part of the total length of a gene). This explains why there is much more DNA than is needed to provide reading frames for all the proteins of the organism. Large parts of an interrupted gene may not be concerned with coding for protein. And there may also be significant lengths of DNA between genes. So it is not possible to deduce from the overall size of the genome anything about the number of genes.

The **C-value paradox** refers to the lack of correlation between genome size and genetic complexity (3040; 3039). There are some extremely curious variations in relative genome size. The toad *Xenopus* and man have genomes of essentially the same size. But we assume that man is more complex in terms of genetic development! And in some phyla there are extremely large variations in DNA content between organisms that do not vary much in complexity (see **Figure 3.5**). (This is especially marked in insects, amphibians, and plants, but does not occur in birds, reptiles, and mammals, which all show little variation within the group, with an  $\sim 2\times$  range of genome sizes.) A cricket has a genome  $11\times$  the size of a fruit fly. In amphibians, the smallest genomes are  $<10^9$  bp, while the largest are  $\sim 10^{11}$  bp. There is unlikely to be a large difference in the number of genes needed to specify these amphibians. We do not understand why natural selection allows this variation and whether it has evolutionary consequences.

## THE CONTENT OF THE GENOME

### 1.3.6 Eukaryotic genomes contain both nonrepetitive and repetitive DNA sequences

---

#### Key Terms

**Nonrepetitive DNA** shows reassociation kinetics expected of unique sequences.

**Repetitive DNA** behaves in a reassociation reaction as though many (related or identical) sequences are present in a component, allowing any pair of complementary sequences to reassociate.

A **transposon (transposable element)** is a DNA sequence able to insert itself (or a copy of itself) at a new location in the genome, without having any sequence relationship with the target locus.

**Selfish DNA** describes sequences that do not contribute to the genotype of the organism but have self-perpetuation within the genome as their sole function.

#### Key Concepts

- The kinetics of DNA reassociation after a genome has been denatured distinguish sequences by their frequency of repetition in the genome.
- Genes are generally coded by sequences in nonrepetitive DNA.
- Larger genomes within a phylum do not contain more genes, but have large amounts of repetitive DNA.
- A large part of repetitive DNA may be made up of transposons.

---

The general nature of the eukaryotic genome can be assessed by the kinetics of reassociation of denatured DNA. This technique was used extensively before large scale DNA sequencing became possible (for review see *Molecular Biology Supplement 32.1 DNA reassociation kinetics*).

Reassociation kinetics identify two general types of genomic sequences (15; 16):

- **Nonrepetitive DNA** consists of sequences that are unique: there is only one copy in a haploid genome.
- **Repetitive DNA** describes sequences that are present in more than one copy in each genome.

Repetitive DNA is often divided into two general types:

- Moderately repetitive DNA consists of relatively short sequences that are repeated typically 10-1000× in the genome. The sequences are dispersed

throughout the genome, and are responsible for the high degree of secondary structure formation in pre-mRNA, when (inverted) repeats in the introns pair to form duplex regions.

- Highly repetitive DNA consists of very short sequences (typically <100 bp) that are present many thousands of times in the genome, often organized as long tandem repeats (see *Molecular Biology 1.4.11 Satellite DNAs often lie in heterochromatin*). Neither class represents protein.

The proportion of the genome occupied by nonrepetitive DNA varies widely. **Figure 3.8** summarizes the genome organization of some representative organisms. Prokaryotes contain only nonrepetitive DNA. For lower eukaryotes, most of the DNA is nonrepetitive; <20% falls into one or more moderately repetitive components. In animal cells, up to half of the DNA often is occupied by moderately and highly repetitive components. In plants and amphibians, the moderately and highly repetitive components may account for up to 80% of the genome, so that the nonrepetitive DNA is reduced to a minority component.

**Figure 3.8** The proportions of different sequence components vary in eukaryotic genomes. The absolute content of nonrepetitive DNA increases with genome size, but reaches a plateau at  $\sim 2 \times 10^9$  bp.

A significant part of the moderately repetitive DNA consists of **transposons**, short sequences of DNA (~1 kb) that have the ability to move to new locations in the genome and/or to make additional copies of themselves (see *Molecular*

*Biology 4.16 Transposons and Molecular Biology 4.17 Retroviruses and retroposons*). In some higher eukaryotic genomes they may even occupy more than half of the genome (see *Molecular Biology 1.3.11 The human genome has fewer genes than expected*).

Transposons are sometimes viewed as fitting the concept of **selfish DNA**, defined as sequences that propagate themselves within a genome, without contributing to the development of the organism. Transposons may sponsor genome rearrangements, and these could confer selective advantages, but it is fair to say that we do not really understand why selective forces do not act against transposons becoming such a large proportion of the genome. Another term that is sometimes used to describe the apparent excess of DNA is *junk DNA*, meaning genomic sequences without any apparent function. Of course, it is likely that there is a balance in the genome between the generation of new sequences and the elimination of unwanted sequences, and some proportion of DNA that apparently lacks function may be in the process of being eliminated.

The length of the nonrepetitive DNA component tends to increase with overall genome size, as we proceed up to a total genome size  $\sim 3 \times 10^9$  (characteristic of mammals). Further increase in genome size, however, generally reflects an increase in the amount and proportion of the repetitive components, so that it is rare for an organism to have a nonrepetitive DNA component  $> 2 \times 10^9$ . The nonrepetitive DNA content of genomes therefore accords better with our sense of the relative complexity of the organism. *E. coli* has  $4.2 \times 10^6$  bp, *C. elegans* increases an order of magnitude to  $6.6 \times 10^7$  bp, *D. melanogaster* increases further to  $\sim 10^8$  bp, and mammals increase another order of magnitude to  $\sim 2 \times 10^9$  bp.

What type of DNA corresponds to protein-coding genes? Reassociation kinetics typically show that mRNA is derived from nonrepetitive DNA. The amount of nonrepetitive DNA is therefore a better indication that the total DNA of the coding potential. (However, more detailed analysis based on genomic sequences shows that many exons have related sequences in other exons [see *Molecular Biology 1.2.5 Exon sequences are conserved but introns vary*]. Such exons evolve by a duplication to give copies that initially are identical, but which then diverge in sequence during evolution.)

## THE CONTENT OF THE GENOME

### 1.3.7 Bacterial gene numbers range over an order of magnitude

#### Key Concepts

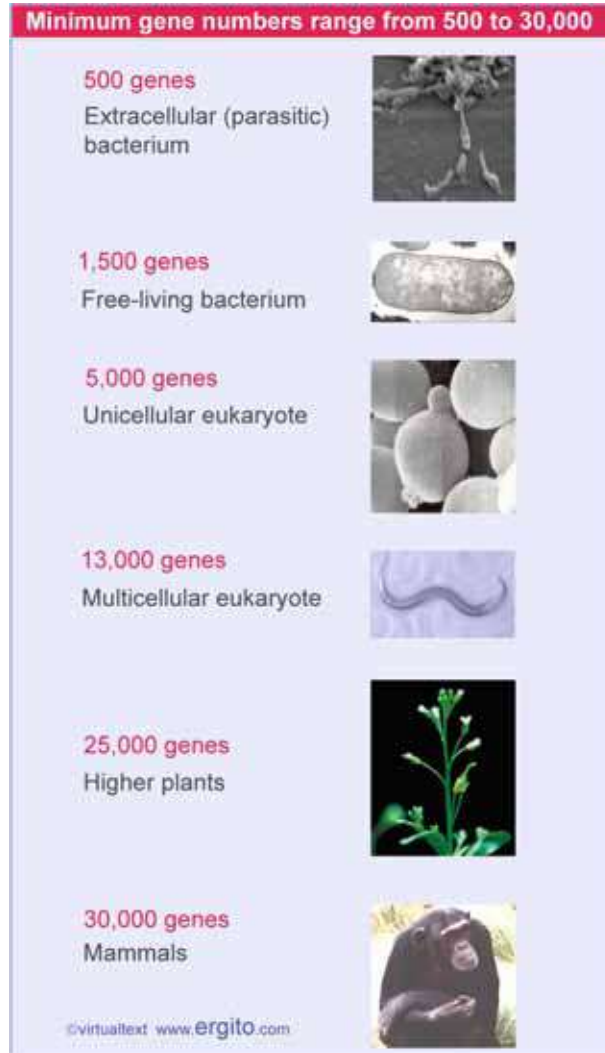

- Genome sequences show that there are 500-1200 genes in parasitic bacteria, 1500-7500 genes in free-living bacteria, and 1500-2700 genes in archaea.

Large-scale efforts have now led to the sequencing of many genomes. A range is summarized in **Figure 3.9**. They extend from the  $0.6 \times 10^6$  bp of a mycoplasma to the  $3.3 \times 10^9$  bp of the human genome, and include several important experimental animals, including yeasts, the fruit fly, and a nematode worm. (Web sites with summaries of genome sequences are listed at the end of this section).

Sequenced genomes vary from 470-30,000 genes			
Species	Genome (Mb)	Genes	Lethal loci
<i>Mycoplasma genitalium</i>	0.58	470	~300
<i>Rickettsia prowazekii</i>	1.11	834	
<i>Haemophilus influenzae</i>	1.83	1,743	
<i>Methanococcus jannaschi</i>	1.66	1,738	
<i>B. subtilis</i>	4.2	4,100	
<i>E. coli</i>	4.6	4,288	1,800
<i>S. cerevisiae</i>	13.5	6,034	1,090
<i>S. pombe</i>	12.5	4,929	
<i>A. thaliana</i>	119	25,498	
<i>O. sativa</i> (rice)	466	~30,000	
<i>D. melanogaster</i>	165	13,601	3,100
<i>C. elegans</i>	97	18,424	
<i>H. sapiens</i>	3,300	~30,000	

**Figure 3.9** Genome sizes and gene numbers are known from complete sequences for several organisms. Lethal loci are estimated from genetic data.

**Figure 3.10** summarizes the minimum number of genes found in each class of organism; of course, many species may have more than the minimum number required for their type.

**Figure 3.10** The minimum gene number required for any type of organism increases with its complexity. Photograph of mycoplasma kindly provided by A. Albay, K. Frantz, and K. Bott. Photograph of bacterium kindly provided by Jonathan King.

The sequences of the genomes of bacteria and archaea show that virtually all of the DNA (typically 85-90%) codes for RNA or protein. **Figure 3.11** shows that the range of genome sizes is about an order of magnitude, and that the genome size is proportional to the number of genes. The typical gene is about 1000 bp in length.

**Figure 3.11** The number of genes in bacterial and archaeal genomes is proportional to genome size.

All of the bacteria with genome sizes below 1.5 Mb are obligate intracellular parasites – they live within a eukaryotic host that provides them with small molecules. Their genomes identify the minimum number of functions required to construct a cell. All classes of genes are reduced in number compared with bacteria with larger genomes, but the most significant reduction is in loci coding for enzymes concerned with metabolic functions (which are largely provided by the host cell) and with regulation of gene expression. *Mycoplasma genitalium* has the smallest genome, ~470 genes.

The archaea have biological properties that are intermediate between the prokaryotes and eukaryotes, but their genome sizes and gene numbers fall in the same range as bacteria. Their genome sizes vary from 1.5 - 3 Mb, corresponding to 1500 - 2700 genes. *M. jannaschii* is a methane-producing species that lives under high pressure and temperature. Its total gene number is similar to that of *H. influenzae*, but fewer of its genes can be identified on the basis of comparison with genes known in other organisms. Its apparatus for gene expression resembles eukaryotes more than prokaryotes, but its apparatus for cell division better resembles prokaryotes.

The archaea and the smallest free-living bacteria identify the minimum number of genes required to make a cell able to function independently in the environment. The smallest archaeal genome has ~1500 genes. The free-living bacterium with the smallest known genome is the thermophile *Aquifex aeolicus*, with 1.5 Mb and 1512 genes (2373). A "typical" gram-negative bacterium, *H. influenzae*, has 1,743 genes each of ~900 bp. So we can conclude that ~1500 genes are required to make a free-living organism.

Bacterial genome sizes extend over almost an order of magnitude to <8 Mb. The larger genomes have more genes. The bacteria with the largest genomes, *S. meliloti* and *M. loti*, are nitrogen-fixing bacteria that live on plant roots. Their genome sizes (~7 Mb) and total gene numbers (>6000) are similar to those of yeasts (2031).

The size of the genome of *E. coli* is in the middle of the range. The common laboratory strain has 4,288 genes, with an average length ~950 bp, and an average separation between genes of 118 bp (406). But there can be quite significant differences between strains. The known extremes of *E. coli* are from the smallest strain that has 4.6 Mb with 4249 genes to the largest strain that has 5.5 Mb bp with 5361 genes

We still do not know the functions of all the genes. In most of these genomes, ~60% of the genes can be identified on the basis of homology with known genes in other species. These genes fall approximately equally into classes whose products are concerned with metabolism, cell structure or transport of components, and gene expression and its regulation. In virtually every genome, >25% of the genes cannot be ascribed any function. Many of these genes can be found in related organisms, which implies that they have a conserved function.

There has been some emphasis on sequencing the genomes of pathogenic bacteria, given their medical importance. An important insight into the nature of pathogenicity has been provided by the demonstration that "pathogenicity islands" are a characteristic feature of their genomes (for review see 2491). These are large regions, ~10-200 kb, that are present in the genome of a pathogenic species, but absent from the genomes of nonpathogenic variants of the same or related species. Their G-C content often differs from that of the rest of the genome, and it is likely that they migrate between bacteria by a process of horizontal transfer. For example, the bacterium that causes anthrax (*B. anthracis*) has two large plasmids (extrachromosomal DNA), one of which has a pathogenicity island that includes the gene coding for the anthrax toxin.

## THE CONTENT OF THE GENOME

### 1.3.8 Total gene number is known for several eukaryotes

#### Key Concepts

- There are 6000 genes in yeast, 18,500 in worm, 13,600 in fly, 25,000 in the small plant *Arabidopsis*, and probably 30,000 in mouse and <40,000 in Man.

As soon as we look at eukaryotic genomes, the relationship between genome size and gene number is lost. The genomes of unicellular eukaryotes fall in the same size range as the largest bacterial genomes. Higher eukaryotes have more genes, but the number does not correlate with genome size, as can be seen from **Figure 3.12**.

**Figure 3.12** The number of genes in a eukaryote varies from 6000 to 40,000 but does not correlate with the genome size or the complexity of the organism.

The most extensive data for lower eukaryotes are available from the sequences of the genomes of the yeasts *S. cerevisiae* and *S. pombe*. **Figure 3.13** summarizes the most important features. The yeast genomes of 13.5 Mb and 12.5 Mb have ~6000 and ~5000 genes, respectively. The average open reading frame is ~1.4 kb, so that ~70% of the genome is occupied by coding regions. The major difference between them is that only 5% of *S. cerevisiae* genes have introns, compared to 43% in *S. pombe*. The density of genes is high; organization is generally similar, although the spaces between genes are a bit shorter in *S. cerevisiae*. About half of the genes identified by sequence were either known previously or related to known genes. The remainder are new, which gives some indication of the number of new types of genes that may be discovered (402, 403, 404, 2372).

**Figure 3.13** The *S. cerevisiae* genome of 13.5 Mb has 6000 genes, almost all uninterrupted. The *S. pombe* genome of 12.5 Mb has 5000 genes, almost half having introns. Gene sizes and spacing are fairly similar.

The identification of long reading frames on the basis of sequence is quite accurate. However, ORFs coding for <100 amino acids cannot be identified solely by sequence because of the high occurrence of false positives. Analysis of gene expression suggests that ~300 of 600 such ORFs in *S. cerevisiae* are likely to be genuine genes.

A powerful way to validate gene structure is to compare sequences in closely related species. If a gene is active, it is likely to be conserved. Comparisons between the sequences of four closely related yeast species suggest that 503 of the genes originally identified in *S. cerevisiae* do not have counterparts in the other species, and therefore should be deleted from the catalog. This reduces the total gene number for *S. cerevisiae* to 5726 (3997).

The genome of *C. elegans* DNA varies between regions rich in genes and regions in which genes are more sparsely organized. The total sequence contains ~18,500 genes. Only ~42% of the genes have putative counterparts outside the Nematoda (405, 407).

Although the fly genome is larger than the worm genome, there are fewer genes (13,600) in *D. melanogaster* (949). The number of different transcripts is slightly larger (14,100) as the result of alternative splicing. We do not understand why the fly—a much more complex organism—has only 70% of the number of genes in the worm. This emphasizes forcefully the lack of an exact relationship between gene number and complexity of the organism.

The plant *Arabidopsis thaliana* has a genome size intermediate between the worm and the fly, but has a larger gene number (25,000) than either (1403). This again shows the lack of a clear relationship, and also emphasizes the special quality of plants, which may have more genes (due to ancestral duplications) than animal cells. A majority of the *Arabidopsis* genome is found in duplicated segments, suggesting that there was an ancient doubling of the genome (to give a tetraploid). Only 35% of *Arabidopsis* genes are present as single copies.

The genome of rice (*Oryza sativa*) is ~4 larger than *Arabidopsis*, but the number of genes is only ~50% larger, probably ~40,000 (2429, 2430). Repetitive DNA occupies 42-45% of the genome. More than 80% of the genes found in *Arabidopsis* are

represented in rice. Of these common genes, ~8000 are found in *Arabidopsis* and rice but not in any of the bacterial or animal genomes that have been sequenced. These are probably the set of genes that code for plant-specific functions, such as photosynthesis.

From the fly genome, we can form an impression of how many genes are devoted to each type of function. **Figure 3.14** breaks down the functions into different categories. Among the genes that are identified, we find 2500 enzymes, ~750 transcription factors, ~700 transporters and ion channels, and ~700 proteins involved with signal transduction. But just over the half genes code for products of unknown function. ~20% of the proteins reside in membranes.

**Figure 3.14** ~20% of *Drosophila* genes code for proteins concerned with maintaining or expressing genes, ~20% for enzymes, <10% for proteins concerned with the cell cycle or signal transduction. Half of the genes of *Drosophila* code for products of unknown function.

Protein size increases from prokaryotes and archaea to eukaryotes. The archaea *M. jannaschi* and bacterium *E. coli* have average protein lengths of 287 and 317 amino acids, respectively; whereas *S. cerevisiae* and *C. elegans* have average lengths of 484 and 442 amino acids, respectively. Large proteins (500 amino acids) are rare in bacteria, but comprise a significant component (~1/3) in eukaryotes. The increase in length is due to the addition of extra domains, with each domain typically constituting 100-300 amino acids. But the increase in protein size is responsible for only a very small part of the increase in genome size.

Another insight into gene number is obtained by counting the number of expressed genes. If we rely upon the estimates of the number of different mRNA species that can be counted in a cell, we would conclude that the average vertebrate cell expresses ~10,000-20,000 genes. The existence of significant overlaps between the messenger populations in different cell types would suggest that the total expressed gene number for the organism should be within a few fold of this. The estimate for the total human genome number of 30,000-40,000 (see *Molecular Biology 1.3.11 The human genome has fewer genes than expected*) would imply that a significant proportion of the total gene number is actually expressed in any given cell.

Eukaryotic genes are transcribed individually, each gene producing a monocistronic messenger. There is only one general exception to this rule; in the genome of *C. elegans*, ~15% of the genes are organized into polycistronic units (which is associated with the use of *trans*-splicing to allow expression of the downstream genes in these units; see *Molecular Biology 5.24.13 trans-splicing reactions use small RNAs*).

## THE CONTENT OF THE GENOME

### 1.3.9 How many different types of genes are there?

---

#### Key Terms

The **proteome** is the complete set of proteins that is expressed by the entire genome.

Because some genes code for multiple proteins, the size of the proteome is greater than the number of genes. Sometimes the term is used to describe complement of proteins expressed by a cell at any one time.

**Orthologs** are corresponding proteins in two species as defined by sequence homologies.

---

Only some genes are unique; others belong to families where the other members are related (but not usually identical). The proportion of unique genes declines with genome size, and the proportion of genes in families increases. The minimum number of gene families required to code a bacterium is >1000, a yeast is >4000, and a higher eukaryote 11,000-14,000.

Because some genes are present in more than one copy or are related to one another, the number of different types of genes is less than the total number of genes. We can divide the total number of genes into sets that have related members, as defined by comparing their exons. (A family of related genes arises by duplication of an ancestral gene followed by accumulation of changes in sequence between the copies. Most often the members of a family are related but not identical.) The number of types of genes is calculated by adding the number of unique genes (where there is no other related gene at all) to the numbers of families that have 2 or more members.

**Figure 3.15** compares the total number of genes with the number of distinct families in each of six genomes (950, 1403, 1439). In bacteria, most genes are unique, so the number of distinct families is close to the total gene number. The situation is different even in the lower eukaryote *S. cerevisiae*, where there is a significant proportion of repeated genes. The most striking effect is that the number of genes increases quite sharply in the higher eukaryotes, but the number of gene families does not change much.

**Figure 3.15** Because many genes are duplicated, the number of different gene families is much less than the total number of genes. The histogram compares the total number of genes with the number of distinct gene families.

**Figure 3.16** shows that the proportion of unique genes drops sharply with genome size. When genes are present in families, the number of members in a family is small in bacteria and lower eukaryotes, but is large in higher eukaryotes. Much of the extra genome size of *Arabidopsis* is accounted for by families with >4 members (1403).

	Unique genes	Families with 2-4 members	Families with >4 members
<i>H. influenzae</i>	89%	10%	1%
<i>S. cerevisiae</i>	72%	19%	9%
<i>D. melanogaster</i>	72%	14%	14%
<i>C. elegans</i>	55%	20%	26%
<i>A. thaliana</i>	35%	24%	41%

**Figure 3.16** The proportion of genes that are present in multiple copies increases with genome size in higher eukaryotes.

If every gene is expressed, the total number of genes will account the total number of proteins required to make the organism (the **proteome**). However, two effects mean that the proteome is different from the total gene number. Because genes are duplicated, some of them code for the same protein (although it may be expressed in a different time or place) and others may code for related proteins that again play the same role in different times or places. And because some genes can produce more

than one protein by means of alternative splicing, the proteome can be larger than the number of genes.

What is the core proteome—the basic number of the different types of proteins in the organism? A minimum estimate is given by the number of gene families, ranging from 1400 in the bacterium, >4000 in the yeast, and a range of 11,000-14,000 for the fly and worm.

What is the distribution of the proteome among types of proteins? The 6000 proteins of the yeast proteome include 5000 soluble proteins and 1000 transmembrane proteins. About half of the proteins are cytoplasmic, a quarter are in the nucleolus, and the remainder are split between the mitochondrion and the ER/Golgi system (2496).

How many genes are common to all organisms (or to groups such as bacteria or higher eukaryotes) and how many are specific for the individual type of organism? **Figure 3.17** summarizes the comparison between yeast, worm, and fly (950). Genes that code for corresponding proteins in different organisms are called **orthologs**. Operationally, we usually reckon that two genes in different organisms can be considered to provide corresponding functions if their sequences are similar over >80% of the length. By this criterion, ~20% of the fly genes have orthologs in both yeast and the worm. These genes are probably required by all eukaryotes. The proportion increases to 30% when fly and worm are compared, probably representing the addition of gene functions that are common to multicellular eukaryotes. This still leaves a major proportion of genes as coding for proteins that are required specifically by either flies or worms, respectively.

**Figure 3.17** The fly genome can be divided into genes that are (probably) present in all eukaryotes, additional genes that are (probably) present in all multicellular eukaryotes, and genes that are more specific to subgroups of species that include flies.

The proteome can be deduced from the number and structures of genes, and can also be directly measured by analyzing the total protein content of a cell or organism. By such approaches, some proteins have been identified that were not suspected on the basis of genome analysis, and that have therefore led to the identification of new genes. Several methods are used for large scale analysis of proteins. Mass

spectrometry can be used for separating and identifying proteins in a mixture obtained directly from cells or tissues (for review see 3755). Hybrid proteins bearing tags can be obtained by expression of cDNAs made by linking the sequences of open reading frames to appropriate expression vectors that incorporate the sequences for affinity tags. This allows array analysis to be used to analyze the products (for review see 3756). These methods also can be effective in comparing the proteins of two tissues, for example, a tissue from a normal individual and one from a patient with disease, to pinpoint the differences (for review see 3758).

Once we know the total number of proteins, we can ask how they interact. By definition, proteins in structural multiprotein assemblies must form stable interactions with one another. Proteins in signaling pathways interact with one another transiently. In both cases, such interactions can be detected in test systems where essentially a readout system magnifies the effect of the interaction. One popular such system is the two hybrid assay discussed in Independent domains bind DNA and activate transcription. Such assays cannot detect all interactions: for example, if one enzyme in a metabolic pathway releases a soluble metabolite that then interacts with the next enzyme, the proteins may not interact directly.

As a practical matter, assays of pairwise interactions can give us an indication of the minimum number of independent structures or pathways. An analysis of the ability of all 6000 (predicted) yeast proteins to interact in pairwise combinations shows that ~1000 proteins can bind to at least one other protein (951). Direct analyses of complex formation have identified 1440 different proteins in 232 multiprotein complexes (2260, 2261). This is the beginning of an analysis that will lead to definition of the number of functional assemblies or pathways (for review see 3757).

In addition to functional genes, there are also copies of genes that have become nonfunctional (identified as such by interruptions in their protein-coding sequences). These are called pseudogenes (see *Molecular Biology 1.4.6 Pseudogenes are dead ends of evolution*). The number of pseudogenes can be large. In the mouse and human genomes, the number of pseudogenes is ~10% of the number of (potentially) active genes (see *Molecular Biology 1.3.10 The conservation of genome organization helps to identify genes*).

Besides needing to know the density of genes to estimate the total gene number, we must also ask: is it important in itself? Are there structural constraints that make it necessary for genes to have a certain spacing, and does this contribute to the large size of eukaryotic genomes?

## THE CONTENT OF THE GENOME

### 1.3.10 The conservation of genome organization helps to identify genes

---

#### Key Terms

**Synteny** describes a relationship between chromosomal regions of different species where homologous genes occur in the same order.

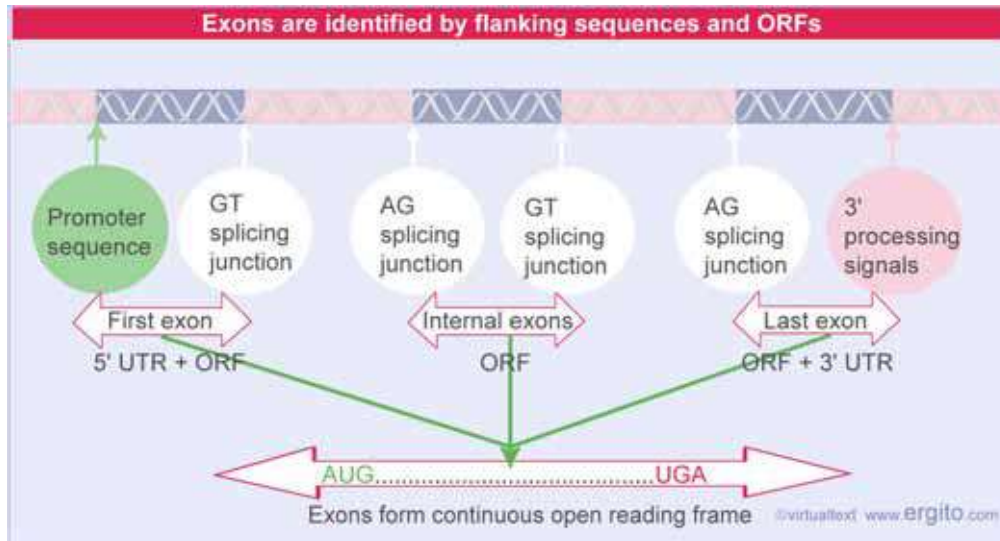

#### Key Concepts

- Algorithms for identifying genes are not perfect and many corrections must be made to the initial data set.
- Pseudogenes must be distinguished from active genes.
- Syntenic relationships are extensive between mouse and human genomes, and most active genes are in a syntenic region.

---

Once we have assembled the sequence of a genome, we still have to identify the genes within it. Coding sequences represent a very small fraction. Exons can be identified as uninterrupted open reading frames flanked by appropriate sequences. What criteria need to be satisfied to identify an active gene from a series of exons?

**Figure 3.18** shows that an active gene should consist of a series of exons where the first exon immediately follows a promoter, the internal exons are flanked by appropriate splicing junctions, the last exon is followed by 3' processing signals, and a single open reading frame starting with an initiation codon and ending with a termination codon can be deduced by joining the exons together. Internal exons can be identified as open reading frames flanked by splicing junctions. In the simplest cases, the first and last exons contain the start and end of the coding region, respectively, (as well as the 5' and 3' untranslated regions), but in more complex cases the first or last exons may have only untranslated regions, and may therefore be more difficult to identify.

**Figure 3.18** Exons of protein-coding genes are identified as coding sequences flanked by appropriate signals (with untranslated regions at both ends). The series of exons must generate an open reading frame with appropriate initiation and termination codons.

The algorithms that are used to connect exons are not completely effective when the genome is very large and the exons may be separated by very large distances. For example, the initial analysis of the human genome mapped 170,000 exons into 32,000 genes. This is unlikely to be correct, because it gives an average of 5.3 exons per gene, whereas the average of individual genes that have been fully characterized is 10.2. Either we have missed many exons, or they should be connected differently into a smaller number of genes in the whole genome sequence.

Even when the organization of a gene is correctly identified, there is the problem of distinguishing active genes from pseudogenes. Many pseudogenes can be recognized by obvious defects in the form of multiple mutations that create an inactive coding sequence. However, pseudogenes that have arisen more recently, and which have not accumulated so many mutations, may be more difficult to recognize. In an extreme example, the mouse has only one active *Gapdh* gene (coding for glyceraldehyde phosphate dehydrogenase), but has ~400 pseudogenes. However, >100 of these pseudogenes initially appeared to be active in the mouse genome sequence. Individual examination was necessary to exclude them from the list of active genes.

Confidence that a gene is active can be increased by comparing regions of the genomes of different species. There has been extensive overall reorganization of sequences between the mouse and human genomes, as seen in the simple fact that there are 23 chromosomes in the human haploid genome and 20 chromosomes in the mouse haploid genome. However, at the local level, the order of genes is generally the same: when pairs of human and mouse homologues are compared, the genes located on either side also tend to be homologues. This relationship is called **synteny**.

**Figure 3.19** shows the relationship between mouse chromosome 1 and the human chromosomal set (3203). We can recognize 21 segments in this mouse chromosome that have syntenic counterparts in human chromosomes. The extent of reshuffling that has occurred between the genomes is shown by the fact that the segments are

spread among 6 different human chromosome. The same types of relationships are found in all mouse chromosomes, except for the X chromosome, which is syntenic only with the human X chromosome. This is explained by the fact that the X is a special case, subject to dosage compensation to adjust for the difference between males (one copy) and females (two copies) (see *Molecular Biology 5.23.17 X chromosomes undergo global changes*). This may apply selective pressure against the translocation of genes to and from the X chromosome.

**Figure 3.19** Mouse chromosome 1 has 21 segments of 1 - 25 Mb that are syntenic with regions corresponding to parts of 6 human chromosomes.

Comparison of the mouse and human genome sequences shows that >90% of each genome lies in syntenic blocks that range widely in size (from 300 kb to 65 Mb). There is a total of 342 syntenic segments, with an average length of 7 Mb (0.3% of the genome) (3203). 99% of mouse genes have a homologue in the human genome; and for 96% that homologue is in a syntenic region.

Comparing the genomes provides interesting information about the evolution of species. The number of gene families in the mouse and human genomes is the same, and a major difference between the species is the differential expansion of particular families in one of the genomes. This is especially noticeable in genes that affect phenotypic features that are unique to the species. Of 25 families where the size has been expanded in mouse, 14 contain genes specifically involved in rodent reproduction, and 5 contain genes specific to the immune system.

A validation of the importance of syntenic blocks comes from pairwise comparisons of the genes within them. Looking for likely pseudogenes on the basis of sequence comparisons, a gene that is not in a syntenic location (that is, its context is different in the two species) is twice as likely to be a pseudogene. Put another way, translocation away from the original locus tends to be associated with the creation of pseudogenes. The lack of a related gene in a syntenic position is therefore grounds for suspecting that an apparent gene may really be a pseudogene. Overall, >10% of the genes that are initially identified by analysis of the genome are likely to turn out to be pseudogenes.

As a general rule, comparisons between genomes add significantly to the effectiveness of gene prediction. When sequence features indicating active genes are conserved, for example, between Man and mouse, there is an increased probability that they identify active homologues.

Identifying genes coding for RNA is more difficult, because we cannot use the

criterion of the open reading frame. It is true here also that comparative genome analysis increased the rigor of the analysis. For example, analysis of either the human or mouse genome alone identifies ~500 genes coding for tRNA in each case, but comparison of features suggests that <350 of these genes are in fact active in each genome.

## THE CONTENT OF THE GENOME

### 1.3.11 The human genome has fewer genes than expected

---

#### Key Concepts

- Only 1% of the human genome consists of coding regions.
  - The exons comprise ~5% of each gene, so genes (exons plus introns) comprise ~25% of the genome.
  - The human genome has 30,000-40,000 genes.
  - ~60% of human genes are alternatively spliced.
  - Up to 80% of the alternative splices change protein sequence, so the proteome has ~50,000-60,000 members.
- 

The human genome was the first vertebrate genome to be sequenced (1439, 1440). This massive task has revealed a wealth of information about the genetic makeup of our species, and about the evolution of the genome in general. (Methods used for genome sequencing are reviewed in *Molecular Biology Supplement 32.12 Genome mapping*.) Our understanding is deepened further by the ability to compare the human genome sequence with the more recently sequenced mouse genome (3203).

Mammal and rodent genomes generally fall into a narrow size range,  $\sim 3 \times 10^9$  bp (see *Molecular Biology 1.3.5 Why are genomes so large?*). The mouse genome is ~14% smaller than the human genome, probably because it has had a higher rate of deletion. The genomes contain similar gene families and genes, with most genes having an ortholog in the other genome, but with differences in the number of members of a family, especially in those cases where the functions are specific to the species (see *Molecular Biology 1.3.10 The conservation of genome organization helps to identify genes*). The estimate of 30,000 genes for the mouse genome is at the lower end of the range of estimates for the human genome. **Figure 3.20** plots the distribution of the mouse genes. The 30,000 protein-coding genes are accompanied by ~4000 pseudogenes. There are ~800 genes representing RNAs that do not code for proteins; these are generally small (aside from the rRNAs). Almost half of these genes code for tRNAs, for which a large number of pseudogenes also have been identified.

**Figure 3.20** The mouse genome has ~30,000 protein-coding genes, which have ~4,000 pseudogenes. There are ~800 RNA-coding genes. The data for RNA-coding genes are replotted on the right, at an expanded scale to show that there are ~350 tRNA genes and 150 pseudogenes, and ~450 other noncoding RNA genes, including snRNAs and miRNAs.

The human (haploid) genome contains 22 autosomes plus the X or Y. The chromosomes range in size from 45-279 Mb of DNA, making a total genome content of 3,286 Mb ( $\sim 3.3 \times 10^9$  bp). On the basis of chromosome structure, the overall genome can be divided into regions of euchromatin (potentially containing active genes) and heterochromatin (see *Molecular Biology 5.19.7 Chromatin is divided into euchromatin and heterochromatin*). The euchromatin comprises the majority of the genome,  $\sim 2.9 \times 10^9$  bp. The identified genome sequence represents ~90% of the euchromatin. In addition to providing information on the genetic content of the genome, the sequence also identifies features that may be of structural importance (see *Molecular Biology 5.19.8 Chromosomes have banding patterns*).

**Figure 3.21** shows that a tiny proportion (~1%) of the human genome is accounted for by the exons that actually code for proteins. The introns that constitute the remaining sequences in the genes bring the total of DNA concerned with producing proteins to ~25%. As shown in **Figure 3.22**, the average human gene is 27 kb long, with 9 exons that include a total coding sequence of 1,340 bp. The average coding sequence is therefore only 5% of the length of the gene.

**Figure 3.21** Genes occupy 25% of the human genome, but protein-coding sequences are only a tiny part of this fraction.

**Figure 3.22** The average human gene is 27 kb long and has 9 exons, usually comprising two longer exons at each end and 7 internal exons. The UTRs in the terminal exons are the untranslated (noncoding) regions at each end of the gene. (This is based on the average. Because some genes are extremely long, the median length is 14 kb with 7 exons.)

Based on comparisons with other species and with known protein-coding genes, there are ~24,000 clearly identifiable genes. Sequence analysis identifies ~12,000 more potential genes. Two independent analyses have produced estimates of ~30,000 and ~40,000 genes, respectively (1439, 1440). One measure of the accuracy of the analyses is whether they identify the same genes. The surprising answer is that the overlap between the two sets of genes is only ~50%, as summarized in **Figure 3.23** (1959). An earlier analysis of the human gene set based on RNA transcripts had identified ~11,000 genes, almost all of which are present in both the large human gene sets, and which account for the major part of the overlap between them. So there is no question about the authenticity of half of each human gene set, but we have yet to establish the relationship between the other half of each set. The discrepancies illustrate the pitfalls of large scale sequence analysis! As the sequence is analyzed further (and as other genomes are sequenced with which it can be compared), the number of valid genes seems to decline, and is now generally thought to be ~30,000.

**Figure 3.23** The two sets of genes identified in the human genome overlap only partially, as shown in the two large upper circles. However, they include almost all previously known genes, as shown by the overlap with the smaller, lower circle (see 1959).

By any measure, the total human gene number is much less than we had expected—most previous estimates had been ~100,000. It shows a relatively small increase over flies and worms (13,600 and 18,500, respectively), not to mention the plant *Arabidopsis* (25,000) (see **Figure 3.9**). However, we should not be particularly surprised by the notion that it does not take a great number of additional genes to make a more complex organism. The difference in DNA sequences between man and chimpanzee is extremely small (there is >99% similarity), so it is clear that the functions and interactions between a similar set of genes can produce very different results. The functions of specific groups of genes may be especially important, because detailed comparisons of orthologous genes in man and chimpanzee suggest that there has been accelerated evolution of certain classes of genes, including some involved in early development, olfaction, hearing—all functions that are relatively specific for the species (4514).

The number of genes is less than the number of potential proteins because of alternative splicing. The extent of alternative splicing is greater in Man than in fly or worms; it may affect as many as 60% of the genes, so the increase in size of the human proteome relative to the other eukaryotes may be larger than the increase in the number of genes. A sample of genes from two chromosomes suggests that the proportion of the alternative splices that actually result in changes in the protein sequence may be as high as 80%. This could increase the size of the proteome to 50,000-60,000 members.

In terms of the diversity of the number of gene families, however, the discrepancy between Man and the other eukaryotes may not be so great. Many of the human genes belong to families. An analysis of ~25,000 genes identified 3500 unique genes and 10,300 gene pairs. As can be seen from **Figure 3.15**, this extrapolates to a number of gene families only slightly larger than worm or fly.

### 1.3.12 How are genes and other sequences distributed in the genome?

#### Key Concepts

- Repeated sequences (present in more than one copy) account for >50% of the human genome.
- The great bulk of repeated sequences consist of copies of nonfunctional transposons.
- There are many duplications of large chromosome regions.

Are genes uniformly distributed in the genome? Some chromosomes are relatively poor in genes, and have >25% of their sequences as "deserts" – regions longer than 500 kb where there are no genes. Even the most gene-rich chromosomes have >10% of their sequences as deserts. So overall ~20% of the human genome consists of deserts that have no genes.

Repetitive sequences account for >50% of the human genome, as seen in **Figure 3.24**. The repetitive sequences fall into five classes:

**Figure 3.24** The largest component of the human genome consists of transposons. Other repetitive sequences include large duplications and simple repeats.

- Transposons (either active or inactive) account for the vast majority (45% of the genome). All transposons are found in multiple copies.
- Processed pseudogenes (~3000 in all, account for ~0.1% of total DNA). (These

are sequences that arise by insertion of a copy of an mRNA sequence into the genome; see *Molecular Biology 1.4.6 Pseudogenes are dead ends of evolution*).

- Simple sequence repeats (highly repetitive DNA such as  $(CA)_n$  account for ~3%).
- Segmental duplications (blocks of 10-300 kb that have been duplicated into a new region) account for ~5%. Only a minority of these duplications are found on the same chromosome; in the other cases, the duplicates are on different chromosomes.
- Tandem repeats form blocks of one type of sequence (especially found at centromeres and telomeres).

The sequence of the human genome emphasizes the importance of transposons. (Transposons have the capacity to replicate themselves and insert into new locations. They may function exclusively as DNA elements [see *Molecular Biology 4.16 Transposons*] or may have an active form that is RNA [see *Molecular Biology 4.17 Retroviruses and retroposons*]. Their distribution in the human genome is summarized in **Figure 17.18**.) Most of the transposons in the human genome are nonfunctional; very few are currently active. However, the high proportion of the genome occupied by these elements indicates that they have played an active role in shaping the genome. One interesting feature is that some present genes originated as transposons, and evolved into their present condition after losing the ability to transpose. Almost 50 genes appear to have originated like this.

Segmental duplication at its simplest involves the tandem duplication of some region within a chromosome (typically because of an aberrant recombination event at meiosis; see *Molecular Biology 1.4.7 Unequal crossing-over rearranges gene clusters*). In many cases, however, the duplicated regions are on different chromosomes, implying that either there was originally a tandem duplication followed by a translocation of one copy to a new site, or that the duplication arose by some different mechanism altogether. The extreme case of a segmental duplication is when a whole genome is duplicated, in which case the diploid genome initially becomes tetraploid. As the duplicated copies develop differences from one another, the genome may gradually become effectively a diploid again, although homologies between the diverged copies leave evidence of the event. This is especially common in plant genomes. The present state of analysis of the human genome identifies many individual duplicated regions, but does not indicate whether there was a whole genome duplication in the vertebrate lineage.

## THE CONTENT OF THE GENOME

### 1.3.13 The Y chromosome has several male-specific genes

---

#### Key Concepts

- The Y chromosome has ~60 genes that are expressed specifically in testis.
  - The male-specific genes are present in multiple copies in repeated chromosomal segments.
  - Gene conversion between multiple copies allows the active genes to be maintained during evolution.
- 

The sequence of the human genome has significantly extended our understanding of the role of the sex chromosomes. It is generally thought that the X and Y chromosomes have descended from a common (very ancient) autosome. Their development has involved a process in which the X chromosome has retained most of the original genes, whereas the Y chromosome has lost most of them.

The X chromosome behaves like the autosomes insofar as females have two copies and recombination can take place between them. The density of genes on the X chromosome is comparable to the density of genes on other chromosomes.

The Y chromosome is much smaller than the X chromosome and has many fewer genes. Its unique role results from the fact that only males have the Y chromosome, and there is only one copy, so Y-linked loci are effectively haploid, instead of diploid like all other human genes.

For many years, the Y chromosome was thought to carry almost no genes except for one (or more) sex-determining genes that determine maleness. The vast majority of the Y chromosome (>95% of its sequence) does not undergo crossing-over with the X chromosome, which led to the view that it could not contain active genes, because there would be no means to prevent the accumulation of deleterious mutations. This region is flanked by short pseudoautosomal regions that exchange frequently with the X chromosome during male meiosis. It was originally called the nonrecombining region, but now has been renamed as the male-specific region.

Detailed sequencing of the Y chromosome shows that the male-specific region contains three types of regions, as illustrated in **Figure 3.25** (4088):

**Figure 3.25** The Y chromosome consists of X-transposed regions, X-degenerate regions, and amplicons. The X-transposed X-degenerate regions have 2 and 14 single-copy genes, respectively. The amplicons have eight large palindromes (P1-P8), which contain 9 gene families. Each family contains at least two copies.

- The *X-transposed sequences* consist of a total of 3.4 Mb comprising some large blocks resulting from a transposition from band q21 in the X chromosome about 3-4 million years ago. This is specific to the human lineage. These sequences do not recombine with the X chromosome and have become largely inactive. They now contain only two active genes.
- The *X-degenerate segments* of the Y are sequences that have a common origin with the X chromosome (going back to the common autosome from which both X and Y have descended) and contain genes or pseudogenes related to X-linked genes. There are 14 active genes and 13 pseudogenes. The active genes have in a sense so far defied the trend for genes to be eliminated from chromosomal regions that cannot recombine at meiosis.
- The *ampliconic segments* have a total length of 10.2 Mb and are internally repeated on the Y chromosome. There are 8 large palindromic blocks. They include 9 protein-coding gene families, with copy numbers per family ranging from 2-35. The name “amplicon” reflects the fact that the sequences have been internally amplified on the Y chromosome.

Totaling the genes in these three regions, the Y chromosome contains many more genes than had been expected. There are 156 transcription units, of which half represent protein-coding genes, and half represent pseudogenes.

The presence of the active genes is explained by the fact that the existence of closely related genes copies in the ampliconic segments allows gene conversion between multiple copies of a gene to be used to regenerate active copies. The most common needs for multiple copies of a gene are quantitative (to provide more protein product) or qualitative (to code for proteins with slightly different properties or that are

expressed in different times or places), but in this case the essential function is evolutionary. In effect, the existence of multiple copies allows recombination within the Y chromosome itself to substitute for the evolutionary diversity that is usually provided by recombination between allelic chromosomes.

Most of the protein-coding genes in the ampliconic segments are expressed specifically in testis, and are likely to be involved in male development. If there are ~60 such genes out of a total human gene set of ~30,000, then the genetic difference between man and woman is ~0.2%.

## THE CONTENT OF THE GENOME

### 1.3.14 More complex species evolve by adding new gene functions

#### Key Concepts

- Comparisons of different genomes show a steady increase in gene number as additional genes are added to make eukaryotes, make multicellular organisms, make animals, and make vertebrates.
- Most of the genes that are unique to vertebrates are concerned with the immune or nervous systems.

Comparison of the human genome sequence with sequences found in other species is revealing about the process of evolution. **Figure 3.26** analyzes human genes according to the breadth of their distribution in Nature. Starting with the most generally distributed (top right corner of the figure), 21% of genes are common to eukaryotes and prokaryotes. These tend to code for proteins that are essential for all living forms – typically basic metabolism, replication, transcription, and translation. Moving clockwise, another 32% of genes are added in eukaryotes in general – for example, they may be found in yeast. These tend to code for proteins involved in functions that are general to eukaryotic cells but not to bacteria – for example, they may be concerned with specifying organelles or cytoskeletal components. Another 24% of genes are needed to specify animals. These include genes necessary for multicellularity and for development of different tissue types. And 22% of genes are unique to vertebrates. These mostly code for proteins of the immune and nervous systems; they code for very few enzymes, consistent with the idea that enzymes have ancient origins, and that metabolic pathways originated early in evolution. We see, therefore, that the progression from bacteria to vertebrates requires addition of groups of genes representing the necessary new functions at each stage.

**Figure 3.26** Human genes can be classified according to how widely their homologues are distributed in other species.

One way to define commonly needed proteins is to identify the proteins present in all proteomes. Comparing the human proteome in more detail with the proteomes of other organisms, 46% of the yeast proteome, 43% of the worm proteome, and 61% of the fly proteome is represented in the human proteome. A key group of ~1300 proteins is present in all four proteomes. The common proteins are basic housekeeping proteins required for essential functions, falling into the types summarized in **Figure 3.27**. The main functions are concerned with transcription and translation (35%), metabolism (22%), transport (12%), DNA replication and modification (10%), protein folding and degradation (8%), and cellular processes (6%).

**Figure 3.27** Common eukaryotic proteins are concerned with essential cellular functions.

One of the striking features of the human proteome is that it has many new proteins compared with other eukaryotes, but it has relatively few new protein domains. Most protein domains appear to be common to the animal kingdom. However, there are many new protein architectures, defined as new combinations of domains. **Figure 3.28** shows that the greatest increase occurs in transmembrane and extracellular proteins. In yeast, the vast majority of architectures are concerned with intracellular proteins. About twice as many intracellular architectures are found in fly (or worm), but there is a very striking increase in transmembrane and extracellular proteins, as might be expected from the addition of functions required for the interactions between the cells of a multicellular organism. The increase in intracellular architectures required to make a vertebrate (Man) is relatively small, but there is again a large increase in transmembrane and extracellular architectures.

**Figure 3.28** Increasing complexity in eukaryotes is accompanied by accumulation of new proteins for transmembrane and extracellular functions

## THE CONTENT OF THE GENOME

### 1.3.15 How many genes are essential?

---

#### Key Terms

**Redundancy** describes the concept that two or more genes may fulfill the same function, so that no single one of them is essential.

**Synthetic lethality** occurs when two mutations that by themselves are viable, cause lethality when combined.

**Synthetic genetic array analysis (SGA)** is an automated technique in budding yeast whereby a mutant is crossed to an array of approximately 5000 deletion mutants to determine if the mutants interact to cause a synthetic lethal phenotype.

#### Key Concepts

- Not all genes are essential. In yeast and fly, deletions of <50% of the genes have detectable effects.
- When two or more genes are redundant, a mutation in any one of them may not have detectable effects.
- We do not fully understand the survival in the genome of genes that are apparently dispensable.

---

Natural selection is the force that ensures that useful genes are retained in the genome. Mutations occur at random, and their most common effect in an open reading frame will be to damage the protein product. An organism with a damaging mutation will be at a disadvantage in evolution, and ultimately the mutation will be eliminated by the competitive failure of organisms carrying it. The frequency of a disadvantageous allele in the population is balanced between the generation of new mutations and the elimination of old mutations. Reversing this argument, whenever we see an intact open reading frame in the genome, we assume that its product plays a useful role in the organism. Natural selection must have prevented mutations from accumulating in the gene. The ultimate fate of a gene that ceases to be useful is to accumulate mutations until it is no longer recognizable.

The maintenance of a gene implies that it confers a selective advantage on the organism. But in the course of evolution, even a small relative advantage may be the subject of natural selection, and a phenotypic defect may not necessarily be immediately detectable as the result of a mutation. However, we should like to know how many genes are actually *essential*. This means that their absence is lethal to the organism. In the case of diploid organisms, it means of course that the homozygous null mutation is lethal.

We might assume that the proportion of essential genes will decline with increase in genome size, given that larger genomes may have multiple, related copies of particular gene functions. So far this expectation has not been borne out by the data (see **Figure 3.9**).

One approach to the issue of gene number is to determine the number of essential genes by mutational analysis. If we saturate some specified region of the chromosome with mutations that are lethal, the mutations should map into a number of complementation groups that corresponds to the number of lethal loci in that region. By extrapolating to the genome as a whole, we may calculate the total essential gene number.

In the organism with the smallest known genome (*Mycoplasma genitalium*), random insertions have detectable effects only in about two thirds of the genes (929). Similarly, fewer than half of the genes of *E. coli* appear to be essential. The proportion is even lower in the yeast *S. cerevisiae*. When insertions were introduced at random into the genome in one early analysis, only 12% were lethal, and another 14% impeded growth. The majority (70%) of the insertions had no effect (401). A more systematic survey based on completely deleting each of 5,916 genes (>96% of the identified genes) shows that only 18.7% are essential for growth on a rich medium (that is, when nutrients are fully provided) (2866). **Figure 3.29** shows that these include genes in all categories. The only notable concentration of defects is in genes coding for products involved in protein synthesis, where ~50% are essential. Of course, this approach underestimates the number of genes that are essential for the yeast to live in the wild, when it is not so well provided with nutrients.

**Figure 3.29** Essential yeast genes are found in all classes. Green bars show total proportion of each class of genes, red bars shows those that are essential.

**Figure 3.30** summarizes the results of a systematic analysis of the effects of loss of

gene function in the worm *C. elegans* (3323). The sequences of individual genes were predicted from the genome sequence, and by targeting an inhibitory RNA against these sequences (see *Molecular Biology 3.11.22 RNA interference is related to gene silencing*), a large set of worms were made in which one (predicted) gene was prevented from functioning in each worm. Detectable effects on the phenotype were only observed for 10% of these knockouts, suggesting that most genes do not play essential roles.

**Figure 3.30** A systematic analysis of loss of function for 86% of worm genes shows that only 10% have detectable effects on the phenotype.

There is a greater proportion of essential genes (21%) among those worm genes that have counterparts in other eukaryotes, suggesting that widely conserved genes tend to play more basic functions. There is also an increased proportion of essential genes among those that are present in only one copy per haploid genome, compared with those where there are multiple copies of related or identical genes. This suggests that many of the multiple genes might be relatively recent duplications that can substitute for one another's functions,

Extensive analyses of essential gene number in a higher eukaryote have been made in *Drosophila* through attempts to correlate visible aspects of chromosome structure with the number of functional genetic units. The notion that this might be possible arose originally from the presence of bands in the polytene chromosomes of *D. melanogaster*. (These chromosomes are found at certain developmental stages and represent an unusually extended physical form, in which a series of bands [more formally called chromomeres] are evident; see *Molecular Biology 5.19.10 Polytene chromosomes form bands*.) From the early concept that the bands might represent a linear order of genes, we have come to the attempt to correlate the organization of genes with the organization of bands. There are ~5000 bands in the *D. melanogaster* haploid set; they vary in size over an order of magnitude, but on average there is ~20 kb of DNA per band.

The basic approach is to saturate a chromosomal region with mutations. Usually the

mutations are simply collected as lethals, without analyzing the cause of the lethality. Any mutation that is lethal is taken to identify a locus that is essential for the organism. Sometimes mutations cause visible deleterious effects short of lethality, in which case we also count them as identifying an essential locus. When the mutations are placed into complementation groups, the number can be compared with the number of bands in the region, or individual complementation groups may even be assigned to individual bands. The purpose of these experiments has been to determine whether there is a consistent relationship between bands and genes; for example, does every band contain a single gene?

Totaling the analyses that have been carried out over the past 30 years, the number of lethal complementation groups is ~70% of the number of bands. It is an open question whether there is any functional significance to this relationship. But irrespective of the cause, the equivalence gives us a reasonable estimate for the lethal gene number of ~3600. By any measure, the number of lethal loci in *Drosophila* is significantly less than the total number of genes.

If the proportion of essential human genes is similar to other eukaryotes, we would predict a range of 4000-8000 genes in which mutations would be lethal or produce evidently damaging effects. At the present, 1300 genes have been identified in which mutations cause evident defects. This is a substantial proportion of the expected total, especially in view of the fact that many lethal genes may act so early that we never see their effects. This sort of bias may also explain the results in **Figure 3.31**, which show that the majority of known genetic defects are due to point mutations (where there is more likely to be at least some residual function of the gene).

Most human mutations causing defects are small	
Missense/nonsense	58%
Splicing	10%
Regulatory	<1%
Small deletions	16%
Small insertions	6%
Large deletions	5%
Large rearrangements	2%

©virtualtext www.ergito.com

**Figure 3.31** Most known genetic defects in human genes are due to point mutations. The majority directly affect the protein sequence. The remainder are due to insertion, deletions, or rearrangements of varying sizes.

How do we explain the survival of genes whose deletion appears to have no effect? The most likely explanation is that the organism has alternative ways of fulfilling the same function. The simplest possibility is that there is **redundancy**, and that some genes are present in multiple copies. This is certainly true in some cases, in which multiple (related) genes must be knocked out in order to produce an effect. In a slightly more complex scenario, an organism might have two separate pathways capable of providing some activity. Inactivation of either pathway by itself would not be damaging, but the simultaneous occurrence of mutations in genes from both pathways would be deleterious.

Such situations can be tested by combining mutations. In principle, deletions in two genes, neither of which is lethal by itself, are introduced into the same strain. If the double mutant dies, the strain is called a **synthetic lethal**. This technique has been used to great effect with yeast, where the isolation of double mutants can be automated. The procedure is called **synthetic genetic array analysis (SGA)**. **Figure 3.32** summarizes the results of an analysis in which an SGA screen was made for each of 132 viable deletions, by testing whether it could survive in combination with any one of 4,700 viable deletions. Every one of the test genes had at least one partner with which the combination was lethal, and most of the test genes had many such partners; the median is ~25 partners, and the greatest number is shown by one test gene that had 146 lethal partners(4831). A small proportion (~10%) of the interacting mutant pairs code for proteins that interact physically.

**Figure 3.32** Every one of 132 mutant test genes has some combinations that are lethal when it is combined with each of 4700 nonlethal mutations. The chart shows how many lethal interacting genes there are for each test gene.

This result goes some way toward explaining the apparent lack of effect of so many deletions. Natural selection will act against these deletions when they find themselves in lethal pairwise combinations. To some degree, the organism has protected itself against the damaging effects of mutations by building in redundancy. However, it pays a price in the form of accumulating the "genetic load" of mutations that are not deleterious in themselves, but that may cause serious problems when combined with other such mutations in future generations. The theory of natural selection would suggest that the loss of the individual genes in such circumstances produces a sufficient disadvantage to maintain the active gene during the course of evolution.

## THE CONTENT OF THE GENOME

### 1.3.16 Genes are expressed at widely differing levels

---

#### Key Terms

The **abundance** of an mRNA is the average number of molecules per cell.

**Abundant mRNAs** consist of a small number of individual species, each present in a large number of copies per cell.

**Scarce mRNA (Complex mRNA)** consists of a large number of individual mRNA species, each present in very few copies per cell. This accounts for most of the sequence complexity in RNA.

#### Key Concepts

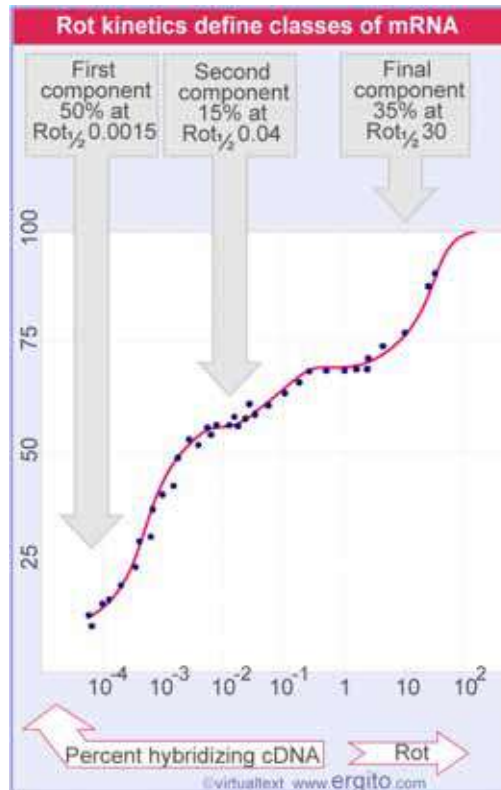

- In any given cell, most genes are expressed at a low level.
- Only a small number of genes, whose products are specialized for the cell type, are highly expressed.

---

The proportion of DNA represented in an mRNA population can be determined by the amount of the DNA that can hybridize with the RNA. Such a saturation analysis typically identifies ~1% of the DNA as providing a template for mRNA. From this we can calculate the number of genes so long as we know the average length of an mRNA. For a lower eukaryote such as yeast, the total number of expressed genes is ~4000. For somatic tissues of higher eukaryotes, the number usually is 10,000-15,000. The value is similar for plants and for vertebrates. (The only consistent exception to this type of value is presented by mammalian brain, where much larger numbers of genes appear to be expressed, although the exact quantitation is not certain.)

Kinetic analysis of the reassociation of an RNA population can be used to determine its sequence complexity (see *Molecular Biology Supplement 32.1 DNA reassociation kinetics*). This type of analysis typically identifies three components in a eukaryotic cell. Just as with a DNA reassociation curve, a single component hybridizes over about two decades of  $Rot$  (RNA concentration  $\times$  time) values, and a reaction extending over a greater range must be resolved by computer curve-fitting into individual components. Again this represents what is really a continuous spectrum of sequences.

An example of an excess mRNA  $\times$  cDNA reaction that generates three components is given in **Figure 3.33**:

**Figure 3.33** Hybridization between excess mRNA and cDNA identifies several components in chick oviduct cells, each characterized by the  $Rot_{1/2}$  of reaction.

- The first component has the same characteristics as a control reaction of ovalbumin mRNA with its DNA copy. This suggests that the first component is in fact just ovalbumin mRNA (which indeed occupies about half of the messenger mass in oviduct tissue).
- The next component provides 15% of the reaction, with a total complexity of 15 kb. This corresponds to 7-8 mRNA species of average length 2000 bases.
- The last component provides 35% of the reaction, which corresponds to a complexity of 26 Mb. This corresponds to ~13,000 mRNA species of average length 2000 bases.

From this analysis, we can see that about half of the mass of mRNA in the cell represents a single mRNA, ~15% of the mass is provided by a mere 7-8 mRNAs, and ~35% of the mass is divided into the large number of 13,000 mRNA species. It is therefore obvious that the mRNAs comprising each component must be present in very different amounts.

The average number of molecules of each mRNA per cell is called its **abundance**. It can be calculated quite simply if the total mass of RNA in the cell is known. In the example shown in **Figure 3.33**, the total mRNA can be accounted for as 100,000 copies of the first component (ovalbumin mRNA), 4000 copies of each of the 7-8

mRNAs in the second component, but only ~5 copies of each of the 13,000 mRNAs that constitute the last component.

We can divide the mRNA population into two general classes, according to their abundance:

- The oviduct is an extreme case, with so much of the mRNA represented in only one species, but most cells do contain a small number of RNAs present in many copies each. This **abundant mRNA** component typically consists of <100 different mRNAs present in 1000-10,000 copies per cell. It often corresponds to a major part of the mass, approaching 50% of the total mRNA.
- About half of the mass of the mRNA consists of a large number of sequences, of the order of 10,000, each represented by only a small number of copies in the mRNA – say, <10. This is the **scarce mRNA** or **complex mRNA** class. It is this class that drives a saturation reaction (396).

## THE CONTENT OF THE GENOME

### 1.3.17 How many genes are expressed?

---

#### Key Terms

The **transcriptome** is the complete set of RNAs present in a cell, tissue, or organism. Its complexity is due mostly to mRNAs, but it also includes noncoding RNAs.

**Housekeeping genes (Constitutive gene)** are those (theoretically) expressed in all cells because they provide basic functions needed for sustenance of all cell types.

**Luxury genes** are those coding for specialized functions synthesized (usually) in large amounts in particular cell types.

#### Key Concepts

- mRNAs expressed at low levels overlap extensively when different cell types are compared.
- The abundantly expressed mRNAs are usually specific for the cell type.
- ~10,000 expressed genes may be common to most cell types of a higher eukaryote.

---

Many somatic tissues of higher eukaryotes have an expressed gene number in the range of 10,000-20,000. How much overlap is there between the genes expressed in different tissues? For example, the expressed gene number of chick liver is ~11,000-17,000, compared with the value for oviduct of ~13,000-15,000. How many of these two sets of genes are identical? How many are specific for each tissue? These questions are usually addressed by analyzing the **transcriptome** – the set of sequences represented in RNA.

We see immediately that there are likely to be substantial differences among the genes expressed in the abundant class. Ovalbumin, for example, is synthesized only in the oviduct, not at all in the liver. This means that 50% of the mass of mRNA in the oviduct is specific to that tissue.

But the abundant mRNAs represent only a small proportion of the number of expressed genes. In terms of the total number of genes of the organism, and of the number of changes in transcription that must be made between different cell types, we need to know the extent of overlap between the genes represented in the scarce mRNA classes of different cell phenotypes.

Comparisons between different tissues show that, for example, ~75% of the sequences expressed in liver and oviduct are the same. In other words, ~12,000 genes are expressed in both liver and oviduct, ~5000 additional genes are expressed only in liver, and ~3000 additional genes are expressed only in oviduct.

The scarce mRNAs overlap extensively. Between mouse liver and kidney, ~90% of the scarce mRNAs are identical, leaving a difference between the tissues of only 1000-2000 in terms of the number of expressed genes. The general result obtained in

several comparisons of this sort is that only ~10% of the mRNA sequences of a cell are unique to it. The majority of sequences are common to many, perhaps even all, cell types.

This suggests that the common set of expressed gene functions, numbering perhaps ~10,000 in a mammal, comprise functions that are needed in all cell types. Sometimes this type of function is referred to as a **housekeeping gene** or **constitutive gene**. It contrasts with the activities represented by specialized functions (such as ovalbumin or globin) needed only for particular cell phenotypes. These are sometimes called **luxury genes**.

## THE CONTENT OF THE GENOME

### 1.3.18 Expressed gene number can be measured *en masse*

#### Key Concepts

- "Chip" technology allows a snapshot to be taken of the expression of the entire genome in a yeast cell.
- ~75% (~4500 genes) of the yeast genome is expressed under normal growth conditions.
- Chip technology allows detailed comparisons of related animal cells to determine (for example) the differences in expression between a normal cell and a cancer cell.

Recent technology allows more systematic and accurate estimates of the number of expressed genes. One approach (SAGE, serial analysis of gene expression) allows a unique sequence tag to be used to identify each mRNA. The technology then allows the abundance of each tag to be measured. This approach identifies 4,665 expressed genes in *S. cerevisiae* growing under normal conditions, with abundances varying from 0.3 to >200 transcripts/cell. This means that ~75% of the total gene number (~6000) is expressed under these conditions (397). **Figure 3.34** summarizes the number of different mRNAs that is found at each different abundance levels.

**Figure 3.34** The abundancies of yeast mRNAs vary from <1 per cell (meaning that not every cell has a copy of the mRNA) to >100 per cell (coding for the more abundant proteins).

The most powerful new technology uses chips that contain high-density

oligonucleotide arrays (HDAs). Their construction is made possible by knowledge of the sequence of the entire genome. In the case of *S. cerevisiae*, each of 6181 ORFs is represented on the HDA by 20 25-mer oligonucleotides that perfectly match the sequence of the message and 20 mismatch oligonucleotides that differ at one base position. The expression level of any gene is calculated by subtracting the average signal of a mismatch from its perfect match partner. The entire yeast genome can be represented on 4 chips. This technology is sensitive enough to detect transcripts of 5460 genes (~90% of the genome), and shows that many genes are expressed at low levels, with abundances of 0.1-2 transcripts/cell. An abundance of <1 transcript/cell means that not all cells have a copy of the transcript at any given moment.

The technology allows not only measurement of levels of gene expression, but also detection of differences in expression in mutant cells compared with wild-type, cells growing under different growth conditions, and so on (1201; for review see 1200). The results of comparing two states are expressed in the form of a grid, in which each square represents a particular gene, and the relative change in expression is indicated by color. The upper part of **Figure 3.35** shows the effect of a mutation in RNA polymerase II, the enzyme that produces mRNA, which as might be expected causes the expression of most genes to be heavily reduced. By contrast, the lower part shows that a mutation in an ancillary component of the transcription apparatus (*SRB10*) has much more restricted effects, causing increases in expression of some genes (398).

**Figure 3.35** HDA analysis allows change in expression of each gene to be measured. Each square represents one gene (top left is first gene on chromosome I, bottom right is last gene on chromosome XVI). Change in expression relative to wild type is indicated by red (reduction), white (no change) or blue (increase). Photograph kindly provided by Rick Young.

The extension of this technology to animal cells will allow the general descriptions based on RNA hybridization analysis to be replaced by exact descriptions of the genes that are expressed, and the abundances of their products, in any given cell type (399).

## THE CONTENT OF THE GENOME

### 1.3.19 Organelles have DNA

---

#### Key Terms

**Maternal inheritance** describes the preferential survival in the progeny of genetic markers provided by one parent.

**Extranuclear genes** reside outside the nucleus in organelles such as mitochondria and chloroplasts.

**Cytoplasmic inheritance** is a property of genes located in mitochondria or chloroplasts.

#### Key Concepts

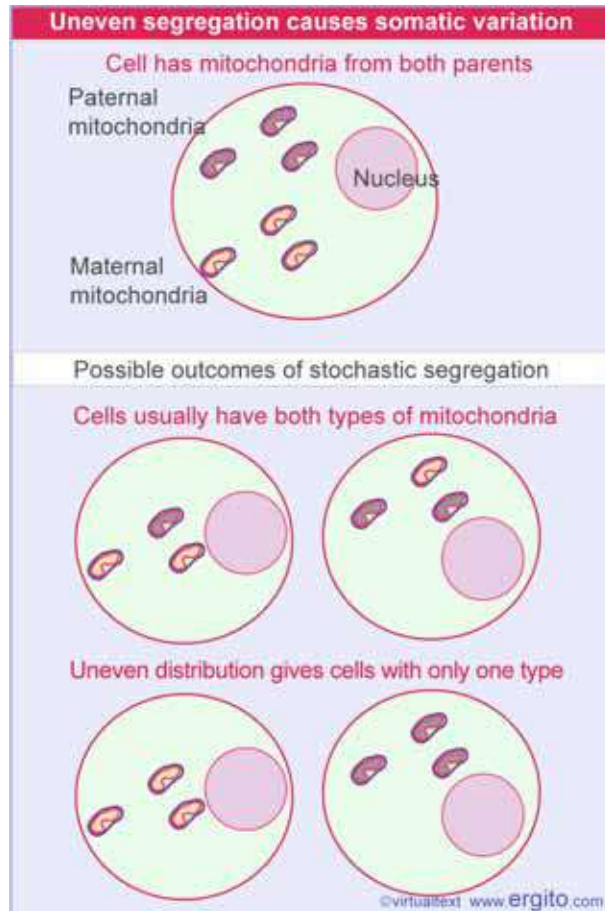

- Mitochondria and chloroplasts have genomes that show nonMendelian inheritance. Typically they are maternally inherited.
- Organelle genomes may undergo somatic segregation in plants.
- Comparisons of mitochondrial DNA suggest that humans are descended from a single female who lived 200,000 years ago in Africa.

---

The first evidence for the presence of genes outside the nucleus was provided by nonMendelian inheritance in plants (observed in the early years of this century, just after the rediscovery of Mendelian inheritance). NonMendelian inheritance is sometimes associated with the phenomenon of somatic segregation. They have a similar cause:

- NonMendelian inheritance is defined by the failure of the progeny of a mating to display Mendelian segregation for parental characters. It reflects lack of association between the segregating character and the meiotic spindle.
- Somatic segregation describes a phenomenon in which parental characters segregate in somatic cells, and therefore display heterogeneity in the organism. This is a notable feature of plant development. It reflects lack of association between the segregating character and the mitotic spindle.

*NonMendelian inheritance and somatic segregation are therefore taken to indicate the presence of genes that reside outside the nucleus and do not utilize segregation on the meiotic and mitotic spindles to distribute replicas to gametes or to daughter cells, respectively.* **Figure 3.36** shows that this happens when the mitochondria inherited from the male and female parents have different alleles, and by chance a daughter cell receives an unbalanced distribution of mitochondria that represents only one parent (see *Molecular Biology 4.13.24 How do mitochondria replicate and segregate?*).

**Figure 3.36** When paternal and maternal mitochondrial alleles differ, a cell has two sets of mitochondrial DNAs. Mitosis usually generates daughter cells with both sets. Somatic variation may result if unequal segregation generates daughter cells with only one set.

The extreme form of nonMendelian inheritance is uniparental inheritance, when the genotype of only one parent is inherited and that of the other parent is permanently lost. In less extreme examples, the progeny of one parental genotype exceed those of the other genotype. Usually it is the mother whose genotype is preferentially (or solely) inherited. This effect is sometimes described as **maternal inheritance**. The important point is that the genotype contributed by the parent of one particular sex predominates, as seen in abnormal segregation ratios when a cross is made between mutant and wild type. This contrasts with the behavior of Mendelian genetics when reciprocal crosses show the contributions of both parents to be equally inherited.

The bias in parental genotypes is established at or soon after the formation of a zygote. There are various possible causes. The contribution of maternal or paternal information to the organelles of the zygote may be unequal; in the most extreme case, only one parent contributes. In other cases, the contributions are equal, but the information provided by one parent does not survive. Combinations of both effects are possible. Whatever the cause, the unequal representation of the information from the two parents contrasts with nuclear genetic information, which derives equally from each parent.

NonMendelian inheritance results from the presence in mitochondria and chloroplasts of DNA genomes that are inherited independently of nuclear genes. In effect, the organelle genome comprises a length of DNA that has been physically sequestered in a defined part of the cell, and is subject to its own form of expression and regulation. An organelle genome can code for some or all of the RNAs, but codes for only some of the proteins needed to perpetuate the organelle. The other proteins are coded in the nucleus, expressed via the cytoplasmic protein synthetic apparatus, and imported into the organelle.

Genes not residing within the nucleus are generally described as **extranuclear genes**; they are transcribed and translated in the *same* organelle compartment (mitochondrion or chloroplast) in which they reside. By contrast, *nuclear* genes are expressed by means of *cytoplasmic* protein synthesis. (The term **cytoplasmic inheritance** is sometimes used to describe the behavior of genes in organelles. However, we shall not use this description, since it is important to be able to distinguish between events in the general cytosol and those in specific organelles.)

Higher animals show maternal inheritance, which can be explained if the mitochondria are contributed entirely by the ovum and not at all by the sperm. **Figure 3.37** shows that the sperm contributes only a copy of the nuclear DNA. So the mitochondrial genes are derived exclusively from the mother; and in males they are discarded each generation.

**Figure 3.37** DNA from the sperm enters the oocyte to form the male pronucleus in the fertilized egg, but all the mitochondria are provided by the oocyte.

Conditions in the organelle are different from those in the nucleus, and organelle DNA therefore evolves at its own distinct rate. If inheritance is uniparental, there can be no recombination between parental genomes; and usually recombination does not occur in those cases where organelle genomes are inherited from both parents. Since organelle DNA has a different replication system from that of the nucleus, the error rate during replication may be different. Mitochondrial DNA accumulates mutations more rapidly than nuclear DNA in mammals, but in plants the accumulation in the mitochondrion is slower than in the nucleus (the chloroplast is intermediate).

One consequence of maternal inheritance is that the sequence of mitochondrial DNA is more sensitive than nuclear DNA to reductions in the size of the breeding population. Comparisons of mitochondrial DNA sequences in a range of human populations allow an evolutionary tree to be constructed. The divergence among human mitochondrial DNAs spans 0.57%. A tree can be constructed in which the mitochondrial variants diverged from a common (African) ancestor. The rate at which mammalian mitochondrial DNA accumulates mutations is 2-4% per million years,  $>10\times$  faster than the rate for globin. Such a rate would generate the observed divergence over an evolutionary period of 140,000-280,000 years. This implies that the human race is descended from a single female, who lived in Africa ~200,000 years ago (414).

## THE CONTENT OF THE GENOME

### 1.3.20 Organelle genomes are circular DNAs that code for organelle proteins

---

#### Key Terms

**Mitochondrial DNA (mtDNA)** is an independent DNA genome, usually circular, that is located in the mitochondrion.

**Chloroplast DNA (ctDNA)** is an independent genome (usually circular) found in a plant chloroplast.

#### Key Concepts

- Organelle genomes are usually (but not always) circular molecules of DNA.
- Organelle genomes code for some but not all of the proteins found in the organelle.

---

Most organelle genomes take the form of a single circular molecule of DNA of unique sequence (denoted **mtDNA** in the mitochondrion and **ctDNA** in the chloroplast). There are a few exceptions where mitochondrial DNA is a linear molecule, generally in lower eukaryotes.

Usually there are several copies of the genome in the individual organelle. Since there are multiple organelles per cell, there are many organelle genomes per cell. Although the organelle genome itself is unique, it constitutes a repetitive sequence relative to any nonrepetitive nuclear sequence.

Chloroplast genomes are relatively large, usually ~140 kb in higher plants, and <200 kb in lower eukaryotes. This is comparable to the size of a large bacteriophage, for example, T4 at ~165 kb. There are multiple copies of the genome per organelle, typically 20-40 in a higher plant, and multiple copies of the organelle per cell, typically 20-40.

Mitochondrial genomes vary in total size by more than an order of magnitude. Animal cells have small mitochondrial genomes, ~16.5 kb in mammals. There are several hundred mitochondria per cell. Each mitochondrion has multiple copies of the DNA. The total amount of mitochondrial DNA relative to nuclear DNA is small, <1%.

In yeast, the mitochondrial genome is much larger. In *S. cerevisiae*, the exact size varies among different strains, but is ~80 kb. There are ~22 mitochondria per cell, which corresponds to ~4 genomes per organelle. In growing cells, the proportion of mitochondrial DNA can be as high as 18%.

Plants show an extremely wide range of variation in mitochondrial DNA size, with a minimum of ~100 kb. The size of the genome makes it difficult to isolate intact, but restriction mapping in several plants suggests that the mitochondrial genome is

usually a single sequence, organized as a circle. Within this circle, there are short homologous sequences. Recombination between these elements generates smaller, subgenomic circular molecules that coexist with the complete, "master" genome, explaining the apparent complexity of plant mitochondrial DNAs.

With mitochondrial genomes sequenced from many organisms, we can now see some general patterns in the representation of functions in mitochondrial DNA (for review see981). **Figure 3.38** summarizes the distribution of genes in mitochondrial genomes. The total number of protein-coding genes is rather small, but does not correlate with the size of the genome. Mammalian mitochondria use their 16 kb genomes to code for 13 proteins, whereas yeast mitochondria use their 60-80 kb genomes to code for as few as 8 proteins. Plants, with much larger mitochondrial genomes, code for more proteins. Introns are found in most mitochondrial genomes, although not in the very small mammalian genomes.

Mitochondria code for RNAs and proteins			
Species	Size (kb)	Protein-coding genes	RNA-coding genes
Fungi	19-100	8-14	10-28
Protists	6-100	3-62	2-29
Plants	186-366	27-34	21-30
Animals	16-17	13	4-24

**Figure 3.38** Mitochondrial genomes have genes coding for (mostly complex I-IV) proteins, rRNAs, and tRNAs.

The two major rRNAs are always coded by the mitochondrial genome. The number of tRNAs coded by the mitochondrial genome varies from none to the full complement (25-26 in mitochondria). This accounts for the variation in **Figure 3.38**.

The major part of the protein-coding activity is devoted to the components of the multisubunit assemblies of respiration complexes I-IV. Many ribosomal proteins are coded in protist and plant mitochondrial genomes, but there are few or none in fungi and animal genomes. There are genes coding for proteins involved in import in many protist mitochondrial genomes.

## THE CONTENT OF THE GENOME

### 1.3.21 Mitochondrial DNA organization is variable

---

#### Key Concepts

- Animal cell mitochondrial DNA is extremely compact and typically codes for 13 proteins, 2 rRNAs, and 22 tRNAs.
- Yeast mitochondrial DNA is 5× longer than animal cell mtDNA because of the presence of long introns.

---

Animal mitochondrial DNA is extremely compact. There are extensive differences in the detailed gene organization found in different animal phyla, but the general principle is maintained of a small genome coding for a restricted number of functions. In mammalian mitochondrial genomes, the organization is extremely compact. There are no introns, some genes actually overlap, and almost every single base pair can be assigned to a gene. With the exception of the D loop, a region concerned with the initiation of DNA replication, no more than 87 of the 16,569 bp of the human mitochondrial genome can be regarded as lying in intergenic regions.

The complete nucleotide sequences of mitochondrial genomes in animal cells show extensive homology in organization (1398). The map of the human mitochondrial genome is summarized in **Figure 3.39**. There are 13 protein-coding regions. All of the proteins are components of the apparatus concerned with respiration. These include cytochrome *b*, 3 subunits of cytochrome oxidase, one of the subunits of ATPase, and 7 subunits (or associated proteins) of NADH dehydrogenase (411; for review see 18; 19; 21).

**Figure 3.39** Human mitochondrial DNA has 22 tRNA genes, 2 rRNA genes, and 13 protein-coding regions. 14 of the 15 protein-coding or rRNA-coding regions are transcribed in the same direction. 14 of the tRNA genes are expressed in the clockwise direction and 8 are read counter clockwise.

The five-fold discrepancy in size between the *S. cerevisiae* (84 kb) and mammalian (16 kb) mitochondrial genomes alone alerts us to the fact that there must be a great difference in their genetic organization in spite of their common function. The number of endogenously synthesized products concerned with mitochondrial enzymatic functions appears to be similar. Does the additional genetic material in yeast mitochondria represent other proteins, perhaps concerned with regulation, or is it unexpressed?

The map shown in **Figure 3.40** accounts for the major RNA and protein products of the yeast mitochondrion. The most notable feature is the dispersion of loci on the map.

**Figure 3.40** The mitochondrial genome of *S. cerevisiae* contains both interrupted and uninterrupted protein-coding genes, rRNA genes, and tRNA genes (positions not indicated). Arrows indicate direction of transcription.

The two most prominent loci are the interrupted genes *box* (coding for cytochrome *b*) and *oxi3* (coding for subunit 1 of cytochrome oxidase). Together these two genes are almost as long as the entire mitochondrial genome in mammals! Many of the long introns in these genes have open reading frames in register with the preceding exon (see *Molecular Biology 5.26.5 Some group I introns code for endonucleases that sponsor mobility*). This adds several proteins, all synthesized in low amounts, to the complement of the yeast mitochondrion.

The remaining genes are uninterrupted. They correspond to the other two subunits of cytochrome oxidase coded by the mitochondrion, to the subunit(s) of the ATPase, and (in the case of *var1*) to a mitochondrial ribosomal protein. The total number of yeast mitochondrial genes is unlikely to exceed ~25.

## THE CONTENT OF THE GENOME

### 1.3.22 Mitochondria evolved by endosymbiosis

How did a situation evolve in which an organelle contains genetic information for some of its functions, while others are coded in the nucleus? **Figure 3.41** shows the endosymbiosis model for mitochondrial evolution, in which primitive cells captured bacteria that provided the functions that evolved into mitochondria and chloroplasts. At this point, the proto-organelle must have contained all of the genes needed to specify its functions.

**Figure 3.41** Mitochondria originated by an endosymbiotic event when a bacterium was captured by a eukaryotic cell.

Sequence homologies suggest that mitochondria and chloroplasts evolved separately, from lineages that are common with eubacteria, with mitochondria sharing an origin with  $\alpha$ -purple bacteria, and chloroplasts sharing an origin with cyanobacteria. The closest known relative of mitochondria among the bacteria is *Rickettsia* (the causative agent of typhus), which is an obligate intracellular parasite that is probably descended from free-living bacteria. This reinforces the idea that mitochondria

originated in an endosymbiotic event involving an ancestor that is also common to *Rickettsia* (for review see 981).

Two changes must have occurred as the bacterium became integrated into the recipient cell and evolved into the mitochondrion (or chloroplast). The organelles have far fewer genes than an independent bacterium, and have lost many of the gene functions that are necessary for independent life (such as metabolic pathways). And since the majority of genes coding for organelle functions are in fact now located in the nucleus, these genes must have been transferred there from the organelle.

Transfer of DNA between organelle and nucleus has occurred over evolutionary time periods, and still continues. The rate of transfer can be measured directly by introducing into an organelle a gene that can function only in the nucleus, for example, because it contains a nuclear intron, or because the protein must function in the cytosol. In terms of providing the material for evolution, the transfer rates from organelle to nucleus are roughly equivalent to the rate of single gene mutation. DNA introduced into mitochondria is transferred to the nucleus at a rate of  $2 \times 10^{-5}$  per generation. Experiments to measure transfer in the reverse direction, from nucleus to mitochondrion, suggest that it is much lower,  $<10^{-10}$  (3691). When a nuclear-specific antibiotic resistance gene is introduced into chloroplasts, its transfer to the nucleus and successful expression can be followed by screening seedlings for resistance to the antibiotic. This shows that transfer occurs at a rate of 1 in 16,000 seedlings, or  $6 \times 10^{-5}$  (3690).

Transfer of a gene from an organelle to the nucleus requires physical movement of the DNA, of course, but successful expression also requires changes in the coding sequence. Organelle proteins that are coded by nuclear genes have special sequences that allow them to be imported into the organelle after they have been synthesized in the cytoplasm (see *Molecular Biology 2.8.17 Post-translational membrane insertion depends on leader sequences*). These sequences are not required by proteins that are synthesized within the organelle. Perhaps the process of effective gene transfer occurred at a period when compartments were less rigidly defined, so that it was easier both for the DNA to be relocated, and for the proteins to be incorporated into the organelle irrespective of the site of synthesis.

Phylogenetic maps show that gene transfers have occurred independently in many different lineages. It appears that transfers of mitochondrial genes to the nucleus occurred only early in animal cell evolution, but it is possible that the process is still continuing in plant cells (1399). The number of transfers can be large; there are >800 nuclear genes in *Arabidopsis* whose sequences are related to genes in the chloroplasts of other plants (1403). These genes are candidates for evolution from genes that originated in the chloroplast

## THE CONTENT OF THE GENOME

### 1.3.23 The chloroplast genome codes for many proteins and RNAs

#### Key Concepts

- Chloroplast genomes vary in size, but are large enough to code for 50-100 proteins as well as the rRNAs and tRNAs.

What genes are carried by chloroplasts? Chloroplast DNAs vary in length from 120-190 kb. The sequenced chloroplast genomes (>10 in total) have 87-183 genes (413; for review see 20; 3055). **Figure 3.42** summarizes the functions coded by the chloroplast genome in land plants. There is more variation in the chloroplast genomes of algae.

©virtualtext www.ergito.com

**Figure 3.42** The chloroplast genome in land plants codes for 4 rRNAs, 30 tRNAs, and ~60 proteins.

The situation is generally similar to that of mitochondria, except that more genes are involved. The chloroplast genome codes for all the rRNA and tRNA species needed for protein synthesis. The ribosome includes two small rRNAs in addition to the major species. The tRNA set may include all of the necessary genes. The chloroplast genome codes for ~50 proteins, including RNA polymerase and ribosomal proteins. Again the rule is that organelle genes are transcribed and translated by the apparatus of the organelle.

About half of the chloroplast genes code for proteins involved in protein synthesis. The endosymbiotic origin of the chloroplast is emphasized by the relationships between these genes and their counterparts in bacteria. The organization of the rRNA genes in particular is closely related to that of a cyanobacterium, which pins down more precisely the last common ancestor between chloroplasts and bacteria.

Introns in chloroplasts fall into two general classes. Those in tRNA genes are usually (although not inevitably) located in the anticodon loop, like the introns found in yeast nuclear tRNA genes (see *Molecular Biology 5.24.14 Yeast tRNA splicing involves cutting and rejoining*). Those in protein-coding genes resemble the introns of mitochondrial genes (see *Molecular Biology 5.26 Catalytic RNA*). This places the endosymbiotic event at a time in evolution before the separation of prokaryotes with uninterrupted genes.

The role of the chloroplast is to undertake photosynthesis. Many of its genes code for proteins of complexes located in the thylakoid membranes. The constitution of these complexes shows a different balance from that of mitochondrial complexes. Although some complexes are like mitochondrial complexes in having some subunits coded by the organelle genome and some by the nuclear genome, other chloroplast complexes are coded entirely by one genome.

## THE CONTENT OF THE GENOME

### 1.3.24 Summary

---

Genomes that have been sequenced include many bacteria and archaea, yeasts, and a worm, fly, mouse, and Man. The minimum number of genes required to make a living cell (an obligatory intracellular parasite) is ~470. The minimum number required to make a free-living cell is ~1700. A typical gram-negative bacterium has ~1500 genes. Strains of *E. coli* vary from 4300 to 5400 genes. The average bacterial gene is ~1000 bp long and is separated from the next gene by a space of ~100 bp. The yeasts *S. pombe* and *S. cerevisiae* have 5000 and 6000 genes, respectively.

Although the fly *D. melanogaster* is a more complex organism and has a larger genome than the worm *C. elegans*, the fly has fewer genes (13,600) than the worm (14,100). The plant *Arabidopsis* has 25,000 genes, and the lack of a clear relationship between genome size and gene number is shown by the fact that the rice genome is 4× larger, but contains only a 50% increase in gene number, to ~40,000. Mouse has ~30,000 genes. Man has <40,000 genes, which is much less than had been expected. The complexity of development of an organism may depend on the nature of the interactions between genes as well as their total number.

About 8000 genes are common to prokaryotes and eukaryotes and are likely to be involved in basic functions. A further 12,000 genes are found in multicellular organisms. Another 8000 genes are added to make an animal, and a further 8000 (largely involved with the immune and nervous systems) are found in vertebrates. In each organism that has been sequenced, only ~50% of the genes have defined functions. Analysis of lethal genes suggests that only a minority of genes are essential in each organism.

The sequences comprising a eukaryotic genome can be classified in three groups: nonrepetitive sequences are unique; moderately repetitive sequences are dispersed and repeated a small number of times in the form of related but not identical copies; and highly repetitive sequences are short and usually repeated as tandem arrays. The proportions of the types of sequence are characteristic for each genome, although larger genomes tend to have a smaller proportion of nonrepetitive DNA. Almost 50% of the human genome consists of repetitive sequences, the vast majority corresponding to transposon sequences. Most structural genes are located in nonrepetitive DNA. The complexity of nonrepetitive DNA is a better reflection of the complexity of the organism than the total genome complexity; nonrepetitive DNA reaches a maximum complexity of  $\sim 2 \times 10^9$  bp.

Genes are expressed at widely varying levels. There may be  $10^5$  copies of mRNA for an abundant gene whose protein is the principal product of the cell,  $10^3$  copies of each mRNA for <10 moderately abundant messages, and <10 copies of each mRNA for >10,000 scarcely expressed genes. Overlaps between the mRNA populations of cells of different phenotypes are extensive; the majority of mRNAs are present in most cells.

NonMendelian inheritance is explained by the presence of DNA in organelles in the cytoplasm. Mitochondria and chloroplasts both represent membrane-bounded

systems in which some proteins are synthesized within the organelle, while others are imported. The organelle genome is usually a circular DNA that codes for all of the RNAs and for some of the proteins that are required.

Mitochondrial genomes vary greatly in size from the 16 kb minimalist mammalian genome to the 570 kb genome of higher plants. It is assumed that the larger genomes code for additional functions. Chloroplast genomes range from 120-200 kb. Those that have been sequenced have a similar organization and coding functions. In both mitochondria and chloroplasts, many of the major proteins contain some subunits synthesized in the organelle and some subunits imported from the cytosol.

Mammalian mtDNAs are transcribed into a single transcript from the major coding strand, and individual products are generated by RNA processing. Rearrangements occur in mitochondrial DNA rather frequently in yeast; and recombination between mitochondrial or between chloroplast genomes has been found. Transfers of DNA have occurred from chloroplasts or mitochondria to nuclear genomes.

## CLUSTERS AND REPEATS

### 1.4.1 Introduction

---

#### Key Terms

A **gene family** consists of a set of genes whose exons are related; the members were derived by duplication and variation from some ancestral gene.

A **translocation** is a rearrangement in which part of a chromosome is detached by breakage or aberrant recombination and then becomes attached to some other chromosome.

A **gene cluster** is a group of adjacent genes that are identical or related.

**Nonreciprocal recombination (unequal crossing-over)** results from an error in pairing and crossing-over in which nonequivalent sites are involved in a recombination event. It produces one recombinant with a deletion of material and one with a duplication.

**Satellite DNA (Simple-sequence DNA)** consists of many tandem repeats (identical or related) of a short basic repeating unit.

**Minisatellite** DNAs consist of ~10 copies of a short repeating sequence. the length of the repeating unit is measured in 10s of base pairs. The number of repeats varies between individual genomes.

---

A set of genes descended by duplication and variation from some ancestral gene is called a **gene family**. Its members may be clustered together or dispersed on different chromosomes (or a combination of both). Genome analysis shows that many genes belong to families; the 40,000 genes identified in the human genome fall into ~15,000 families, so the average gene has a couple of relatives in the genome (see **Figure 3.15**). Gene families vary enormously in the degree of relatedness between members, from those consisting of multiple identical members to those where the relationship is quite distant. Genes are usually related only by their exons, with introns having diverged (see *Molecular Biology 1.2.5 Exon sequences are conserved but introns vary*). Genes may also be related by only some of their exons, while others are unique (see *Molecular Biology 1.2.10 Some exons can be equated with protein functions*).

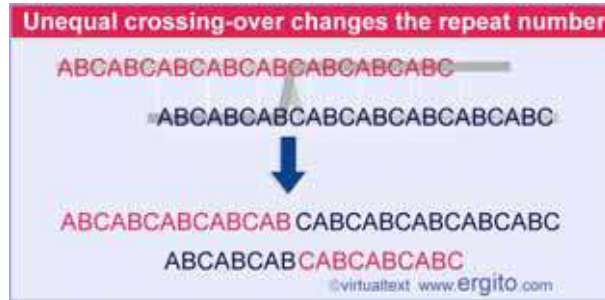

The initial event that allows related exons or genes to develop is a duplication, when a copy is generated of some sequence within the genome. Tandem duplication (when the duplicates remain together) may arise through errors in replication or recombination. Separation of the duplicates can occur by a **translocation** that transfers material from one chromosome to another. A duplicate at a new location may also be produced directly by a transposition event that is associated with copying a region of DNA from the vicinity of the transposon. Duplications may apply either to intact genes or to collections of exons or even individual exons. When an intact gene is involved, the act of duplication generates two copies of a gene whose activities are indistinguishable, but then usually the copies diverge as each accumulates different mutations.

The members of a well-related structural gene family usually have related or even identical functions, although they may be expressed at different times or in different cell types. So different globin proteins are expressed in embryonic and adult red blood cells, while different actins are utilized in muscle and nonmuscle cells. When genes have diverged significantly, or when only some exons are related, the proteins may have different functions.

Some gene families consist of identical members. Clustering is a prerequisite for maintaining identity between genes, although clustered genes are not necessarily identical. **Gene clusters** range from extremes where a duplication has generated two adjacent related genes to cases where hundreds of identical genes lie in a tandem array. Extensive tandem repetition of a gene may occur when the product is needed in unusually large amounts. Examples are the genes for rRNA or histone proteins. This creates a special situation with regards to the maintenance of identity and the effects of selective pressure.

Gene clusters offer us an opportunity to examine the forces involved in evolution of the genome over larger regions than single genes. Duplicated sequences, especially those that remain in the same vicinity, provide the substrate for further evolution by recombination. A population evolves by the classical recombination illustrated in **Figure 1.31 - Figure 1.32**, in which an exact crossing-over occurs. The recombinant chromosomes have the same organization as the parental chromosome. They contain precisely the same loci in the same order, but contain different combinations of alleles, providing the raw material for natural selection. However, the existence of duplicated sequences allows aberrant events to occur occasionally, changing the content of genes and not just the combination of alleles.

**Unequal crossing-over** describes a recombination event occurring between two sites that are not homologous. The feature that makes such events possible is the existence of repeated sequences. **Figure 4.1** shows that this allows one copy of a repeat in one chromosome to misalign for recombination with a different copy of the repeat in the homologous chromosome, instead of with the corresponding copy. When recombination occurs, this increases the number of repeats in one chromosome and decreases it in the other. In effect, one recombinant chromosome has a deletion and the other has an insertion. This mechanism is responsible for the evolution of clusters of related sequences. We can trace its operation in expanding or contracting the size of an array in both gene clusters and regions of highly repeated DNA.

**Figure 4.1** Unequal crossing-over results from pairing between non-equivalent repeats in regions of DNA consisting of repeating units. Here the repeating unit is the sequence ABC, and the third repeat of the red allele has aligned with the first repeat of the blue allele. Throughout the region of pairing, ABC units of one allele are aligned with ABC units of the other allele. Crossing-over generates chromosomes with 10 and 6 repeats each, instead of the 8 repeats of each parent.

The highly repetitive fraction of the genome consists of multiple tandem copies of very short repeating units. These often have unusual properties. One is that they may be identified as a separate peak on a density gradient analysis of DNA, which gave rise to the name **satellite DNA**. They are often associated with inert regions of the chromosomes, and in particular with centromeres (which contain the points of attachment for segregation on a mitotic or meiotic spindle). Because of their repetitive organization, they show some of the same behavior with regard to evolution as the tandem gene clusters. In addition to the satellite sequences, there are shorter stretches of DNA that show similar behavior, called **minisatellites**. They are useful in showing a high degree of divergence between individual genomes that can be used for mapping purposes.

All of these events that change the constitution of the genome are rare, but they are significant over the course of evolution.

## CLUSTERS AND REPEATS

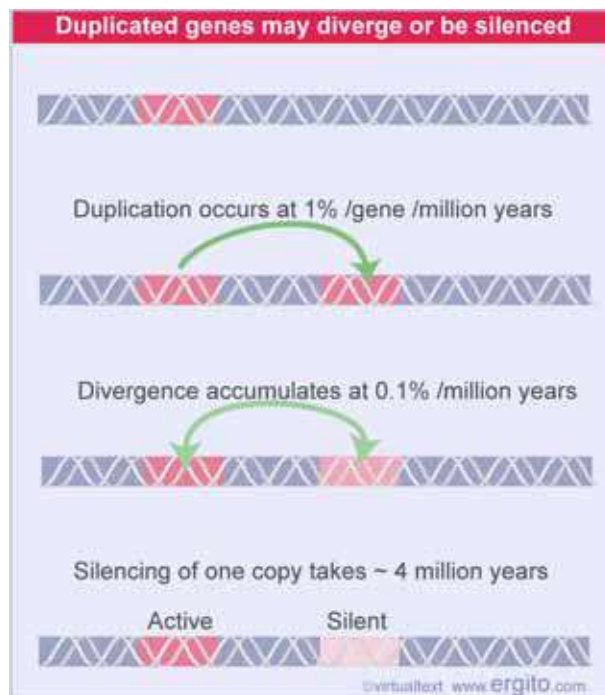

### 1.4.2 Gene duplication is a major force in evolution

#### Key Concepts

- Duplicated genes may diverge to generate different genes or one copy may become inactive.

Exons behave like modules for building genes that are tried out in the course of evolution in various combinations. At one extreme, an individual exon from one gene may be copied and used in another gene. At the other extreme, an entire gene, including both exons and introns, may be duplicated. In such a case, mutations can accumulate in one copy without attracting the adverse attention of natural selection. This copy may then evolve to a new function; it may become expressed in a different time or place from the first copy, or it may acquire different activities.

**Figure 4.2** summarizes our present view of the rates at which these processes occur. There is ~1% probability that a given gene will be included in a duplication in a period of 1 million years. After the gene has duplicated, differences develop as the result of the occurrence of different mutations in each copy. These accumulate at a rate of ~0.1% per million years (see *Molecular Biology 1.4.4 Sequence divergence is the basis for the evolutionary clock*).

**Figure 4.2** After a gene has been duplicated, differences may accumulate between the copies. The genes may acquire different functions or one of the copies may become inactive.

The organism is not likely to need to retain two identical copies of the gene. As differences develop between the duplicated genes, one of two types of event is likely to occur.

- Both of the genes become necessary. This can happen either because the differences between them generate proteins with different functions, or because they are expressed specifically in different times or places.
- If this does not happen, one of the genes is likely to be eliminated, because it will by chance gain a deleterious mutation, and there will be no adverse selection to eliminate this copy. Typically this takes ~ 4 million years. In such a situation, it is purely a matter of chance which of the two copies becomes inactive. (This can contribute to incompatibility between different individuals, and ultimately to speciation, if different copies become inactive in different populations.)

Analysis of the human genome sequence shows that ~5% comprises duplications of identifiable segments ranging in length from 10-300 kb (2847). These have arisen relatively recently, that is, there has not been sufficient time for divergence between them to eliminate their relationship. They include a proportional share (~6%) of the expressed exons, which shows that the duplications are occurring more or less irrespective of genetic content. The genes in these duplications may be especially interesting because of the implication that they have evolved recently, and therefore could be important for recent evolutionary developments (such as the separation of Man from the monkeys).

## CLUSTERS AND REPEATS

### 1.4.3 Globin clusters are formed by duplication and divergence

---

#### Key Terms

**Nonallelic** genes are two (or more) copies of the same gene that are present at *different* locations in the genome (contrasted with alleles which are copies of the same gene derived from different parents and present at the same location on the homologous chromosomes).

**Pseudogenes** are inactive but stable components of the genome derived by mutation of an ancestral active gene. Usually they are inactive because of mutations that block transcription or translation or both.

#### Key Concepts

- All globin genes are descended by duplication and mutation from an ancestral gene that had three exons.
- The ancestral gene gave rise to myoglobin, leghemoglobin, and  $\alpha$ - and  $\beta$ -globins.
- The  $\alpha$ - and  $\beta$ -globin genes separated in the period of early vertebrate evolution, after which duplications generated the individual clusters of separate  $\alpha$ -like and  $\beta$ -like genes.
- Once a gene has been inactivated by mutation, it may accumulate further mutations and become a pseudogene, which is homologous to the active gene(s) but has no functional role.

---

The most common type of duplication generates a second copy of the gene close to the first copy. In some cases, the copies remain associated, and further duplication may generate a cluster of related genes. The best characterized example of a gene cluster is presented by the globin genes, which constitute an ancient gene family, concerned with a function that is central to the animal kingdom: the transport of oxygen through the bloodstream.

The major constituent of the red blood cell is the globin tetramer, associated with its heme (iron-binding) group in the form of hemoglobin. Functional globin genes in all species have the same general structure, divided into three exons as shown previously in **Figure 2.7**. We conclude that all globin genes are derived from a single ancestral gene; so by tracing the development of individual globin genes within and between species, we may learn about the mechanisms involved in the evolution of gene families.

In adult cells, the globin tetramer consists of two identical  $\alpha$  chains and two identical  $\beta$  chains. Embryonic blood cells contain hemoglobin tetramers that are different from the adult form. Each tetramer contains two identical  $\alpha$ -like chains and two identical  $\beta$ -like chains, each of which is related to the adult polypeptide and is later replaced

by it. This is an example of developmental control, in which different genes are successively switched on and off to provide alternative products that fulfill the same function at different times.

The division of globin chains into  $\alpha$ -like and  $\beta$ -like reflects the organization of the genes. Each type of globin is coded by genes organized into a single cluster. The structures of the two clusters in the higher primate genome are illustrated in **Figure 4.3**.

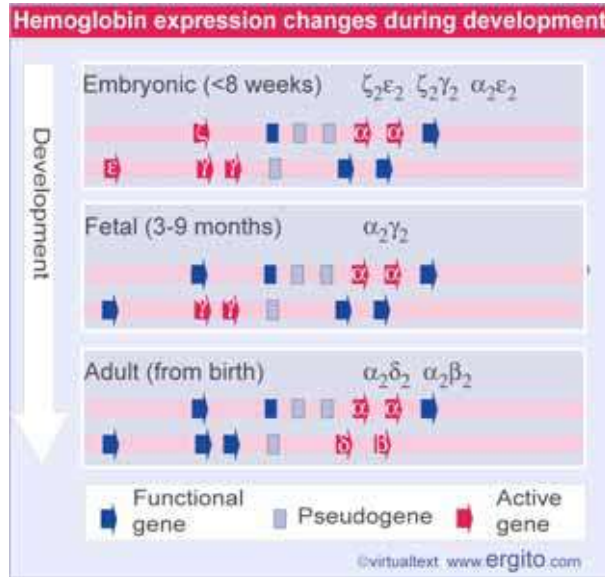

**Figure 4.3** Each of the  $\alpha$ -like and  $\beta$ -like globin gene families is organized into a single cluster that includes functional genes and pseudogenes ( $\psi$ ).

Stretching over 50 kb, the  $\beta$  cluster contains five functional genes ( $\epsilon$ , two  $\gamma$ ,  $\delta$ , and  $\beta$ ) and one nonfunctional gene ( $\psi\beta$ ). The two  $\gamma$  genes differ in their coding sequence in only one amino acid; the G variant has glycine at position 136, where the A variant has alanine.

The more compact  $\alpha$  cluster extends over 28 kb and includes one active  $\zeta$  gene, one  $\zeta$  nonfunctional gene, two  $\alpha$  genes, two  $\alpha$  nonfunctional genes, and the  $\theta$  gene of unknown function. The two  $\alpha$  genes code for the same protein. Two (or more) identical genes present on the same chromosome are described as **nonallelic** copies.

The details of the relationship between embryonic and adult hemoglobins vary with the organism. The human pathway has three stages: embryonic, fetal, and adult. The distinction between embryonic and adult is common to mammals, but the number of pre-adult stages varies. In Man, zeta and alpha are the two  $\alpha$ -like chains. Epsilon, gamma, delta, and beta are the  $\beta$ -like chains. **Figure 4.4** shows how the chains are expressed at different stages of development.

**Figure 4.4** Different hemoglobin genes are expressed during embryonic, fetal, and adult periods of human development.

In the human pathway,  $\zeta$  is the first  $\alpha$ -like chain to be expressed, but is soon replaced by  $\alpha$ . In the  $\beta$ -pathway,  $\varepsilon$  and  $\gamma$  are expressed first, with  $\delta$  and  $\beta$  replacing them later. In adults, the  $\alpha_2\beta_2$  form provides 97% of the hemoglobin,  $\alpha_2\delta_2$  is ~2%, and ~1% is provided by persistence of the fetal form  $\alpha_2\gamma_2$ .

What is the significance of the differences between embryonic and adult globins? The embryonic and fetal forms have a higher affinity for oxygen. This is necessary in order to obtain oxygen from the mother's blood. This explains why there is no equivalent in (for example) chicken, where the embryonic stages occur outside the body (that is, within the egg).

Functional genes are defined by their expression in RNA, and ultimately by the proteins for which they code. Nonfunctional genes are defined as such by their inability to code for proteins; the reasons for inactivity vary, and the deficiencies may be in transcription or translation (or both). They are called **pseudogenes** and given the symbol  $\psi$ .

A similar general organization is found in other vertebrate globin gene clusters, but details of the types, numbers, and order of genes all vary, as illustrated in **Figure 4.5**. Each cluster contains both embryonic and adult genes. The total lengths of the clusters vary widely. The longest is found in the goat, where a basic cluster of 4 genes has been duplicated twice. The distribution of active genes and pseudogenes differs in each case, illustrating the random nature of the conversion of one copy of a duplicated gene into the inactive state.

**Figure 4.5** Clusters of  $\beta$ -globin genes and pseudogenes are found in vertebrates. Seven mouse genes include 2 early embryonic, 1 late embryonic, 2 adult genes, and 2 pseudogenes. Rabbit and chick each have four genes.

The characterization of these gene clusters makes an important general point. *There may be more members of a gene family, both functional and nonfunctional, than we would suspect on the basis of protein analysis.* The extra functional genes may represent duplicates that code for identical polypeptides; or they may be related to known proteins, although different from them (and presumably expressed only briefly or in low amounts).

With regard to the question of how much DNA is needed to code for a particular function, we see that coding for the  $\beta$ -like globins requires a range of 20-120 kb in different mammals. This is much greater than we would expect just from scrutinizing the known  $\beta$ -globin proteins or even considering the individual genes. However, clusters of this type are not common; most genes are found as individual loci.

From the organization of globin genes in a variety of species, we should be able to trace the evolution of present globin gene clusters from a single ancestral globin gene. Our present view of the evolutionary descent is pictured in **Figure 4.6** (for review see 3041).

**Figure 4.6** All globin genes have evolved by a series of duplications, transpositions, and mutations from a single ancestral gene.

The leghemoglobin gene of plants, which is related to the globin genes, may represent the ancestral form. The furthest back that we can trace a globin gene in modern form is provided by the sequence of the single chain of mammalian myoglobin, which diverged from the globin line of descent ~800 million years ago. The myoglobin gene has the same organization as globin genes, so we may take the three-exon structure to represent their common ancestor.

Some "primitive fish" have only a single type of globin chain, so they must have diverged from the line of evolution before the ancestral globin gene was duplicated to give rise to the  $\alpha$  and  $\beta$  variants. This appears to have occurred ~500 million years ago, during the evolution of the bony fish.

The next stage of evolution is represented by the state of the globin genes in the frog *X. laevis*, which has two globin clusters. However, each cluster contains *both*  $\alpha$  and  $\beta$  genes, of both larval and adult types. The cluster must therefore have evolved by duplication of a linked  $\alpha$ - $\beta$  pair, followed by divergence between the individual copies. Later the entire cluster was duplicated.

The amphibians separated from the mammalian/avian line ~350 million years ago, so the separation of the  $\alpha$ - and  $\beta$ -globin genes must have resulted from a transposition in the mammalian/avian forerunner after this time. This probably occurred in the period of early vertebrate evolution. Since there are separate clusters for  $\alpha$  and  $\beta$  globins in both birds and mammals, the  $\alpha$  and  $\beta$  genes must have been physically separated before the mammals and birds diverged from their common ancestor, an event that occurred probably ~270 million years ago.

Changes have occurred within the separate  $\alpha$  and  $\beta$  clusters in more recent times, as we see from the description of the divergence of the individual genes in *Molecular Biology 1.4.4 Sequence divergence is the basis for the evolutionary clock*.

## CLUSTERS AND REPEATS

### 1.4.4 Sequence divergence is the basis for the evolutionary clock

---

#### Key Terms

A **neutral** mutation has no significant effect on evolutionary fitness and usually has no effect on the phenotype.

**Random drift** describes the chance fluctuation (without selective pressure) of the levels of two alleles in a population.

**Fixation** is the process by which a new allele replaces the allele that was previously predominant in a population.

**Divergence** is the percent difference in nucleotide sequence between two related DNA sequences or in amino acid sequences between two proteins.

**Replacement sites** in a gene are those at which mutations alter the amino acid that is coded.

A **silent site** in a coding region is one where mutation does not change the sequence of the protein.

The **evolutionary clock** is defined by the rate at which mutations accumulate in a given gene.

#### Key Concepts

- The sequences of homologous genes in different species vary at replacement sites (where mutation causes amino acid substitutions) and silent sites (where mutation does not affect the protein sequence).
- Mutations accumulate at silent sites  $\sim 10\times$  faster than at replacement sites.
- The evolutionary divergence between two proteins is measured by the per cent of positions at which the corresponding amino acids are different.
- Mutations accumulate at a more or less even speed after genes separate, so that the divergence between any pair of globin sequences is proportional to the time since their genes separated.

---

Most changes in protein sequences occur by small mutations that accumulate slowly with time. Point mutations and small insertions and deletions occur by chance, probably with more or less equal probability in all regions of the genome, except for hotspots at which mutations occur much more frequently. Most mutations that change the amino acid sequence are deleterious and will be eliminated by natural selection.

Few mutations are advantageous, but when a rare one occurs, it is likely to spread through the population, eventually replacing the former sequence. When a new variant replaces the previous version of the gene, it is said to have become *fixed* in

the population.

A contentious issue is what proportion of mutational changes in an amino acid sequence are **neutral**, that is, without any effect on the function of the protein, and able therefore to accrue as the result of **random drift** and **fixation**.

The rate at which mutational changes accumulate is a characteristic of each protein, presumably depending at least in part on its flexibility with regard to change. Within a species, a protein evolves by mutational substitution, followed by elimination or fixation within the single breeding pool. Remember that when we scrutinize the gene pool of a species, we see only the variants that have survived. When multiple variants are present, they may be stable (because neither has any selective advantage) or one may in fact be transient because it is in process of being displaced.

When a species separates into two new species, each now constitutes an independent pool for evolution. By comparing the corresponding proteins in two species, we see the differences that have accumulated between them *since the time when their ancestors ceased to interbreed*. Some proteins are highly conserved, showing little or no change from species to species. This indicates that almost any change is deleterious and therefore selected against.

The difference between two proteins is expressed as their **divergence**, the percent of positions at which the amino acids are different. The divergence between proteins can be different from the divergence between the corresponding nucleic acid sequences. The source of this difference is the representation of each amino acid in a three-base codon, in which often the third base has no effect on the meaning.

We may divide the nucleotide sequence of a coding region into potential **replacement sites** and **silent sites**:

- At replacement sites, a mutation alters the amino acid that is coded. The effect of the mutation (deleterious, neutral, or advantageous) depends on the result of the amino acid replacement.
- At silent sites, mutation only substitutes one synonym codon for another, so there is no change in the protein. Usually the replacement sites account for 75% of a coding sequence and the silent sites provide 25%.

In addition to the coding sequence, a gene contains nontranslated regions. Here again, mutations are potentially neutral, apart from their effects on either secondary structure or (usually rather short) regulatory signals.

Although silent mutations are neutral with regard to the protein, they could affect gene expression via the sequence change in RNA. For example, a change in secondary structure might influence transcription, processing, or translation. Another possibility is that a change in synonym codons calls for a different tRNA to respond, influencing the efficiency of translation.

The mutations in replacement sites should correspond with the amino acid divergence (determined by the percent of changes in the protein sequence). A nucleic

acid divergence of 0.45% at replacement sites corresponds to an amino acid divergence of 1% (assuming that the average number of replacement sites per codon is 2.25). Actually, the measured divergence underestimates the differences that have occurred during evolution, because of the occurrence of multiple events at one codon. Usually a correction is made for this.

To take the example of the human  $\beta$ - and  $\delta$ -globin chains, there are 10 differences in 146 residues, a divergence of 6.9%. The DNA sequence has 31 changes in 441 residues. However, these changes are distributed very differently in the replacement and silent sites. There are 11 changes in the 330 replacement sites, but 20 changes in only 111 silent sites. This gives (corrected) rates of divergence of 3.7% in the replacement sites and 32% in the silent sites, almost an order of magnitude in difference.

The striking difference in the divergence of replacement and silent sites demonstrates the existence of much greater constraints on nucleotide positions that influence protein constitution relative to those that do not. So probably very few of the amino acid changes are neutral.

Suppose we take the rate of mutation at silent sites to indicate the underlying rate of mutational fixation (this assumes that there is no selection at all at the silent sites). Then over the period since the  $\beta$  and  $\delta$  genes diverged, there should have been changes at 32% of the 330 replacement sites, a total of 105. All but 11 of them have been eliminated, which means that ~90% of the mutations did not survive.

The divergence between any pair of globin sequences is (more or less) proportional to the time since they separated. This provides an **evolutionary clock** that measures the accumulation of mutations at an apparently even rate during the evolution of a given protein.

The rate of divergence can be measured as the percent difference per million years, or as its reciprocal, the unit evolutionary period (UEP), the time in millions of years that it takes for 1% divergence to develop. Once the clock has been established by pairwise comparisons between species (remembering the practical difficulties in establishing the actual time of speciation), it can be applied to related genes *within* a species. From their divergence, we can calculate how much time has passed since the duplication that generated them.

By comparing the sequences of homologous genes in different species, the rate of divergence at both replacement and silent sites can be determined, as plotted in **Figure 4.7**.

**Figure 4.7** Divergence of DNA sequences depends on evolutionary separation. Each point on the graph represents a pairwise comparison.

In pairwise comparisons, there is an average divergence of 10% in the replacement sites of either the  $\alpha$ - or  $\beta$ -globin genes of mammals that have been separated since the mammalian radiation occurred ~85 million years ago. This corresponds to a replacement divergence rate of 0.12% per million years.

The rate is steady when the comparison is extended to genes that diverged in the more distant past. For example, the average replacement divergence between corresponding mammalian and chicken globin genes is 23%. Relative to a separation ~270 million years ago, this gives a rate of 0.09% per million years.

Going further back, we can compare the  $\alpha$ - with the  $\beta$ -globin genes within a species. They have been diverging since the individual gene types separated  $\geq 500$  million years ago (see **Figure 4.6**). They have an average replacement divergence of ~50%, which gives a rate of 0.1% per million years.

The summary of these data in **Figure 4.7** shows that replacement divergence in the globin genes has an average rate of ~0.096% per million years (or a UEP of 10.4). Considering the uncertainties in estimating the times at which the species diverged, the results lend good support to the idea that there is a linear clock.

The data on silent site divergence are much less clear. In every case, it is evident that the silent site divergence is much greater than the replacement site divergence, by a factor that varies from 2 to 10. But the spread of silent site divergences in pairwise comparisons is too great to show whether a clock is applicable (so we must base temporal comparisons on the replacement sites).

From **Figure 4.7**, it is clear that the rate at silent sites is not linear with regard to time. *If we assume that there must be zero divergence at zero years of separation, we*

see that the rate of silent site divergence is much greater for the first ~100 million years of separation. One interpretation is that a fraction of roughly half of the silent sites is rapidly (within 100 million years) saturated by mutations; this fraction behaves as neutral sites. The other fraction accumulates mutations more slowly, at a rate approximately the same as that of the replacement sites; this fraction identifies sites that are silent with regard to the protein, but that come under selective pressure for some other reason.

Now we can reverse the calculation of divergence rates to estimate the times since genes within a species have been apart. The difference between the human  $\beta$  and  $\delta$  genes is 3.7% for replacement sites. At a UEP of 10.4, these genes must have diverged  $10.4 \times 3.7 = 40$  million years ago – about the time of the separation of the lines leading to New World monkeys, Old World monkeys, great apes, and man. All of these higher primates have both  $\beta$  and  $\delta$  genes, which suggests that the gene divergence commenced just before this point in evolution.

Proceeding further back, the divergence between the replacement sites of  $\gamma$  and  $\epsilon$  genes is 10%, which corresponds to a time of separation ~100 million years ago. The separation between embryonic and fetal globin genes therefore may have just preceded or accompanied the mammalian radiation.

An evolutionary tree for the human globin genes is constructed in **Figure 4.8**. Features that evolved before the mammalian radiation – such as the separation of  $\beta/\delta$  from  $\gamma$  – should be found in all mammals. Features that evolved afterward – such as the separation of  $\beta$ - and  $\delta$ -globin genes – should be found in individual lines of mammals.

**Figure 4.8** Replacement site divergences between pairs of  $\beta$ -globin genes allow the history of the human cluster to be reconstructed. This tree accounts for the separation of classes of globin genes.

In each species, there have been comparatively recent changes in the structures of the clusters, since we see differences in gene number (one adult  $\beta$ -globin gene in man, two in mouse) or in type (most often concerning whether there are separate

embryonic and fetal genes).

When sufficient data have been collected on the sequences of a particular gene, the arguments can be reversed, and comparisons between genes in different species can be used to assess taxonomic relationships.

*This content is available online at <http://www.ergito.com/main.jsp?bcs=MBIO.1.4.4>*

## CLUSTERS AND REPEATS

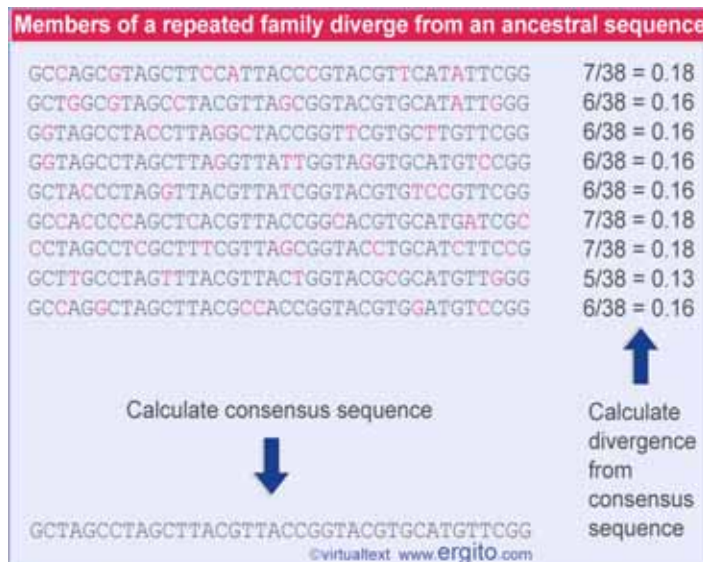

### 1.4.5 The rate of neutral substitution can be measured from divergence of repeated sequences

#### Key Concepts

- The rate of substitution per year at neutral sites is greater in the mouse than in the human genome.

We can make the best estimate of the rate of substitution at neutral sites by examining sequences that do not code for protein. (We use the term neutral here rather than silent, because there is no coding potential). An informative comparison can be made by comparing the members of common repetitive family in the human and mouse genomes (3203).

The principle of the analysis is summarized in **Figure 4.9**. We start with a family of related sequences that have evolved by duplication and substitution from an original family member. We assume that the common ancestral sequence can be deduced by taking the base that is most common at each position. Then we can calculate the divergence of each individual family member as the proportion of bases that differ from the deduced ancestral sequence. In this example, individual members vary from 0.13 - 0.18 divergence, and the average is 0.16.

**Figure 4.9** An ancestral consensus sequence for a family is calculated by taking the most common base at each position. The divergence of each existing current member of the family is calculated as the proportion of bases at which it differs from the ancestral sequence.

One family used for this analysis in the human and mouse genomes derives from a sequence that is thought to have ceased to be active at about the time of the

divergence between Man and rodents (the LINES family; see *Molecular Biology 4.17.9 Retroposons fall into three classes*). This means that it has been diverging without any selective pressure for the same length of time in both species. Its average divergence in Man is ~0.17 substitutions per site, corresponding to a rate of  $2.2 \times 10^{-9}$  substitutions per base per year over the 75 million years since the separation. In the mouse genome, however, neutral substitutions have occurred at twice this rate, corresponding to 0.34 substitutions per site in the family, or a rate of  $4.5 \times 10^{-9}$ . However, note that if we calculated the rate per generation instead of per year, it would be greater in Man than in mouse ( $\sim 2.2 \times 10^{-8}$  as opposed to  $\sim 10^{-9}$ ).

These figures probably underestimate the rate of substitution in the mouse, because at the time of divergence the rates in both species would have been the same, and the difference must have evolved since then. The current rate of neutral substitution per year in the mouse is probably 2-3 $\times$  greater than the historical average. These rates reflect the balance between the occurrence of mutations and the ability of the genetic system of the organism to correct them. The difference between the species demonstrates that each species has systems that operate with a characteristic efficiency.

Comparing the mouse and human genomes allows us to assess whether syntenic (corresponding) sequences show signs of conservation or have differed at the rate expected from accumulation of neutral substitutions. The proportion of sites that show signs of selection is ~5%. This is much higher than the proportion that codes for protein or RNA (~1%). It implies that the genome includes many more stretches whose sequence is important for non-coding functions than for coding functions. Known regulatory elements are likely to comprise only a small part of this proportion. This number also suggests that most (i.e., the rest) of the genome sequences do not have any function that depends on the exact sequence.

## CLUSTERS AND REPEATS

### 1.4.6 Pseudogenes are dead ends of evolution

---

#### Key Concepts

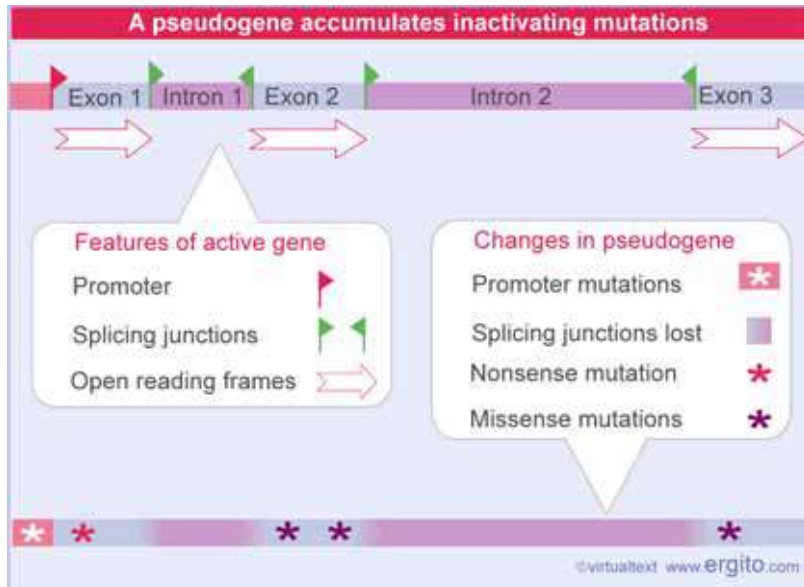

- Pseudogenes have no coding function, but they can be recognized by sequence similarities with existing functional genes. They arise by the accumulation of mutations in (formerly) functional genes.
- 

Pseudogenes ( $\Psi$ ) are defined by their possession of sequences that are related to those of the functional genes, but that cannot be translated into a functional protein.

Some pseudogenes have the same general structure as functional genes, with sequences corresponding to exons and introns in the usual locations. They may have been rendered inactive by mutations that prevent any or all of the stages of gene expression. The changes can take the form of abolishing the signals for initiating transcription, preventing splicing at the exon-intron junctions, or prematurely terminating translation.

Usually a pseudogene has several deleterious mutations. Presumably once it ceased to be active, there was no impediment to the accumulation of further mutations. Pseudogenes that represent inactive versions of currently active genes have been found in many systems, including globin, immunoglobulins, and histocompatibility antigens, where they are located in the vicinity of the gene cluster, often interspersed with the active genes.

A typical example is the rabbit pseudogene,  $\Psi \beta 2$ , which has the usual organization of exons and introns, and is related most closely to the functional globin gene  $\beta 1$ . But it is not functional. **Figure 4.10** summarizes the many changes that have occurred in the pseudogene. The deletion of a base pair at codon 20 of  $\Psi \beta 2$  has caused a frameshift that would lead to termination shortly after. Several point mutations have changed later codons representing amino acids that are highly conserved in the  $\beta$  globins. Neither of the two introns any longer possesses recognizable boundaries with the exons, so probably the introns could not be spliced out even if the gene were transcribed. However, there are no transcripts corresponding to the gene, possibly because there have been changes in the 5' flanking region.

**Figure 4.10** Many changes have occurred in a  $\beta$  globin gene since it became a pseudogene.

Since this list of defects includes mutations potentially preventing each stage of gene expression, we have no means of telling which event originally inactivated this gene. However, from the divergence between the pseudogene and the functional gene, we can estimate when the pseudogene originated and when its mutations started to accumulate.

If the pseudogene had become inactive as soon as it was generated by duplication from  $\beta 1$ , we should expect both replacement site and silent site divergence rates to be the same. (They will be different only if the gene is translated to create selective pressure on the replacement sites.) But actually there are fewer replacement site substitutions than silent site substitutions. This suggests that at first (while the gene was expressed) there was selection against replacement site substitution. From the relative extents of substitution in the two types of site, we can calculate that  $\Psi \beta 2$  diverged from  $\beta 1$  ~55 million years ago, remained a functional gene for 22 million years, but has been a pseudogene for the last 33 million years.

Similar calculations can be made for other pseudogenes. Some appear to have been active for some time before becoming pseudogenes, but others appear to have been inactive from the very time of their original generation. The general point made by the structures of these pseudogenes is that each has evolved independently during the development of the globin gene cluster in each species. This reinforces the conclusion that the creation of new genes, followed by their acceptance as functional duplicates, variation to become new functional genes, or inactivation as pseudogenes, is a continuing process in the gene cluster. Most gene families have members that are pseudogenes. Usually the pseudogenes represent a small minority of the total gene number.

The mouse  $\Psi \alpha 3$  globin gene has an interesting property: it precisely lacks both introns. Its sequence can be aligned (allowing for accumulated mutations) with the  $\alpha$ -globin mRNA. The apparent time of inactivation coincides with the original

---

duplication, which suggests that the original inactivating event was associated with the loss of introns.

Inactive genomic sequences that resemble the RNA transcript are called processed pseudogenes. They originate by insertion at some random site of a product derived from the RNA, following a retrotransposition event, as discussed in Retroviruses and retroposons . Their characteristic features are summarized in **Figure 17.19**.

If pseudogenes are evolutionary dead ends, simply an unwanted accompaniment to the rearrangement of functional genes, why are they still present in the genome? Do they fulfill any function or are they entirely without purpose, in which case there should be no selective pressure for their retention?

We should remember that we see those genes that have survived in present populations. In past times, any number of other pseudogenes may have been eliminated. This elimination could occur by deletion of the sequence as a sudden event or by the accretion of mutations to the point where the pseudogene can no longer be recognized as a member of its original sequence family (probably the ultimate fate of any pseudogene that is not suddenly eliminated).

Even relics of evolution can be duplicated. In the  $\beta$ -globin genes of the goat, there are three adult species,  $\beta A$ ,  $\beta B$ , and  $\beta C$  (see **Figure 4.5**). Each of these has a pseudogene a few kb upstream of it. The pseudogenes are better related to each other than to the adult  $\beta$ -globin genes; in particular, they share several inactivating mutations. Also, the adult  $\beta$ -globin genes are better related to each other than to the pseudogenes. This implies that an original  $\Psi \beta - \beta$  structure was itself duplicated, giving functional  $\beta$  genes (which diverged further) and two nonfunctional genes (which diverged into the current pseudogenes).

*The mechanisms responsible for gene duplication, deletion, and rearrangement act on all sequences that are recognized as members of the cluster, whether or not they are functional.* It is left to selection to discriminate among the products.

By definition, pseudogenes do not code for proteins, and usually they have no function at all, but in at least one exceptional case, a pseudogene has a regulatory function. Transcription of a pseudogene inhibits degradation of the mRNA produced by its homologous active gene (3996). Probably there is a protein responsible for this degradation that binds a specific sequence in the mRNA. If this sequence is also present in the RNA transcribed from the pseudogene, the effect of the protein will be diluted when the pseudogene is transcribed. It is not clear how common such effects may be, but as a general rule, we might expect dilution effects of this type to be possible whenever pseudogenes are transcribed.

## CLUSTERS AND REPEATS

### 1.4.7 Unequal crossing-over rearranges gene clusters

---

#### Key Terms

**Nonreciprocal recombination (unequal crossing-over)** results from an error in pairing and crossing-over in which nonequivalent sites are involved in a recombination event. It produces one recombinant with a deletion of material and one with a duplication.

**Thalassemia** is disease of red blood cells resulting from lack of either  $\alpha$  or  $\beta$  globin.

**HbH** disease results from a condition in which there is a disproportionate amount of the abnormal tetramer  $\beta_4$  relative to the amount of normal hemoglobin ( $\beta_2$ ).

**Hydrops fetalis** is a fatal disease resulting from the absence of the hemoglobin  $\alpha$  gene.

**Hb Lepore** is an unusual globin protein that results from unequal crossing-over between the  $\beta$  and  $\delta$  genes. The genes become fused together to produce a single  $\beta$ -like chain that consists of the N-terminal sequence of  $\delta$  joined to the C-terminal sequence of  $\beta$ .

**Hb anti-Lepore** is a fusion gene produced by unequal crossing-over that has the N-terminal part of  $\beta$  globin and the C-terminal part of  $\delta$  globin.

**Hb Kenya** is a fusion gene produced by unequal crossing-over between the between  $\gamma$  and  $\beta$  globin genes.

#### Key Concepts

- When a genome contains a cluster of genes with related sequences, mispairing between nonallelic genes can cause unequal crossing-over. This produces a deletion in one recombinant chromosome and a corresponding duplication in the other.
- Different thalassemias are caused by various deletions that eliminate  $\alpha$ - or  $\beta$ -globin genes. The severity of the disease depends on the individual deletion.

---

There are frequent opportunities for rearrangement in a cluster of related or identical genes. We can see the results by comparing the mammalian  $\beta$  clusters included in **Figure 4.5**. Although the clusters serve the same function, and all have the same general organization, each is different in size, there is variation in the total number and types of  $\beta$ -globin genes, and the numbers and structures of pseudogenes are different. All of these changes must have occurred since the mammalian radiation, ~85 million years ago (the last point in evolution common to all the mammals).

The comparison makes the general point that gene duplication, rearrangement, and variation is as important a factor in evolution as the slow accumulation of point mutations in individual genes. What types of mechanisms are responsible for gene reorganization?

**Unequal crossing-over** (also known as **nonreciprocal recombination**) can occur as the result of pairing between two sites that are *not* homologous. Usually, recombination involves corresponding sequences of DNA held in exact alignment between the two homologous chromosomes. However, when there are two copies of a gene on each chromosome, an occasional misalignment allows pairing between them. (This requires some of the adjacent regions to go unpaired.) This can happen in a region of short repeats (see **Figure 4.1**) or in a gene cluster. **Figure 4.11** shows that unequal crossing-over in a gene cluster can have two consequences, quantitative and qualitative:

**Figure 4.11** Gene number can be changed by unequal crossing-over. If gene 1 of one chromosome pairs with gene 2 of the other chromosome, the other gene copies are excluded from pairing. Recombination between the mispaired genes produces one chromosome with a single (recombinant) copy of the gene and one chromosome with three copies of the gene (one from each parent and one recombinant).

- The number of repeats increases in one chromosome and decreases in the other. In effect, one recombinant chromosome has a deletion and the other has an insertion. This happens irrespective of the exact location of the crossover. In the figure, the first recombinant has an increase in the number of gene copies from 2 to 3, while the second has a decrease from 2 to 1.
- If the recombination event occurs within a gene (as opposed to between genes), the result depends on whether the recombining genes are identical or only related. If the noncorresponding gene copies 1 and 2 are entirely homologous,

there is no change in the sequence of either gene. However, unequal crossing-over also can occur when the adjacent genes are well related (although the probability is less than when they are identical). In this case, each of the recombinant genes has a sequence that is different from either parent.

Whether the chromosome has a selective advantage or disadvantage will depend on the consequence of any change in the sequence of the gene product as well as on the change in the number of gene copies.

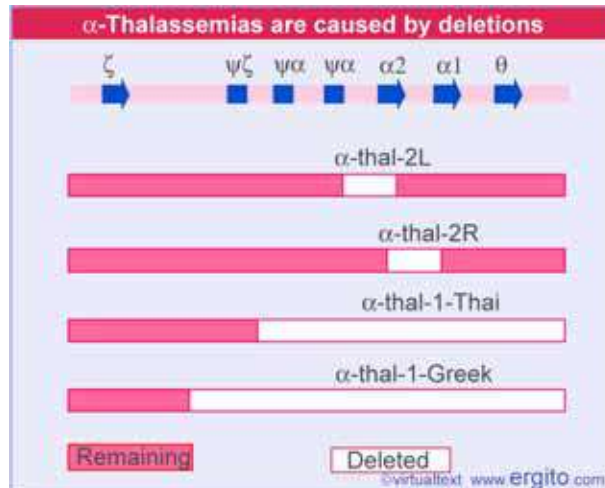

An obstacle to unequal crossing-over is presented by the interrupted structure of the genes. In a case such as the globins, the corresponding exons of adjacent gene copies are likely to be well enough related to support pairing; but the sequences of the introns have diverged appreciably. The restriction of pairing to the exons considerably reduces the continuous length of DNA that can be involved. This lowers the chance of unequal crossing-over. So divergence between introns could enhance the stability of gene clusters by hindering the occurrence of unequal crossing-over.

**Thalassemias** result from mutations that reduce or prevent synthesis of either  $\alpha$  or  $\beta$  globin. The occurrence of unequal crossing-over in the human globin gene clusters is revealed by the nature of certain thalassemias.

Many of the most severe thalassemias result from deletions of part of a cluster. In at least some cases, the ends of the deletion lie in regions that are homologous, which is exactly what would be expected if it had been generated by unequal crossing-over.

**Figure 4.12** summarizes the deletions that cause the  $\alpha$ -thalassemias.  $\alpha$ -thal-1 deletions are long, varying in the location of the left end, with the positions of the right ends located beyond the known genes. They eliminate both the  $\alpha$  genes. The  $\alpha$ -thal-2 deletions are short and eliminate only one of the two  $\alpha$  genes. The L deletion removes 4.2 kb of DNA, including the  $\alpha 2$  gene. It probably results from unequal crossing-over, because the ends of the deletion lie in homologous regions, just to the right of the  $\psi \alpha$  and  $\alpha 2$  genes, respectively. The R deletion results from the removal of exactly 3.7 kb of DNA, the precise distance between the  $\alpha 1$  and  $\alpha 2$  genes. It appears to have been generated by unequal crossing-over between the  $\alpha 1$  and  $\alpha 2$  genes themselves. This is precisely the situation depicted in **Figure 4.11**.

**Figure 4.12** Thalassems result from various deletions in the  $\alpha$  -globin gene cluster.

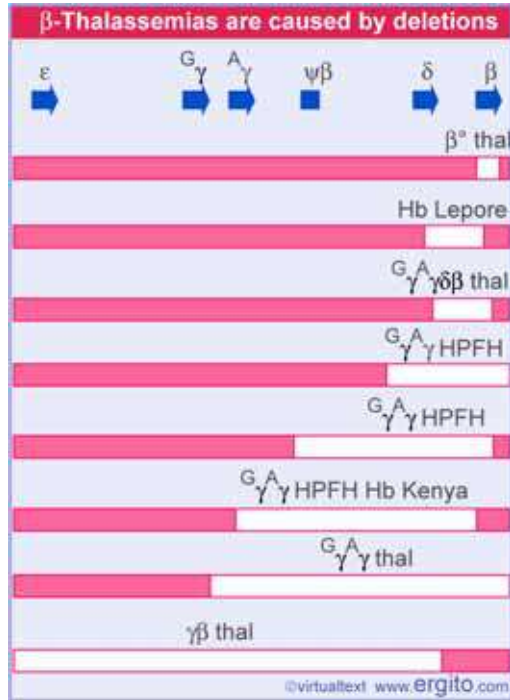

Depending on the diploid combination of thalassemic chromosomes, an affected individual may have any number of  $\alpha$  chains from zero to three. There are few differences from the wild type (four  $\alpha$  genes) in individuals with three or two  $\alpha$  genes. But with only one  $\alpha$  gene, the excess  $\beta$  chains form the unusual tetramer  $\beta_4$ , which causes **HbH** disease. The complete absence of  $\alpha$  genes results in **hydrops fetalis**, which is fatal at or before birth.

The same unequal crossing-over that generated the thalassemic chromosome should also have generated a chromosome with three  $\alpha$  genes. Individuals with such chromosomes have been identified in several populations. In some populations, the frequency of the triple  $\alpha$  locus is about the same as that of the single  $\alpha$  locus; in others, the triple  $\alpha$  genes are much *less* common than single  $\alpha$  genes. This suggests that (unknown) selective factors operate in different populations to adjust the gene levels.

Variations in the number of  $\alpha$  genes are found relatively frequently, which argues that unequal crossing-over in the cluster must be fairly common. It occurs more often in the  $\alpha$  cluster than in the  $\beta$  cluster, possibly because the introns in  $\alpha$  genes are much shorter, and therefore present less impediment to mispairing between nonhomologous genes.

The deletions that cause  $\beta$ -thalassemias are summarized in **Figure 4.13**. In some (rare) cases, only the  $\beta$  gene is affected. These have a deletion of 600 bp, extending from the second intron through the 3' flanking regions. In the other cases, more than one gene of the cluster is affected. Many of the deletions are very long, extending from the 5' end indicated on the map for >50 kb toward the right.

**Figure 4.13** Deletions in the  $\beta$ -globin gene cluster cause several types of thalassemia.

The **Hb Lepore** type provided the classic evidence that deletion can result from unequal crossing-over between linked genes. The  $\beta$  and  $\delta$  genes differ only ~7% in sequence. Unequal recombination deletes the material between the genes, thus fusing them together (see **Figure 4.11**). The fused gene produces a single  $\beta$ -like chain that consists of the N-terminal sequence of  $\delta$  joined to the C-terminal sequence of  $\beta$ .

Several types of Hb Lepore now are known, the difference between them lying in the point of transition from  $\delta$  to  $\beta$  sequences. So when the  $\delta$  and  $\beta$  genes pair for unequal crossing-over, the exact point of recombination determines the position at which the switch from  $\delta$  to  $\beta$  sequence occurs in the amino acid chain.

The reciprocal of this event has been found in the form of **Hb anti-Lepore**, which is produced by a gene that has the N-terminal part of  $\beta$  and the C-terminal part of  $\delta$ . The fusion gene lies between normal  $\delta$  and  $\beta$  genes.

Evidence that unequal crossing-over can occur between more distantly related genes is provided by the identification of **Hb Kenya**, another fused hemoglobin. This contains the N-terminal sequence of the  $^A\gamma$  gene and the C-terminal sequence of the  $\beta$  gene. The fusion must have resulted from unequal crossing-over between  $^A\gamma$  and  $\beta$ , which differ ~20% in sequence.

From the differences between the globin gene clusters of various mammals, we see that duplication followed (sometimes) by variation has been an important feature in the evolution of each cluster. The human thalassemic deletions demonstrate that unequal crossing-over continues to occur in both globin gene clusters. Each such event generates a duplication as well as the deletion, and we must account for the

fate of both recombinant loci in the population. Deletions can also occur (in principle) by recombination between homologous sequences lying on the *same* chromosome. This does not generate a corresponding duplication.

It is difficult to estimate the natural frequency of these events, because selective forces rapidly adjust the levels of the variant clusters in the population. Generally a contraction in gene number is likely to be deleterious and selected against. However, in some populations, there may be a balancing advantage that maintains the deleted form at a low frequency.

The structures of the present human clusters show several duplications that attest to the importance of such mechanisms. The *functional* sequences include two  $\alpha$  genes coding the same protein, fairly well related  $\beta$  and  $\delta$  genes, and two almost identical  $\gamma$  genes. These comparatively recent independent duplications have survived in the population, not to mention the more distant duplications that originally generated the various types of globin genes. Other duplications may have given rise to pseudogenes or have been lost. We expect continual duplication and deletion to be a feature of all gene clusters.

## CLUSTERS AND REPEATS

### 1.4.8 Genes for rRNA form tandem repeats

---

#### Key Terms

**Ribosomal DNA (rDNA)** is usually a tandemly repeated series of genes coding for a precursor to the two large rRNAs.

The **nucleolus (nucleoli)** is a discrete region of the nucleus where ribosomes are produced.

The **nucleolar organizer** is the region of a chromosome carrying genes coding for rRNA.

The **nontranscribed spacer** is the region between transcription units in a tandem gene cluster.

#### Key Concepts

- Ribosomal RNA is coded by a large number of identical genes that are tandemly repeated to form one or more clusters.
- Each rDNA cluster is organized so that transcription units giving a joint precursor to the major rRNAs alternate with nontranscribed spacers.

---

In the cases we have discussed so far, there are differences between the individual members of a gene cluster that allow selective pressure to act independently upon each gene. A contrast is provided by two cases of large gene clusters that contain many identical copies of the same gene or genes. Most organisms contain multiple copies of the genes for the histone proteins that are a major component of the chromosomes; and there are almost always multiple copies of the genes that code for the ribosomal RNAs. These situations pose some interesting evolutionary questions.

Ribosomal RNA is the predominant product of transcription, constituting some 80-90% of the total mass of cellular RNA in both eukaryotes and prokaryotes. The number of major rRNA genes varies from 7 in *E. coli*, 100-200 in lower eukaryotes, to several hundred in higher eukaryotes. The genes for the large and small rRNA (found respectively in the large and small subunits of the ribosome) usually form a tandem pair. (The sole exception is the yeast mitochondrion.)

The lack of any detectable variation in the sequences of the rRNA molecules implies that all the copies of each gene must be identical, or at least must have differences below the level of detection in rRNA (~1%). A point of major interest is what mechanism(s) are used to prevent variations from accruing in the individual sequences.

In bacteria, the multiple rRNA gene pairs are dispersed. In most eukaryotic nuclei, the rRNA genes are contained in a tandem cluster or clusters. Sometimes these regions are called **rDNA**. (In some cases, the proportion of rDNA in the total DNA, together with its atypical base composition, is great enough to allow its isolation as a

separate fraction directly from sheared genomic DNA.) An important diagnostic feature of a tandem cluster is that it generates a circular restriction map, as shown in **Figure 4.14**.

**Figure 4.14** A tandem gene cluster has an alternation of transcription unit and nontranscribed spacer and generates a circular restriction map.

Suppose that each repeat unit has 3 restriction sites. In the example shown in the figure, fragments A and B are contained entirely within a repeat unit, and fragment C contains the end of one repeat and the beginning of the next. When we map these fragments by conventional means, we find that A is next to B, which is next to C, which is next to A, generating the circular map. If the cluster is large, the internal fragments (A, B, C) will be present in much greater quantities than the terminal fragments (X, Y) which connect the cluster to adjacent DNA. In a cluster of 100 repeats, X and Y would be present at 1% of the level of A, B, C. This can make it difficult to obtain the ends of a gene cluster for mapping purposes.

The region of the nucleus where rRNA synthesis occurs has a characteristic appearance, with a core of fibrillar nature surrounded by a granular cortex. The fibrillar core is where the rRNA is transcribed from the DNA template; and the granular cortex is formed by the ribonucleoprotein particles into which the rRNA is assembled. The whole area is called the **nucleolus**. Its characteristic morphology is evident in **Figure 4.15**.

**Figure 4.15** The nucleolar core identifies rDNA under transcription, and the surrounding granular cortex consists of assembling ribosomal subunits. This thin section shows the nucleolus of the newt *Notophthalmus viridescens*. Photograph kindly provided by Oscar Miller.

The particular chromosomal regions associated with a nucleolus are called **nucleolar organizers**. Each nucleolar organizer corresponds to a cluster of tandemly repeated rRNA genes on one chromosome. The concentration of the tandemly repeated rRNA genes, together with their very intensive transcription, is responsible for creating the characteristic morphology of the nucleoli.

The pair of major rRNAs is transcribed as a single precursor in both bacteria and eukaryotic nuclei. Following transcription, the precursor is cleaved to release the individual rRNA molecules. The transcription unit is shortest in bacteria and is longest in mammals (where it is known as 45S RNA, according to its rate of sedimentation). An rDNA cluster contains many transcription units, each separated from the next by a **nontranscribed spacer**. The alternation of transcription unit and nontranscribed spacer can be seen directly in electron micrographs. The example shown in **Figure 4.16** is taken from the newt *N. viridescens*, in which each transcription unit is intensively expressed, so that many RNA polymerases are simultaneously engaged in transcription on one repeating unit. The polymerases are so closely packed that the RNA transcripts form a characteristic matrix displaying increasing length along the transcription unit.

**Figure 4.16** Transcription of rDNA clusters generates a series of matrices, each corresponding to one transcription unit and separated from the next by the nontranscribed spacer. Photograph kindly provided by Oscar Miller.

---

## CLUSTERS AND REPEATS

### 1.4.9 The repeated genes for rRNA maintain constant sequence

---

#### Key Terms

**Bam islands** are a series of short, repeated sequences found in the nontranscribed spacer of *Xenopus* rDNA genes. The name reflects their isolation by use of the BamI restriction enzyme.

#### Key Concepts

- The genes in an rDNA cluster all have an identical sequence.
- The nontranscribed spacers consist of shorter repeating units whose number varies so that the lengths of individual spacers are different.

---

The nontranscribed spacer varies widely in length between and (sometimes) within species. In yeast there is a short nontranscribed spacer, relatively constant in length. In *D. melanogaster*, there is almost a twofold variation in the length of the nontranscribed spacer between different copies of the repeating unit. A similar situation is seen in *X. laevis*. In each of these cases, all of the repeating units are present as a single tandem cluster on one particular chromosome. (In the example of *D. melanogaster*, this happens to be the sex chromosome. The cluster on the X chromosome is larger than that on the Y chromosome, so female flies have more copies of the rRNA genes than male flies.)

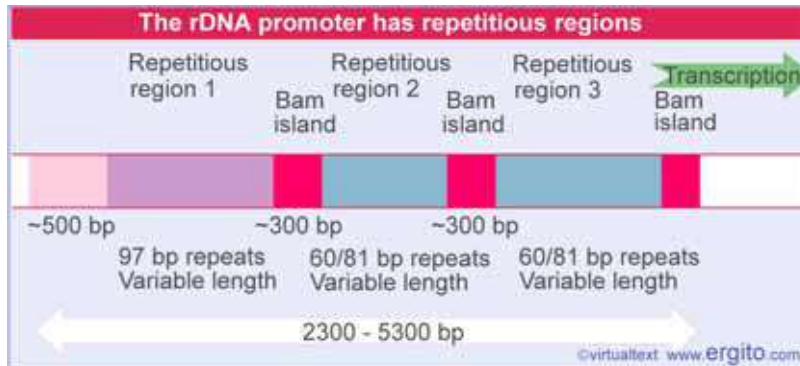

In mammals the repeating unit is very much larger, comprising the transcription unit of ~13 kb and a nontranscribed spacer of ~30 kb. Usually, the genes lie in several dispersed clusters – in the case of man and mouse residing on five and six chromosomes, respectively. One interesting (but unanswered) question is how the corrective mechanisms that presumably function within a single cluster to ensure constancy of rRNA sequence are able to work when there are several clusters.

The variation in length of the nontranscribed spacer in a single gene cluster contrasts with the conservation of sequence of the transcription unit. In spite of this variation, the sequences of longer nontranscribed spacers remain homologous with those of the shorter nontranscribed spacers. This implies that each nontranscribed spacer is *internally repetitious*, so that the variation in length results from changes in the number of repeats of some subunit.

The general nature of the nontranscribed spacer is illustrated by the example of *X. laevis*. **Figure 4.17** illustrates the situation. Regions that are fixed in length alternate with regions that vary. Each of the three repetitious regions comprises a variable number of repeats of a rather short sequence. One type of repetitious region has repeats of a 97 bp sequence; the other, which occurs in two locations, has a repeating unit found in two forms, 60 bp and 81 bp long. The variation in the number of repeating units in the repetitious regions accounts for the overall variation in spacer

length. The repetitious regions are separated by shorter constant sequences called **Bam islands**. (This description takes its name from their isolation via the use of the BamHI restriction enzyme.) From this type of organization, we see that the cluster has evolved by duplications involving the promoter region.

**Figure 4.17** The nontranscribed spacer of *X. laevis* rDNA has an internally repetitious structure that is responsible for its variation in length. The Bam islands are short constant sequences that separate the repetitious regions.

We need to explain the lack of variation in the expressed copies of the repeated genes. One model would suppose that there is a quantitative demand for a certain number of "good" sequences. But this would enable mutated sequences to accumulate up to a point at which their proportion of the cluster is great enough for selective pressure to be exerted. We can exclude such models because of the lack of such variation in the cluster.

The lack of variation implies the existence of selective pressure in some form that is sensitive to individual variations. One model would suppose that the entire cluster is regenerated periodically from one or from a very few members. As a practical matter any mechanism would need to involve regeneration every generation. We can exclude such models because a regenerated cluster would not show variation in the nontranscribed regions of the individual repeats.

We are left with a dilemma. Variation in the nontranscribed regions suggests that there is frequent unequal crossing over. This will change the size of the cluster, but will not otherwise change the properties of the individual repeats. So how are mutations prevented from accumulating? We see in *Molecular Biology 1.4.10 Crossover fixation could maintain identical repeats* that continuous contraction and expansion of a cluster may provide a mechanism for homogenizing its copies.

This content is available online at <http://www.ergito.com/main.jsp?bcs=MBIO.1.4.9>

---

## CLUSTERS AND REPEATS

### 1.4.10 Crossover fixation could maintain identical repeats

---

#### Key Terms

**Concerted evolution** describes the ability of two related genes to evolve together as though constituting a single locus.

**Coincidental evolution (Coevolution)** describes a situation in which two genes evolve together as a single unit.

**Gene conversion** is the alteration of one strand of a heteroduplex DNA to make it complementary with the other strand at any position(s) where there were mismatched bases.

**Crossover fixation** refers to a possible consequence of unequal crossing-over that allows a mutation in one member of a tandem cluster to spread through the whole cluster (or to be eliminated).

#### Key Concepts

- Unequal crossing-over changes the size of a cluster of tandem repeats.
- Individual repeating units can be eliminated or can spread through the cluster.

---

The same problem is encountered whenever a gene has been duplicated. How can selection be imposed to prevent the accumulation of deleterious mutations?

The duplication of a gene is likely to result in an immediate relaxation of the evolutionary pressure on its sequence. Now that there are two identical copies, a change in the sequence of either one will not deprive the organism of a functional protein, since the original amino acid sequence continues to be coded by the other copy. Then the selective pressure on the two genes is diffused, until one of them mutates sufficiently away from its original function to refocus all the selective pressure on the other.

Immediately following a gene duplication, changes might accumulate more rapidly in one of the copies, leading eventually to a new function (or to its disuse in the form of a pseudogene). If a new function develops, the gene then evolves at the same, slower rate characteristic of the original function. Probably this is the sort of mechanism responsible for the separation of functions between embryonic and adult globin genes.

Yet there are instances where duplicated genes retain the same function, coding for the identical or nearly identical proteins. Identical proteins are coded by the two human  $\alpha$ -globin genes, and there is only a single amino acid difference between the two  $\gamma$ -globin proteins. How is selective pressure exerted to maintain their sequence identity?

The most obvious possibility is that the two genes do not actually have identical functions, but differ in some (undetected) property, such as time or place of expression. Another possibility is that the need for two copies is quantitative, because neither by itself produces a sufficient amount of protein.

In more extreme cases of repetition, however, it is impossible to avoid the conclusion that no single copy of the gene is essential. When there are many copies of a gene, the immediate effects of mutation in any one copy must be very slight. The consequences of an individual mutation are diluted by the large number of copies of the gene that retain the wild-type sequence. Many mutant copies could accumulate before a lethal effect is generated.

Lethality becomes quantitative, a conclusion reinforced by the observation that half of the units of the rDNA cluster of *X. laevis* or *D. melanogaster* can be deleted without ill effect. So how are these units prevented from gradually accumulating deleterious mutations? And what chance is there for the rare favorable mutation to display its advantages in the cluster?

The basic principle of models to explain the maintenance of identity among repeated copies is to suppose that nonallelic genes are not independently inherited, but must be continually regenerated from *one* of the copies of a preceding generation. In the simplest case of two identical genes, when a mutation occurs in one copy, either it is by chance eliminated (because the sequence of the other copy takes over), or it is spread to both duplicates (because the mutant copy becomes the dominant version). Spreading exposes a mutation to selection. The result is that the two genes evolve together as though only a single locus existed. This is called **coincidental evolution** or **concerted evolution** (occasionally **coevolution**). It can be applied to a pair of identical genes or (with further assumptions) to a cluster containing many genes.

One mechanism supposes that the sequences of the nonallelic genes are directly compared with one another and homogenized by enzymes that recognize any differences. This can be done by exchanging single strands between them, to form genes one of whose strands derives from one copy, one from the other copy. Any differences show as improperly paired bases, which attract attention from enzymes able to excise and replace a base, so that only A·T and G·C pairs survive. This type of event is called **gene conversion** and is associated with genetic recombination as described in *Molecular Biology 4.15 Recombination and repair*.

We should be able to ascertain the scope of such events by comparing the sequences of duplicate genes. If they are subject to concerted evolution, we should not see the accumulation of silent site substitutions between them (because the homogenization process applies to these as well as to the replacement sites). We know that the extent of the maintenance mechanism need not extend beyond the gene itself, since there are cases of duplicate genes whose flanking sequences are entirely different. Indeed, we may see abrupt boundaries that mark the ends of the sequences that were homogenized.

We must remember that the existence of such mechanisms can invalidate the determination of the history of such genes via their divergence, *because the divergence reflects only the time since the last homogenization/regeneration event, not the original duplication*.

The **crossover fixation** model supposes that an entire cluster is subject to continual rearrangement by the mechanism of unequal crossing-over. Such events can explain the concerted evolution of multiple genes if unequal crossing-over causes all the copies to be regenerated physically from one copy.

Following the sort of event depicted in , for example, the chromosome carrying a triple locus could suffer deletion of one of the genes. Of the two remaining genes,  $1\frac{1}{2}$  represent the sequence of one of the original copies; only  $\frac{1}{2}$  of the sequence of the other original copy has survived. Any mutation in the first region now exists in both genes and is subject to selective pressure.

Tandem clustering provides frequent opportunities for "mispairing" of genes whose sequences are the same, but that lie in different positions in their clusters. By continually expanding and contracting the number of units via unequal crossing-over, it is possible for all the units in one cluster to be derived from rather a small proportion of those in an ancestral cluster. The variable lengths of the spacers are consistent with the idea that unequal crossing-over events take place in spacers that are internally mispaired. This can explain the homogeneity of the genes compared with the variability of the spacers. The genes are exposed to selection when individual repeating units are amplified within the cluster; but the spacers are irrelevant and can accumulate changes.

In a region of nonrepetitive DNA, recombination occurs between precisely matching points on the two homologous chromosomes, generating reciprocal recombinants. The basis for this precision is the ability of two duplex DNA sequences to align exactly. We know that unequal recombination can occur when there are multiple copies of genes whose exons are related, even though their flanking and intervening sequences may differ. This happens because of the mispairing between corresponding exons in *nonallelic* genes.

Imagine how much more frequently misalignment must occur in a tandem cluster of identical or nearly identical repeats. Except at the very ends of the cluster, the close relationship between successive repeats makes it impossible even to define the exactly corresponding repeats! This has two consequences: there is continual adjustment of the size of the cluster; and there is homogenization of the repeating unit.

Consider a sequence consisting of a repeating unit "ab" with ends "x" and "y." If we represent one chromosome in black and the other in color, the exact alignment between "allelic" sequences would be:

```
xabababababababababababababababababy
xabababababababababababababababababy
```

But probably *any* sequence *ab* in one chromosome could pair with *any* sequence *ab* in the other chromosome. In a misalignment such as:

xabababababababababababababababababy  
 xabababababababababababababababababy

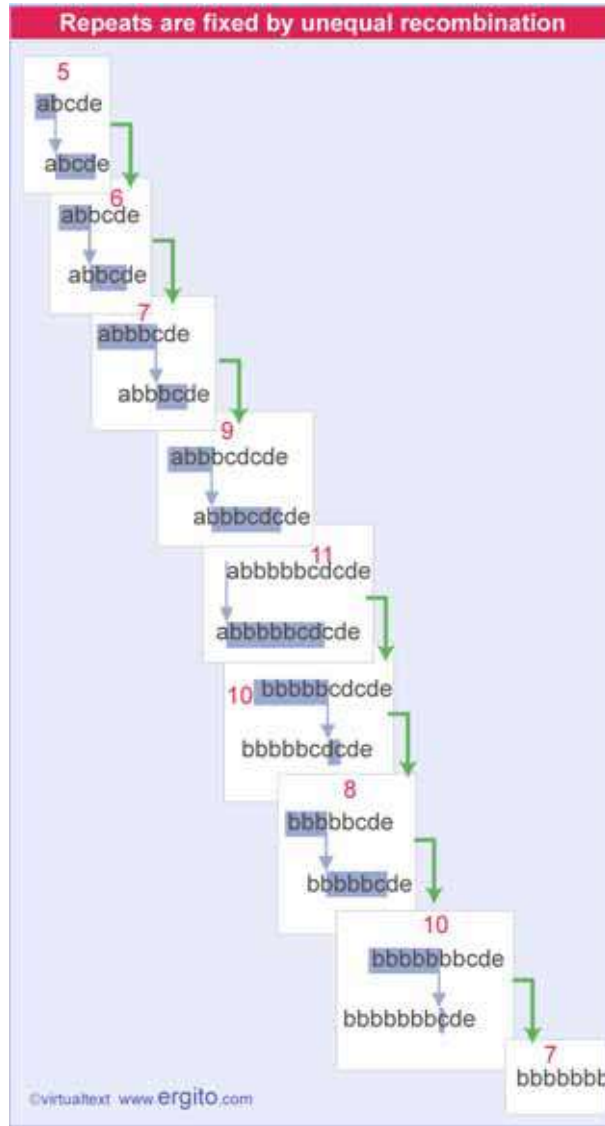

the region of pairing is no less stable than in the perfectly aligned pair, although it is shorter. We do not know very much about how pairing is initiated prior to recombination, but very likely it starts between short corresponding regions and then spreads. If it starts within satellite DNA, it is more likely than not to involve repeating units that do not have exactly corresponding locations in their clusters.

Now suppose that a recombination event occurs within the unevenly paired region. The recombinants will have different numbers of repeating units. In one case, the cluster has become longer; in the other, it has become shorter,

where "x" indicates the site of the crossover.

If this type of event is common, clusters of tandem repeats will undergo continual expansion and contraction. This can cause a particular repeating unit to spread through the cluster, as illustrated in **Figure 4.18**. Suppose that the cluster consists initially of a sequence *abcde*, where each letter represents a repeating unit. The different repeating units are closely enough related to one another to mispair for recombination. Then by a series of unequal recombination events, the size of the repetitive region increases or decreases, and also one unit spreads to replace all the others.

**Figure 4.18** Unequal recombination allows one particular repeating unit to occupy the entire cluster. The numbers indicate the length of the repeating unit at each stage.

The crossover fixation model predicts that *any sequence of DNA that is not under selective pressure will be taken over by a series of identical tandem repeats generated in this way* (for review see 3042). The critical assumption is that the process of crossover fixation is fairly rapid relative to mutation, so that new mutations either are eliminated (their repeats are lost) or come to take over the entire cluster. In the case of the rDNA cluster, of course, a further factor is imposed by selection for an effective transcribed sequence.

## CLUSTERS AND REPEATS

### 1.4.11 Satellite DNAs often lie in heterochromatin

---

#### Key Terms

**Highly repetitive DNA (Simple sequence DNA)** is the first component to reassociate and is equated with satellite DNA.

**Satellite DNA (Simple-sequence DNA)** consists of many tandem repeats (identical or related) of a short basic repeating unit.

A **density gradient** is used to separate macromolecules on the basis of differences in their density. It is prepared from a heavy soluble compound such as CsCl.

A **cryptic satellite** is a satellite DNA sequence not identified as such by a separate peak on a density gradient; that is, it remains present in main-band DNA.

**In situ hybridization (Cytological hybridization)** is performed by denaturing the DNA of cells squashed on a microscope slide so that reaction is possible with an added single-stranded RNA or DNA; the added preparation is radioactively labeled and its hybridization is followed by autoradiography.

**Heterochromatin** describes regions of the genome that are highly condensed, are not transcribed, and are late-replicating. Heterochromatin is divided into two types, which are called constitutive and facultative.

**Euchromatin** comprises all of the genome in the interphase nucleus except for the heterochromatin. The euchromatin is less tightly coiled than heterochromatin, and contains the active or potentially active genes.

#### Key Concepts

- Highly repetitive DNA has a very short repeating sequence and no coding function.
- It occurs in large blocks that can have distinct physical properties.
- It is often the major constituent of centromeric heterochromatin.

---

Repetitive DNA is defined by its (relatively) rapid rate of renaturation. The component that renatures most rapidly in a eukaryotic genome is called *highly repetitive DNA*, and consists of very short sequences repeated many times in tandem in large clusters. Because of its short repeating unit, it is sometimes described as **simple sequence DNA**. This type of component is present in almost all higher eukaryotic genomes, but its overall amount is extremely variable. In mammalian genomes it is typically <10%, but in (for example) *Drosophila virilis*, it amounts to ~50%. In addition to the large clusters in which this type of sequence was originally discovered, there are smaller clusters interspersed with nonrepetitive DNA. It typically consists of short sequences that are repeated in identical or related copies in the genome.

The tandem repetition of a short sequence often creates a fraction with distinctive physical properties that can be used to isolate it. In some cases, the repetitive sequence has a base composition distinct from the genome average, which allows it

to form a separate fraction by virtue of its distinct buoyant density. A fraction of this sort is called **satellite DNA**. The term satellite DNA is essentially synonymous with simple sequence DNA. Consistent with its simple sequence, this DNA is not transcribed or translated.

Tandemly repeated sequences are especially liable to undergo misalignments during chromosome pairing, and thus the sizes of tandem clusters tend to be highly polymorphic, with wide variations between individuals. In fact, the smaller clusters of such sequences can be used to characterize individual genomes in the technique of "DNA fingerprinting" (see *Molecular Biology 1.4.14 Minisatellites are useful for genetic mapping*).

The buoyant density of a duplex DNA depends on its G·C content according to the empirical formula

$$\rho = 1.660 + 0.00098 (\%G\cdot C) \text{ g}\cdot\text{cm}^{-3}$$

Buoyant density usually is determined by centrifuging DNA through a **density gradient** of CsCl. The DNA forms a band at the position corresponding to its own density. Fractions of DNA differing in G·C content by >5% can usually be separated on a density gradient.

When eukaryotic DNA is centrifuged on a density gradient, two types of material may be distinguished:

- Most of the genome forms a continuum of fragments that appear as a rather broad peak centered on the buoyant density corresponding to the average G·C content of the genome. This is called the main band.
- Sometimes an additional, smaller peak (or peaks) is seen at a different value. This material is the satellite DNA.

Satellites are present in many eukaryotic genomes. They may be either heavier or lighter than the main band; but it is uncommon for them to represent >5% of the total DNA. A clear example is provided by mouse DNA, shown in **Figure 4.19**. The graph is a quantitative scan of the bands formed when mouse DNA is centrifuged through a CsCl density gradient. The main band contains 92% of the genome and is centered on a buoyant density of 1.701 g·cm<sup>-3</sup> (corresponding to its average G·C of 42%, typical for a mammal). The smaller peak represents 8% of the genome and has a distinct buoyant density of 1.690 g·cm<sup>-3</sup>. It contains the mouse satellite DNA, whose G·C content (30%) is much lower than any other part of the genome.

**Figure 4.19** Mouse DNA is separated into a main band and a satellite by centrifugation through a density gradient of CsCl.

The behavior of satellite DNA on density gradients is often anomalous. When the actual base composition of a satellite is determined, it is different from the prediction based on its buoyant density. The reason is that  $\rho$  is a function not just of base composition, but of the constitution in terms of nearest neighbor pairs. For simple sequences, these are likely to deviate from the random pairwise relationships needed to obey the equation for buoyant density. Also, satellite DNA may be methylated, which changes its density.

Often most of the highly repetitive DNA of a genome can be isolated in the form of satellites. When a highly repetitive DNA component does not separate as a satellite, on isolation its properties often prove to be similar to those of satellite DNA. That is to say that it consists of multiple tandem repeats with anomalous centrifugation. Material isolated in this manner is sometimes referred to as a **cryptic satellite**. Together the cryptic and apparent satellites usually account for all the large tandemly repeated blocks of highly repetitive DNA. When a genome has more than one type of highly repetitive DNA, each exists in its own satellite block (although sometimes different blocks are adjacent).

Where in the genome are the blocks of highly repetitive DNA located? An extension of nucleic acid hybridization techniques allows the location of satellite sequences to be determined directly in the chromosome complement. In the technique of ***in situ* hybridization**, the chromosomal DNA is denatured by treating cells that have been squashed on a cover slip. Then a solution containing a radioactively labeled DNA or RNA probe is added. The probe hybridizes with its complements in the denatured genome. The location of the sites of hybridization can be determined by autoradiography (see **Figure 19.19**).

Satellite DNAs are found in regions of **heterochromatin**. Heterochromatin is the term used to describe regions of chromosomes that are permanently tightly coiled up and inert, in contrast with the **euchromatin** that represents most of the genome (see *Molecular Biology 5.19.7 Chromatin is divided into euchromatin and heterochromatin*). Heterochromatin is commonly found at centromeres (the regions

where the kinetochores are formed at mitosis and meiosis for controlling chromosome movement). The centromeric location of satellite DNA suggests that it has some structural function in the chromosome. This function could be connected with the process of chromosome segregation.

An example of the localization of satellite DNA for the mouse chromosomal complement is shown in **Figure 4.20**. In this case, one end of each chromosome is labeled, because this is where the centromeres are located in *M. musculus* chromosomes.

**Figure 4.20** Cytological hybridization shows that mouse satellite DNA is located at the centromeres. Photograph kindly provided by Mary Lou Pardue and Joe Gall.

## CLUSTERS AND REPEATS

### 1.4.12 Arthropod satellites have very short identical repeats

#### Key Terms

**Heavy strands** and light strands of a DNA duplex refer to the density differences that result when there is an asymmetry between base representation in the two strands such that one strand is rich in T and G bases and the other is rich in C and A bases. This occurs in some satellite and mitochondrial DNAs.

#### Key Concepts

- The repeating units of arthropod satellite DNAs are only a few nucleotides long. Most of the copies of the sequence are identical.

In the arthropods, as typified by insects and crabs, each satellite DNA appears to be rather homogeneous. Usually, a single very short repeating unit accounts for >90% of the satellite. This makes it relatively straightforward to determine the sequence.

*Drosophila virilis* has three major satellites and also a cryptic satellite, together representing >40% of the genome. The sequences of the satellites are summarized in **Figure 4.21**. The three major satellites have closely related sequences. A single base substitution is sufficient to generate either satellite II or III from the sequence of satellite I.

<i>D. virilis</i> has four related satellites			
Satellite	Predominant Sequence	Total Length	Genome Proportion
I	ACAAACT TGTTTGA	$1.1 \times 10^7$	25%
II	ATAAACT TATTTGA	$3.6 \times 10^6$	8%
III	ACAAATT TGTTTAA	$3.6 \times 10^6$	8%
Cryptic	AATATAG TTATATC		

**Figure 4.21** Satellite DNAs of *D. virilis* are related. More than 95% of each satellite consists of a tandem repetition of the predominant sequence.

The satellite I sequence is present in other species of *Drosophila* related to *virilis*, and so may have preceded speciation. The sequences of satellites II and III seem to be specific to *D. virilis*, and so may have evolved from satellite I after speciation.

The main feature of these satellites is their very short repeating unit: only 7 bp. Similar satellites are found in other species. *D. melanogaster* has a variety of

satellites, several of which have very short repeating units (5, 7, 10, or 12 bp). Comparable satellites are found in the crabs.

The close sequence relationship found among the *D. virilis* satellites is not necessarily a feature of other genomes, where the satellites may have unrelated sequences. *Each satellite has arisen by a lateral amplification of a very short sequence.* This sequence may represent a variant of a previously existing satellite (as in *D. virilis*), or could have some other origin.

Satellites are continually generated and lost from genomes. This makes it difficult to ascertain evolutionary relationships, since a current satellite could have evolved from some previous satellite that has since been lost. The important feature of these satellites is that *they represent very long stretches of DNA of very low sequence complexity, within which constancy of sequence can be maintained*

One feature of many of these satellites is a pronounced asymmetry in the orientation of base pairs on the two strands. In the example of the *D. virilis* satellites shown in **Figure 4.20**, in each of the major satellites one of the strands is much richer in T and G bases. This increases its buoyant density, so that upon denaturation this **heavy strand** (H) can be separated from the complementary light strand (L). This can be useful in sequencing the satellite.

## CLUSTERS AND REPEATS

### 1.4.13 Mammalian satellites consist of hierarchical repeats

---

#### Key Concepts

- Mouse satellite DNA has evolved by duplication and mutation of a short repeating unit to give a basic repeating unit of 234 bp in which the original half, quarter, and eighth repeats can be recognized.

---

In the mammals, as typified by various rodents, the sequences comprising each satellite show appreciable divergence between tandem repeats. Common short sequences can be recognized by their preponderance among the oligonucleotide fragments released by chemical or enzymatic treatment. However, the predominant short sequence usually accounts for only a small minority of the copies. The other short sequences are related to the predominant sequence by a variety of substitutions, deletions, and insertions.

But a series of these variants of the short unit can constitute a longer repeating unit that is itself repeated in tandem with some variation. So mammalian satellite DNAs are constructed from a hierarchy of repeating units. These longer repeating units constitute the sequences that renature in reassociation analysis. They can also be recognized by digestion with restriction enzymes.

When any satellite DNA is digested with an enzyme that has a recognition site in its repeating unit, one fragment will be obtained for every repeating unit in which the site occurs. In fact, when the DNA of a eukaryotic genome is digested with a restriction enzyme, most of it gives a general smear, due to the random distribution of cleavage sites. But satellite DNA generates sharp bands, because a large number of fragments of identical or almost identical size are created by cleavage at restriction sites that lie a regular distance apart.

Determining the sequence of satellite DNA can be difficult. Using the discrete bands generated by restriction cleavage, we can attempt to obtain a sequence directly. However, if there is appreciable divergence between individual repeating units, different nucleotides will be present at the same position in different repeats, so the sequencing gels will be obscure. If the divergence is not too great – say, within ~2% – it may be possible to determine an average repeating sequence.

Individual segments of the satellite can be inserted into plasmids for cloning. A difficulty is that the satellite sequences tend to be excised from the chimeric plasmid by recombination in the bacterial host. However, when the cloning succeeds, it is possible to determine the sequence of the cloned segment unambiguously. While this gives the actual sequence of a repeating unit or units, we should need to have many individual such sequences to reconstruct the type of divergence typical of the satellite as a whole.

By either sequencing approach, the information we can gain is limited to the distance that can be analyzed on one set of sequence gels. The repetition of divergent tandem copies makes it impossible to reconstruct longer sequences by obtaining overlaps between individual restriction fragments.

The satellite DNA of the mouse *M. musculus* is cleaved by the enzyme EcoRII into a series of bands, including a predominant monomeric fragment of 234 bp. This sequence must be repeated with few variations throughout the 60-70% of the satellite that is cleaved into the monomeric band. We may analyze this sequence in terms of its successively smaller constituent repeating units.

**Figure 4.22** depicts the sequence in terms of two half-repeats. By writing the 234 bp sequence so that the first 117 bp are aligned with the second 117 bp, we see that the two halves are quite well related. They differ at 22 positions, corresponding to 19% divergence. This means that the current 234 bp repeating unit must have been generated at some time in the past by duplicating a 117 bp repeating unit, after which differences accumulated between the duplicates.

**Figure 4.22** The repeating unit of mouse satellite DNA contains two half-repeats, which are aligned to show the identities (in red).

Within the 117 bp unit, we can recognize two further subunits. Each of these is a quarter-repeat relative to the whole satellite. The four quarter-repeats are aligned in **Figure 4.23**. The upper two lines represent the first half-repeat of **Figure 4.22**; the lower two lines represent the second half-repeat. We see that the divergence between the four quarter-repeats has increased to 23 out of 58 positions, or 40%. The first three quarter-repeats are somewhat better related, and a large proportion of the divergence is due to changes in the fourth quarter-repeat.

**Figure 4.23** The alignment of quarter-repeats identifies homologies between the first and second half of each half-repeat. Positions that are the same in all 4 quarter-repeats are shown in color; identities that extend only through 3 quarter-repeats are indicated by grey letters in the pink area.

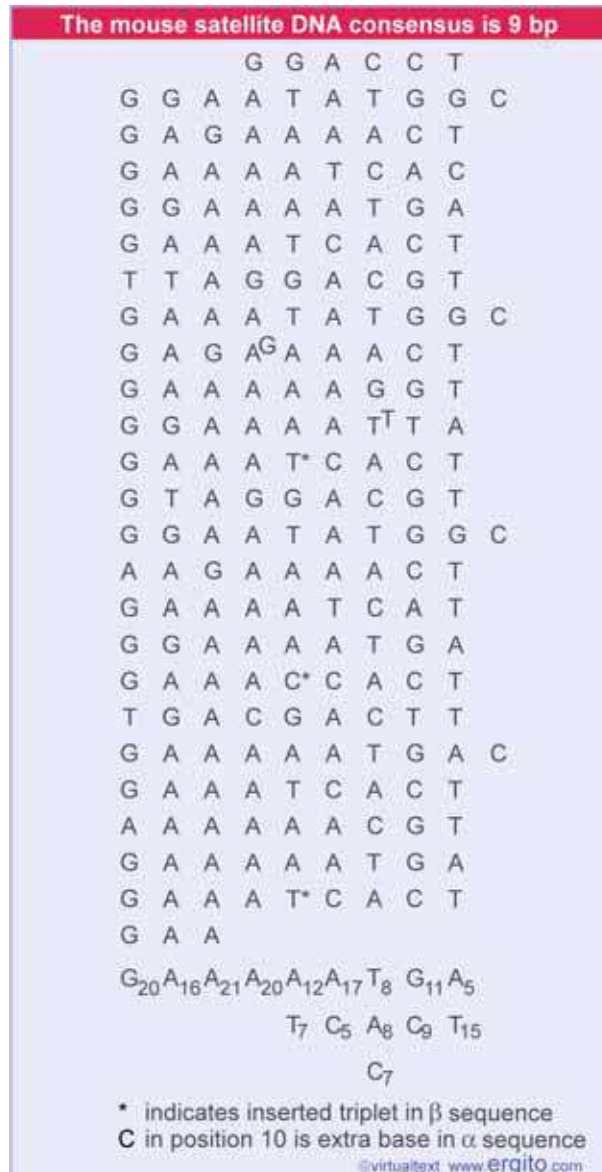

Looking within the quarter-repeats, we find that each consists of two related subunits (one-eighth-repeats), shown as the  $\alpha$  and  $\beta$  sequences in **Figure 4.24**. The  $\alpha$  sequences all have an insertion of a C, and the  $\beta$  sequences all have an insertion of a trinucleotide, relative to a common consensus sequence. This suggests that the quarter-repeat originated by the duplication of a sequence like the consensus sequence, after which changes occurred to generate the components we now see as  $\alpha$  and  $\beta$ . Further changes then took place between tandemly repeated  $\alpha$   $\beta$  sequences to generate the individual quarter- and half-repeats that exist today. Among the one-eighth-repeats, the present divergence is  $19/31 = 61\%$ .

**Figure 4.24** The alignment of eighth-repeats shows that each quarter-repeat consists of an  $\alpha$  and a  $\beta$  half. The consensus sequence gives the most common base at each position. The "ancestral" sequence shows a sequence very closely related to the consensus sequence, which could have been the predecessor to the  $\alpha$  and  $\beta$  units. (The satellite sequence is continuous, so that for the purposes of deducing the consensus sequence, we can treat it as a circular permutation, as indicated by joining the last GAA triplet to the first 6 bp.)

The consensus sequence is analyzed directly in **Figure 4.25**, which demonstrates that the current satellite sequence can be treated as derivatives of a 9 bp sequence. We can recognize three variants of this sequence in the satellite, as indicated at the bottom of **Figure 4.25**. If in one of the repeats we take the next most frequent base at two positions instead of the most frequent, we obtain three well-related 9 bp sequences.

**Figure 4.25** The existence of an overall consensus sequence is shown by writing the satellite sequence in terms of a 9 bp repeat.

G A A A A A C G T

G A A A A A T G A

G A A A A A A C T

The origin of the satellite could well lie in an amplification of one of these three nonamers. The overall consensus sequence of the present satellite is  $G A A A A A^{AG}_{TC} T$ , which is effectively an amalgam of the three 9 bp repeats.

The average sequence of the monomeric fragment of the mouse satellite DNA explains its properties. The longest repeating unit of 234 bp is identified by the restriction cleavage. The unit of reassociation between single strands of denatured satellite DNA is probably the 117 bp half-repeat, because the 234 bp fragments can anneal both in register and in half-register (in the latter case, the first half-repeat of one strand renatures with the second half-repeat of the other).

So far, we have treated the present satellite as though it consisted of identical copies of the 234 bp repeating unit. Although this unit accounts for the majority of the satellite, variants of it also are present. Some of them are scattered at random throughout the satellite; others are clustered.

The existence of variants is implied by our description of the starting material for the sequence analysis as the "monomeric" fragment. When the satellite is digested by an enzyme that has one cleavage site in the 234 bp sequence, it also generates dimers, trimers, and tetramers relative to the 234 bp length. They arise when a repeating unit has lost the enzyme cleavage site as the result of mutation.

The monomeric 234 bp unit is generated when two adjacent repeats each have the recognition site. A dimer occurs when one unit has lost the site, a trimer is generated when two adjacent units have lost the site, and so on. With some restriction enzymes, most of the satellite is cleaved into a member of this repeating series, as shown in the example of **Figure 4.26**. The declining number of dimers, trimers, etc. shows that there is a random distribution of the repeats in which the enzyme's recognition site has been eliminated by mutation.

**Figure 4.26** Digestion of mouse satellite DNA with the restriction enzyme EcoRII identifies a series of repeating units (1, 2, 3) that are multimers of 234 bp and also a minor series ( $\frac{1}{2}$ ,  $1\frac{1}{2}$ ,  $2\frac{1}{2}$ ) that includes half-repeats (see text later). The band at the far left is a fraction resistant to digestion.

Other restriction enzymes show a different type of behavior with the satellite DNA. They continue to generate the same series of bands. But they cleave only a small proportion of the DNA, say 5-10%. This implies that a certain region of the satellite

contains a concentration of the repeating units with this particular restriction site. Presumably the series of repeats in this domain all are derived from an ancestral variant that possessed this recognition site (although in the usual way, some members since have lost it by mutation).

A satellite DNA suffers unequal recombination. This has additional consequences when there is internal repetition in the repeating unit. Let us return to our cluster consisting of "ab" repeats. Suppose that the "a" and "b" components of the repeating unit are themselves sufficiently well related to pair. Then the two clusters can align in *half-register*, with the "a" sequence of one aligned with the "b" sequence of the other. How frequently this occurs will depend on the closeness of the relationship between the two halves of the repeating unit. In mouse satellite DNA, reassociation between the denatured satellite DNA strands *in vitro* commonly occurs in the half-register.

When a recombination event occurs out of register, it changes the length of the repeating units that are involved in the reaction.

In the upper recombinant cluster, an "ab" unit has been replaced by an "aab" unit. In the lower cluster, the "ab" unit has been replaced by a "b" unit.

This type of event explains a feature of the restriction digest of mouse satellite DNA. **Figure 4.25** shows a fainter series of bands at lengths of  $\frac{1}{2}$ ,  $1\frac{1}{2}$ ,  $2\frac{1}{2}$ , and  $3\frac{1}{2}$  repeating units, in addition to the stronger integral length repeats. Suppose that in the preceding example, "ab" represents the 234 bp repeat of mouse satellite DNA, generated by cleavage at a site in the "b" segment. The "a" and "b" segments correspond to the 117 bp half-repeats.

Then in the upper recombinant cluster, the "aab" unit generates a fragment of  $1\frac{1}{2}$  times the usual repeating length. And in the lower recombinant cluster, the "b" unit generates a fragment of half of the usual length. (The multiple fragments in the half-repeat series are generated in the same way as longer fragments in the integral series, when some repeating units have lost the restriction site by mutation.)

Turning the argument the other way around, the identification of the half-repeat series on the gel shows that the 234 bp repeating unit consists of two half-repeats well enough related to pair sometimes for recombination. Also visible in **Figure 4.26** are some rather faint bands corresponding to  $\frac{1}{4}$ - and  $\frac{3}{4}$ -spacings. These will be

generated in the same way as the  $\frac{1}{2}$ -spacings, when recombination occurs between clusters aligned in a quarter-register. The decreased relationship between quarter-repeats compared with half-repeats explains the reduction in frequency of the  $\frac{1}{4}$ - and  $\frac{3}{4}$ -bands compared with the  $\frac{1}{2}$ -bands.

## CLUSTERS AND REPEATS

### 1.4.14 Minisatellites are useful for genetic mapping

---

#### Key Terms

**Microsatellite** DNAs consist of repetitions of extremely short (typically <10 bp) units.

**Minisatellite** DNAs consist of ~10 copies of a short repeating sequence. the length of the repeating unit is measured in 10s of base pairs. The number of repeats varies between individual genomes.

**VNTR** (variable number tandem repeat) regions describe very short repeated sequences, including microsatellites and minisatellites.

**DNA fingerprinting** analyzes the differences between individuals of the fragments generated by using restriction enzymes to cleave regions that contain short repeated sequences. Because these are unique to every individual, the presence of a particular subset in any two individuals can be used to define their common inheritance (e.g. a parent-child relationship).

#### Key Concepts

- The variation between microsatellites or minisatellites in individual genomes can be used to identify heredity unequivocally by showing that 50% of the bands in an individual are derived from a particular parent.

---

Sequences that resemble satellites in consisting of tandem repeats of a short unit, but that overall are much shorter, consisting of (for example) from 5-50 repeats, are common in mammalian genomes. They were discovered by chance as fragments whose size is extremely variable in genomic libraries of human DNA. The variability is seen when a population contains fragments of many different sizes that represent the same genomic region; when individuals are examined, it turns out that there is extensive polymorphism, and that many different alleles can be found (416).

The name **microsatellite** is usually used when the length of the repeating unit is <10 bp, and the name **minisatellite** is used when the length of the repeating unit is ~10-100 bp, but the terminology is not precisely defined. These types of sequences are also called **VNTR** (variable number tandem repeat) regions.

The cause of the variation between individual genomes at microsatellites or minisatellites is that individual alleles have different numbers of the repeating unit. For example, one minisatellite has a repeat length of 64 bp, and is found in the population with the following distribution:

7% 18 repeats

11% 16 repeats

43% 14 repeats

36% 13 repeats

4% 10 repeats

The rate of genetic exchange at minisatellite sequences is high,  $\sim 10^{-4}$  per kb of DNA. (The frequency of exchanges per actual locus is assumed to be proportional to the length of the minisatellite.) This rate is  $\sim 10\times$  greater than the rate of homologous recombination at meiosis, that is, in any random DNA sequence.

The high variability of minisatellites makes them especially useful for genomic mapping, because there is a high probability that individuals will vary in their alleles at such a locus. An example of mapping by minisatellites is illustrated in **Figure 4.27**. This shows an extreme case in which two individuals both are heterozygous at a minisatellite locus, and in fact all four alleles are different. All progeny gain one allele from each parent in the usual way, and it is possible unambiguously to determine the source of every allele in the progeny. In the terminology of human genetics, the meioses described in this figure are highly informative, because of the variation between alleles.

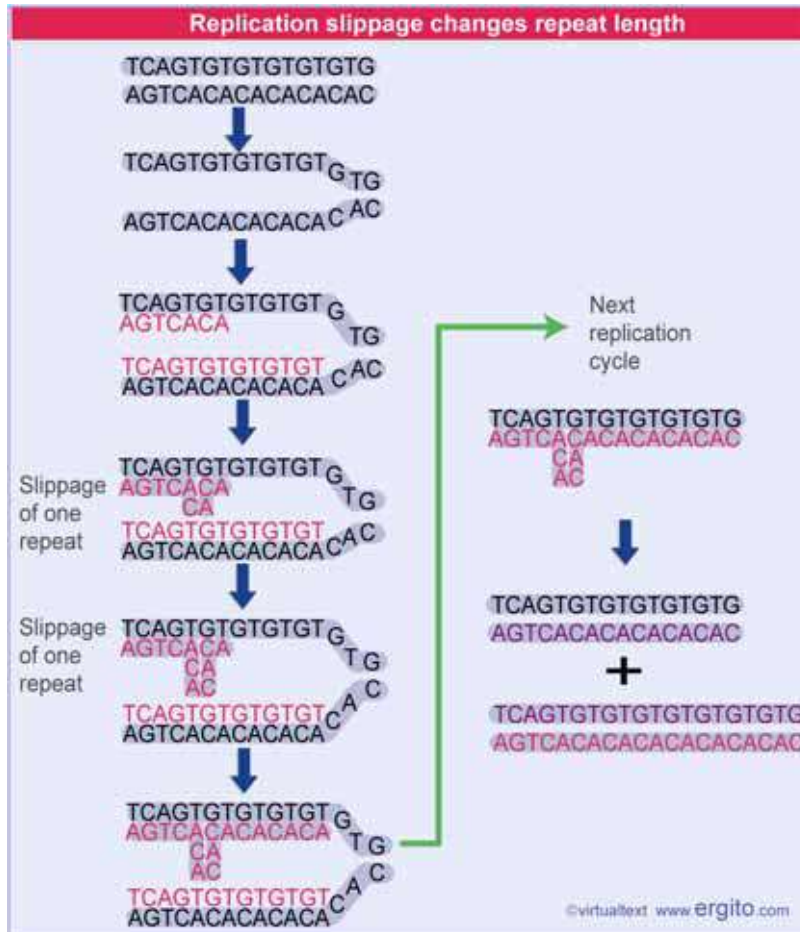

**Figure 4.27** Alleles may differ in the number of repeats at a minisatellite locus, so that cleavage on either side generates restriction fragments that differ in length. By using a minisatellite with alleles that differ between parents, the pattern of inheritance can be followed.

One family of minisatellites in the human genome share a common "core" sequence. The core is a G#C-rich sequence of 10-15 bp, showing an asymmetry of purine/pyrimidine distribution on the two strands. Each individual minisatellite has a variant of the core sequence, but ~1000 minisatellites can be detected on Southern blot by a probe consisting of the core sequence.

Consider the situation shown in **Figure 4.27**, but multiplied 1000×. The effect of the variation at individual loci is to create a unique pattern for every individual. This makes it possible to assign heredity unambiguously between parents and progeny, by showing that 50% of the bands in any individual are derived from a particular parent. This is the basis of the technique known as **DNA fingerprinting**.

Both microsatellites and minisatellites are unstable, although for different reasons. Microsatellites undergo intrastrand mispairing, when slippage during replication leads to expansion of the repeat, as shown in **Figure 4.28** (3044). Systems that repair damage to DNA, in particular those that recognize mismatched base pairs, are

important in reversing such changes, as shown by a large increase in frequency when repair genes are inactivated (2255). Because mutations in repair systems are an important contributory factor in the development of cancer, tumor cells often display variations in microsatellite sequences (see *Molecular Biology 6.30.29 Defects in repair systems cause mutations to accumulate in tumors*).

**Figure 4.28** Replication slippage occurs when the daughter strand slips back one repeating unit in pairing with the template strand. Each slippage event adds one repeating unit to the daughter strand. The extra repeats are extruded as a single strand loop. Replication of this daughter strand in the next cycle generates a duplex DNA with an increased number of repeats.

Minisatellites undergo the same sort of unequal crossing-over between repeats that we have discussed for satellites (see **Figure 4.1**). One telling case is that increased variation is associated with a meiotic hotspot (3049). The recombination event is not usually associated with recombination between flanking markers, but has a complex form in which the new mutant allele gains information from both the sister chromatid and the other (homologous) chromosome (3048).

It is not clear at what repeating length the cause of the variation shifts from replication slippage to recombination.

## CLUSTERS AND REPEATS

### 1.4.15 Summary

---

Almost all genes belong to families, defined by the possession of related sequences in the exons of individual members. Families evolve by the duplication of a gene (or genes), followed by divergence between the copies. Some copies suffer inactivating mutations and become pseudogenes that no longer have any function. Pseudogenes also may be generated as DNA copies of the mRNA sequences.

An evolving set of genes may remain together in a cluster or may be dispersed to new locations by chromosomal rearrangement. The organization of existing clusters can sometimes be used to infer the series of events that has occurred. These events act with regard to sequence rather than function, and therefore include pseudogenes as well as active genes.

Mutations accumulate more rapidly in silent sites than in replacement sites (which affect the amino acid sequence). The rate of divergence at replacement sites can be used to establish a clock, calibrated in percent divergence per million years. The clock can then be used to calculate the time of divergence between any two members of the family.

A tandem cluster consists of many copies of a repeating unit that includes the transcribed sequence(s) and a nontranscribed spacer(s). rRNA gene clusters code only for a single rRNA precursor. Maintenance of active genes in clusters depends on mechanisms such as gene conversion or unequal crossing-over that cause mutations to spread through the cluster, so that they become exposed to evolutionary pressure.

Satellite DNA consists of very short sequences repeated many times in tandem. Its distinct centrifugation properties reflect its biased base composition. Satellite DNA is concentrated in centromeric heterochromatin, but its function (if any) is unknown. The individual repeating units of arthropod satellites are identical. Those of mammalian satellites are related, and can be organized into a hierarchy reflecting the evolution of the satellite by the amplification and divergence of randomly chosen sequences.

Unequal crossing-over appears to have been a major determinant of satellite DNA organization. Crossover fixation explains the ability of variants to spread through a cluster.

Minisatellites and microsatellites consist of even shorter repeating sequences than satellites, <10 bp for microsatellites and 10-50 bp for minisatellites. The number of repeating units is usually 5-50. There is high variation in the repeat number between individual genomes. Microsatellite repeat number varies as the result of slippage during replication; the frequency is affected by systems that recognize and repair damage in DNA. Minisatellite repeat number varies as the result of recombination-like events. Variations in repeat number can be used to determine hereditary relationships by the technique known as DNA fingerprinting.

## MESSENGER RNA

### 2.5.1 Introduction

---

#### Key Terms

**Messenger RNA (mRNA)** is the intermediate that represents one strand of a gene coding for protein. Its coding region is related to the protein sequence by the triplet genetic code.

**Transfer RNA (tRNA)** is the intermediate in protein synthesis that interprets the genetic code. Each tRNA can be linked to an amino acid. The tRNA has an anticodon sequence that complementary to a triplet codon representing the amino acid.

**Ribosomal RNA (rRNA)** is a major component of the ribosome. Each of the two subunits of the ribosome has a major rRNA as well as many proteins.

---

RNA is a central player in gene expression. It was first characterized as an intermediate in protein synthesis, but since then many other RNAs have been discovered that play structural or functional roles at other stages of gene expression. The involvement of RNA in many functions concerned with gene expression supports the general view that the entire process may have evolved in an "RNA world" in which RNA was originally the active component in maintaining and expressing genetic information. Many of these functions were subsequently assisted or taken over by proteins, with a consequent increase in versatility and probably efficiency.

As summarized in **Figure 5.1**, three major classes of RNA are directly involved in the production of proteins:

**Figure 5.1** The three types of RNA universally required for gene expression are mRNA (carries the coding sequence), tRNA (provides the amino acid corresponding to each codon), and rRNA (a major component of the ribosome that provides the environment for protein synthesis).

- Messenger RNA (**mRNA**) provides an intermediate that carries the copy of a DNA sequence that represents protein.
- Transfer RNAs (**tRNA**) are small RNAs that are used to provide amino acids corresponding to each particular codon in mRNA.
- Ribosomal RNAs (**rRNA**) are components of the ribosome, a large ribonucleoprotein complex that contains many proteins as well as its RNA components, and which provides the apparatus for actually polymerizing amino acids into a polypeptide chain.

The type of role that RNA plays in each of these cases is distinct. For messenger RNA, its sequence is the important feature: each nucleotide triplet within the coding region of the mRNA represents an amino acid in the corresponding protein. However, the structure of the mRNA, in particular the sequences on either side of the coding region, can play an important role in controlling its activity, and therefore the amount of protein that is produced from it.

In tRNA, we see two of the common themes governing the use of RNA: its three dimensional structure is important; and it has the ability to base pair with another RNA (mRNA). The three dimensional structure is recognized first by an enzyme as providing a target that is appropriate for linkage to a specific amino acid. The linkage creates an aminoacyl-tRNA, which is recognized as the structure that is used for protein synthesis. The specificity with which an aminoacyl-tRNA is used is controlled by base pairing, when a short triplet sequence (the anticodon) pairs with the nucleotide triplet representing its amino acid.

With rRNA, we see another type of activity. One role of RNA is structural, in providing a framework to which ribosomal proteins attach. But it also participates directly in the activities of the ribosome. One of the crucial activities of the ribosome is the ability to catalyze the formation of a peptide bond by which an amino acid is incorporated into protein. This activity resides in one of the rRNAs.

The important thing about this background is that, as we consider the role of RNA in protein synthesis, we have to view it as a component that plays an active role and that can be a target for regulation by either proteins or by other RNAs, and we should remember that the RNAs may have been the basis for the original apparatus. The theme that runs through all of the activities of RNA, in both protein synthesis and elsewhere, is that its functions depend critically upon base pairing, both to form its secondary structure, and to interact specifically with other RNA molecules. The coding function of mRNA is unique, but tRNA and rRNA are examples of a much broader class of noncoding RNAs with a variety of functions in gene expression.

## MESSENGER RNA

### 2.5.2 mRNA is produced by transcription and is translated

---

#### Key Terms

**Transcription** describes synthesis of RNA on a DNA template.

**Translation** is synthesis of protein on the mRNA template.

A **coding region** is a part of the gene that represents a protein sequence.

The **antisense strand (Template strand)** of DNA is complementary to the sense strand, and is the one that acts as the template for synthesis of mRNA.

The **coding strand (Sense strand)** of DNA has the same sequence as the mRNA and is related by the genetic code to the protein sequence that it represents.

#### Key Concepts

- Only one of the two strands of DNA is transcribed into RNA.
- 

Gene expression occurs by a two-stage process.

- **Transcription** generates a single-stranded RNA identical in sequence with one of the strands of the duplex DNA.
- **Translation** converts the nucleotide sequence of mRNA into the sequence of amino acids comprising a protein. The entire length of an mRNA is not translated, but each mRNA contains at least one **coding region** that is related to a protein sequence by the genetic code: each nucleotide triplet (codon) of the coding region represents one amino acid.

Only one strand of a DNA duplex is transcribed into a messenger RNA. We distinguish the two strands of DNA as depicted in **Figure 5.2**:

**Figure 5.2** Transcription generates an RNA which is complementary to the DNA template strand and has the same sequence as the DNA coding strand. Translation reads each triplet of bases into one amino acid. Three turns of the DNA double helix contain 30 bp, which code for 10 amino acids.

- The strand of DNA that directs synthesis of the mRNA via complementary base pairing is called the **template strand** or **antisense strand**. (*Antisense* is used as a general term to describe a sequence of DNA or RNA that is complementary to mRNA.)
- The other DNA strand bears the *same* sequence as the mRNA (except for possessing T instead of U), and is called the **coding strand** or **sense strand**.

In this chapter we discuss mRNA and its use as a template for protein synthesis. In *Molecular Biology 2.6 Protein synthesis* we discuss the process by which a protein is synthesized. In *Molecular Biology 2.7 Using the genetic code* we discuss the way the genetic code is used to interpret the meaning of a sequence of mRNA. And in *Molecular Biology 2.8 Protein localization* we turn to the question of how a protein finds its proper location in the cell when or after it is synthesized.

---

**MESSENGER RNA****2.5.3 Transfer RNA forms a cloverleaf**

---

**Key Terms**

**Transfer RNA (tRNA)** is the intermediate in protein synthesis that interprets the genetic code. Each tRNA can be linked to an amino acid. The tRNA has an anticodon sequence that complementary to a triplet codon representing the amino acid.

The **anticodon** is a trinucleotide sequence in tRNA which is complementary to the codon in mRNA and enables the tRNA to place the appropriate amino acid in response to the codon.

The **cloverleaf** describes the structure of tRNA drawn in two dimensions, forming four distinct arm-loops.

A **stem** is the base-paired segment of a hairpin structure in RNA.

A **loop** is a single-stranded region at the end of a hairpin in RNA (or single-stranded DNA); it corresponds to the sequence between inverted repeats in duplex DNA.

An **arm** of tRNA is one of the four (or in some cases five) stem-loop structures that make up the secondary structure.

The **acceptor arm** of tRNA is a short duplex that terminates in the CCA sequence to which an amino acid is linked.

The **anticodon arm** of tRNA is a stem loop structure that exposes the anticodon triplet at one end.

The **D arm** of tRNA has a high content of the base dihydrouridine.

The **extra arm** of tRNA lies between the T $\psi$ C and anticodon arms. It is the most variable in length in tRNA, from 3-21 bases. tRNAs are called class 1 if they lack it, and class 2 if they have it.

**Invariant** base positions in tRNA have the same nucleotide in virtually all (>95%) of tRNAs.

**Conserved** positions are defined when many examples of a particular nucleic acid or protein are compared and the same individual bases or amino acids are always found at particular locations.

A **semiconserved (Semiinvariant)** position is one where comparison of many individual sequences finds the same type of base (pyrimidine or purine) always present.

An **aminoacyl-tRNA** is a tRNA linked to an amino acid. The COOH group of the amino acid is linked to the 3' - or 2' -OH group of the terminal base of the tRNA.

**Aminoacyl-tRNA synthetases** are enzymes responsible for covalently linking amino acids to the 2' - or 3' -OH position of tRNA.

**Key Concepts**

- A tRNA has a sequence of 74-95 bases that folds into a clover-leaf secondary

structure with four constant arms (and an additional arm in the longer tRNAs).

- tRNA is charged to form aminoacyl-tRNA by forming an ester link from the 2' or 3' OH group of the adenylic acid at the end of the acceptor arm to the COOH group of the amino acid.
  - The sequence of the anticodon is solely responsible for the specificity of the aminoacyl-tRNA.
- 

Messenger RNA can be distinguished from the apparatus responsible for its translation by the use of *in vitro* cell-free systems to synthesize proteins. A *protein-synthesizing system from one cell type can translate the mRNA from another, demonstrating that both the genetic code and the translation apparatus are universal.*

Each nucleotide triplet in the mRNA represents an amino acid. The incongruity of structure between trinucleotide and amino acid immediately raises the question of how each codon is matched to its particular amino acid. The "adapter" is **transfer RNA (tRNA)**. A tRNA has two crucial properties:

- It represents a single amino acid, to which it is *covalently linked*.
- It contains a trinucleotide sequence, the **anticodon**, which is *complementary to the codon representing its amino acid*. The anticodon enables the tRNA to recognize the codon via complementary base pairing (417; 446).

All tRNAs have common secondary and tertiary structures. The tRNA secondary structure can be written in the form of a **cloverleaf**, illustrated in **Figure 5.3**, in which complementary base pairing forms **stems** for single-stranded **loops**. The stem-loop structures are called the **arms** of tRNA. Their sequences include "unusual" bases that are generated by modification of the 4 standard bases after synthesis of the polynucleotide chain (for review see 42).

**Figure 5.3** A tRNA has the dual properties of an adaptor that recognizes both the amino acid and codon. The 3' adenosine is covalently linked to an amino acid. The anticodon base pairs with the codon on mRNA.

The construction of the cloverleaf is illustrated in more detail in **Figure 5.4**. The four major arms are named for their structure or function:

**Figure 5.4** The tRNA cloverleaf has invariant and semi-invariant bases, and a conserved set of base pairing interactions.

- The **acceptor arm** consists of a base-paired stem that ends in an unpaired sequence whose free 2' – or 3' –OH group can be linked to an amino acid.
- The **T ψC arm** is named for the presence of this triplet sequence. ( ψ stands for pseudouridine, a modified base.)
- The **anticodon arm** always contains the anticodon triplet in the center of the loop.
- The **D arm** is named for its content of the base dihydrouridine (another of the modified bases in tRNA).
- The **extra arm** lies between the T ψC and anticodon arms and varies from 3-21 bases.

The numbering system for tRNA illustrates the constancy of the structure. Positions are numbered from 5' to 3' according to the most common tRNA structure, which has 76 residues. The overall range of tRNA lengths is 74-95 bases. The variation in length is caused by differences in the D arm and extra arm (for more details see *Molecular Biology Supplement 32.8 tRNA sequences*).

The base pairing that maintains the secondary structure is shown in **Figure 5.4**. Within a given tRNA, most of the base pairings are conventional partnerships of A·U and G·C, but occasional G·U, G·ψ, or A·ψ pairs are found. The additional types of base pairs are less stable than the regular pairs, but still allow a double-helical structure to form in RNA.

When the sequences of tRNAs are compared, the bases found at some positions are **invariant** (or **conserved**); almost always a particular base is found at the position (see *Molecular Biology Supplement 32.8 tRNA sequences*). Some positions are described as **semiinvariant** (or **semiconserved**) because they are restricted to one type of base (purine versus pyrimidine), but either base of that type may be present.

When a tRNA is *charged* with the amino acid corresponding to its anticodon, it is called **aminoacyl-tRNA**. The amino acid is linked by an ester bond from its carboxyl group to the 2' or 3' hydroxyl group of the ribose of the 3' terminal base of the tRNA (which is always adenine). The process of charging a tRNA is catalyzed by a specific enzyme, **aminoacyl-tRNA synthetase**. There are (at least) 20 aminoacyl-tRNA synthetases. Each recognizes a single amino acid and all the tRNAs on to which it can legitimately be placed.

There is at least one tRNA (but usually more) for each amino acid. A tRNA is named by using the three letter abbreviation for the amino acid as a superscript. If there is more than one tRNA for the same amino acid, subscript numerals are used to distinguish them. So two tRNAs for tyrosine would be described as tRNA<sup>Tyr</sup><sub>1</sub> and tRNA<sup>Tyr</sup><sub>2</sub>. A tRNA carrying an amino acid – that is, an aminoacyl-tRNA – is indicated by a prefix that identifies the amino acid. Ala-tRNA describes tRNA<sup>Ala</sup> carrying its amino acid.

Does the anticodon sequence alone allow aminoacyl-tRNA to recognize the correct codon? A classic experiment to test this question is illustrated in **Figure 5.5**. Reductive desulfuration converts the amino acid of cysteinyl-tRNA into alanine, generating alanyl-tRNA<sup>Cys</sup>. The tRNA has an anticodon that responds to the codon UGU. Modification of the amino acid does not influence the specificity of the anticodon-codon interaction, so the alanine residue is incorporated into protein in place of cysteine. *Once a tRNA has been charged, the amino acid plays no further role in its specificity, which is determined exclusively by the anticodon* (421).

**Figure 5.5** The meaning of tRNA is determined by its anticodon and not by its amino acid.

## MESSENGER RNA

### 2.5.4 The acceptor stem and anticodon are at ends of the tertiary structure

---

#### Key Concepts

- The clover-leaf forms an L-shaped tertiary structure with the acceptor arm at one end and the anticodon arm at the other end.
- 

The secondary structure of each tRNA folds into a compact L-shaped tertiary structure in which the 3' end that binds the amino acid is distant from the anticodon that binds the mRNA. All tRNAs have the same general tertiary structure, although they are distinguished by individual variations.

The base paired double-helical stems of the secondary structure are maintained in the tertiary structure, but their arrangement in three dimensions essentially creates two double helices at right angles to each other, as illustrated in **Figure 5.6**. The acceptor stem and the T  $\psi$ C stem form one continuous double helix with a single gap; the D stem and anticodon stem form another continuous double helix, also with a gap. The region between the double helices, where the turn in the L-shape is made, contains the T  $\psi$ C loop and the D loop. So the amino acid resides at the extremity of one arm of the L-shape, and the anticodon loop forms the other end.

**Figure 5.6** Transfer RNA folds into a compact L-shaped tertiary structure with the amino acid at one end and the anticodon at the other end.

The tertiary structure is created by hydrogen bonding, mostly involving bases that are unpaired in the secondary structure. Many of the invariant and semiinvariant bases are involved in these H-bonds, which explains their conservation. Not every one of these interactions is universal, but probably they identify the *general* pattern for establishing tRNA structure.

A molecular model of the structure of yeast tRNA<sup>Phe</sup> is shown in **Figure 5.7**. The left view corresponds with the bottom panel in **Figure 5.6**. Differences in the structure are found in other tRNAs, thus accommodating the dilemma that all tRNAs must have a similar shape, yet it must be possible to recognize differences between them. For example, in tRNA<sup>Asp</sup>, the angle between the two axes is slightly greater, so the molecule has a slightly more open conformation.

**Figure 5.7** A space-filling model shows that tRNA<sup>Phe</sup> tertiary structure is compact. The two views of tRNA are rotated by 90°. Photograph kindly provided by S. H. Kim.

The structure suggests a general conclusion about the function of tRNA. *Its sites for exercising particular functions are maximally separated.* The amino acid is as far distant from the anticodon as possible, which is consistent with their roles in protein synthesis.

This content is available online at <http://www.ergito.com/main.jsp?bcs=MBIO.2.5.4>

---

**MESSENGER RNA****2.5.5 Messenger RNA is translated by ribosomes**

---

**Key Terms**

The **ribosome** is a large assembly of RNA and proteins that synthesizes proteins under direction from an mRNA template. Bacterial ribosomes sediment at 70S, eukaryotic ribosomes at 80S. A ribosome can be dissociated into two subunits.

A **ribonucleoprotein** is a complex of RNA with proteins.

The **large subunit** of the ribosome (50S in bacteria, 60S in eukaryotes) has the peptidyl transferase active site that synthesizes the peptide bond.

The **small subunit** of the ribosome (30S in bacteria, 40S in eukaryotes) binds the mRNA.

**Key Concepts**

- Ribosomes are characterized by their rate of sedimentation (70S for bacterial ribosomes and 80S for eukaryotic ribosomes).
- A ribosome consists of a large subunit (50S or 60S for bacteria and eukaryotes) and a small subunit (30S or 40S).
- The ribosome provides the environment in which aminoacyl-tRNAs add amino acids to the growing polypeptide chain in response to the corresponding triplet codons.
- A ribosome moves along an mRNA from 5' to 3'.

---

Translation of an mRNA into a polypeptide chain is catalyzed by the **ribosome**. Ribosomes are traditionally described in terms of their (approximate) rate of sedimentation (measured in Svedbergs, in which a higher S value indicates a greater rate of sedimentation and a larger mass). Bacterial ribosomes generally sediment at ~70S. The ribosomes of the cytoplasm of higher eukaryotic cells are larger, usually sedimenting at ~80S.

The ribosome is a compact **ribonucleoprotein** particle consisting of two subunits. Each subunit has an RNA component, including one very large RNA molecule, and many proteins. The relationship between a ribosome and its subunits is depicted in **Figure 5.8**. The two subunits dissociate *in vitro* when the concentration of  $Mg^{2+}$  ions is reduced. In each case, the **large subunit** is about twice the mass of the **small subunit**. Bacterial (70S) ribosomes have subunits that sediment at 50S and 30S. The subunits of eukaryotic cytoplasmic (80S) ribosomes sediment at 60S and 40S. The two subunits work together as part of the complete ribosome, but each undertakes distinct reactions in protein synthesis.

**Figure 5.8** A ribosome consists of two subunits.

All the ribosomes of a given cell compartment are identical. *They undertake the synthesis of different proteins by associating with the different mRNAs that provide the actual coding sequences.*

The ribosome provides the environment that controls the recognition between a codon of mRNA and the anticodon of tRNA. Reading the genetic code as a series of adjacent triplets, protein synthesis proceeds from the start of a coding region to the end. *A protein is assembled by the sequential addition of amino acids in the direction from the N-terminus to the C-terminus as a ribosome moves along the mRNA (419).*

A ribosome begins translation at the 5' end of a coding region; it translates each triplet codon into an amino acid as it proceeds towards the 3' end. At each codon, the appropriate aminoacyl-tRNA associates with the ribosome, donating its amino acid to the polypeptide chain. At any given moment, the ribosome can accommodate the two aminoacyl-tRNAs corresponding to successive codons, making it possible for a peptide bond to form between the two corresponding amino acids. At each step, the growing polypeptide chain becomes longer by one amino acid.

**MESSENGER RNA****2.5.6 Many ribosomes bind to one mRNA****Key Terms**

A **polyribosome (Polysome)** is an mRNA that is simultaneously being translated by several ribosomes.

A **nascent protein** has not yet completed its synthesis; the polypeptide chain is still attached to the ribosome via a tRNA.

**Key Concepts**

- An mRNA is simultaneously translated by several ribosomes. Each ribosome is at a different stage of progression along the mRNA.

When active ribosomes are isolated in the form of the fraction associated with newly synthesized proteins, they are found in the form of a complex consisting of an mRNA associated with several ribosomes. This is the **polyribosome** or **polysome**. The 30S subunit of each ribosome is associated with the mRNA, and the 50S subunit carries the newly synthesized protein. The tRNA spans both subunits.

Each ribosome in the polysome independently synthesizes a single polypeptide during its traverse of the messenger sequence. Essentially the mRNA is pulled through the ribosome, and each triplet nucleotide is translated into an amino acid. So the mRNA has a series of ribosomes that carry increasing lengths of the protein product, moving from the 5' to the 3' end, as illustrated in **Figure 5.9**. A polypeptide chain in the process of synthesis is sometimes called a **nascent protein**.

**Figure 5.9** A polyribosome consists of an mRNA being translated simultaneously by several ribosomes moving in the direction from 5' -3'. Each ribosome has two tRNA molecules, one carrying the nascent protein, the second carrying the next amino acid to be added.

Roughly the most recent 30-35 amino acids added to a growing polypeptide chain are protected from the environment by the structure of the ribosome. Probably all of the preceding part of the polypeptide protrudes and is free to start folding into its proper conformation. So proteins can display parts of the mature conformation even before synthesis has been completed.

A classic characterization of polysomes is shown in the electron micrograph of **Figure 5.10**. Globin protein is synthesized by a set of 5 ribosomes attached to each mRNA (pentasomes). The ribosomes appear as squashed spherical objects of ~7 nm (70 Å) in diameter, connected by a thread of mRNA. The ribosomes are located at various positions along the messenger. Those at one end have just started protein synthesis; those at the other end are about to complete production of a polypeptide chain (422).

**Figure 5.10** Protein synthesis occurs on polysomes.  
Photograph kindly provided by Alex Rich.

The size of the polysome depends on several variables. In bacteria, it is very large, with tens of ribosomes simultaneously engaged in translation. Partly the size is due to the length of the mRNA (which usually codes for several proteins); partly it is due to the high efficiency with which the ribosomes attach to the mRNA.

Polysomes in the cytoplasm of a eukaryotic cell are likely to be smaller than those in bacteria; again, their size is a function both of the length of the mRNA (usually representing only a single protein in eukaryotes) and of the characteristic frequency with which ribosomes attach. An average eukaryotic mRNA probably has ~8 ribosomes attached at any one time.

**Figure 5.11** illustrates the life cycle of the ribosome. Ribosomes are drawn from a pool (actually the pool consists of ribosomal subunits), used to translate an mRNA, and then return to the pool for further cycles. The number of ribosomes on each mRNA molecule synthesizing a particular protein is not precisely determined, in either bacteria or eukaryotes, but is a matter of statistical fluctuation, determined by the variables of mRNA size and efficiency.

**Figure 5.11** Messenger RNA is translated by ribosomes that cycle through a pool.

An overall view of the attention devoted to protein synthesis in the intact bacterium is given in **Figure 5.12**. The 20,000 or so ribosomes account for a quarter of the cell mass. There are >3000 copies of each tRNA, and altogether, the tRNA molecules outnumber the ribosomes by almost tenfold; most of them are present as aminoacyl-tRNAs, that is, ready to be used at once in protein synthesis. Because of their instability, it is difficult to calculate the number of mRNA molecules, but a reasonable guess would be ~1500, in varying states of synthesis and decomposition. There are ~600 different types of mRNA in a bacterium. This suggests that there are usually only 2-3 copies of each mRNA per bacterium. On average, each probably codes for ~3 proteins. If there are 1850 different soluble proteins, there must on average be >1000 copies of each protein in a bacterium.

25% of bacterial dry mass is concerned with gene expression				
Component	Dry Cell Mass (%)	Molecules /cell	Different types	Copies of each type
Wall	10	1	1	1
Membrane	10	2	2	1
DNA	1.5	1	1	1
mRNA	1	1,500	600	2-3
tRNA	3	200,000	60	>3,000

**MESSENGER RNA****2.5.7 The life cycle of bacterial messenger RNA**

---

**Key Terms**

**Nascent RNA** is a ribonucleotide chain that is still being synthesized, so that its 3' end is paired with DNA where RNA polymerase is elongating.

**Monocistronic** mRNA codes for one protein.

**Polycistronic mRNA** includes coding regions representing more than one gene.

A **coding region** is a part of the gene that represents a protein sequence.

The **leader** of a protein is a short N-terminal sequence responsible for initiating passage into or through a membrane.

The **leader (5' UTR)** of an mRNA is the nontranslated sequence at the 5' end that precedes the initiation codon.

A **trailer (3' UTR)** is a nontranslated sequence at the 3' end of an mRNA following the termination codon.

The **intercistronic region** is the distance between the termination codon of one gene and the initiation codon of the next gene.

**Key Concepts**

- Transcription and translation occur simultaneously in bacteria, as ribosomes begin translating an mRNA before its synthesis has been completed.
- Bacterial mRNA is unstable and has a half-life of only a few minutes.
- A bacterial mRNA may be polycistronic in having several coding regions that represent different genes.

---

Messenger RNA has the same function in all cells, but there are important differences in the details of the synthesis and structure of prokaryotic and eukaryotic mRNA.

A major difference in the production of mRNA depends on the locations where transcription and translation occur:

- In bacteria, mRNA is transcribed and translated in the single cellular compartment; and the two processes are so closely linked that they occur simultaneously. Since ribosomes attach to bacterial mRNA even before its transcription has been completed, the polysome is likely still to be attached to DNA. Bacterial mRNA usually is unstable, and is therefore translated into proteins for only a few minutes.
- In a eukaryotic cell, synthesis and maturation of mRNA occur exclusively in the nucleus. Only after these events are completed is the mRNA exported to the

cytoplasm, where it is translated by ribosomes. Eukaryotic mRNA is relatively stable and continues to be translated for several hours.

**Figure 5.13** shows that transcription and translation are intimately related in bacteria. Transcription begins when the enzyme RNA polymerase binds to DNA and then moves along making a copy of one strand. As soon as transcription begins, ribosomes attach to the 5' end of the mRNA and start translation, even before the rest of the message has been synthesized. A bunch of ribosomes moves along the mRNA while it is being synthesized. The 3' end of the mRNA is generated when transcription terminates. Ribosomes continue to translate the mRNA while it survives, but it is degraded in the overall 5' → 3' direction quite rapidly. The mRNA is synthesized, translated by the ribosomes, and degraded, all in rapid succession. An individual molecule of mRNA survives for only a matter of minutes or even less.

**Figure 5.13** Overview: mRNA is transcribed, translated, and degraded simultaneously in bacteria.

Bacterial transcription and translation take place at similar rates. At 37°C, transcription of mRNA occurs at ~40 nucleotides/second. This is very close to the rate of protein synthesis, roughly 15 amino acids/second. It therefore takes ~2 minutes to transcribe and translate an mRNA of 5000 bp, corresponding to 180 kD of protein. When expression of a new gene is initiated, its mRNA typically will appear in the cell within ~2.5 minutes. The corresponding protein will appear within perhaps another 0.5 minute.

Bacterial translation is very efficient, and most mRNAs are translated by a large number of tightly packed ribosomes. In one example (*trp* mRNA), about 15 initiations of transcription occur every minute, and each of the 15 mRNAs probably is translated by ~30 ribosomes in the interval between its transcription and degradation.

The instability of most bacterial mRNAs is striking. Degradation of mRNA closely follows its translation. Probably it begins within 1 minute of the start of transcription. The 5' end of the mRNA starts to decay before the 3' end has been synthesized or translated. Degradation seems to follow the last ribosome of the convoy along the mRNA. But degradation proceeds more slowly, probably at about half the speed of transcription or translation.

The stability of mRNA has a major influence on the amount of protein that is produced. It is usually expressed in terms of the half-life. The mRNA representing any particular gene has a characteristic half-life, but the average is ~2 minutes in bacteria.

This series of events is only possible, of course, because transcription, translation, and degradation all occur in the same direction. The dynamics of gene expression have been caught *in flagrante delicto* in the electron micrograph of **Figure 5.14**. In these (unknown) transcription units, several mRNAs are under synthesis simultaneously; and each carries many ribosomes engaged in translation. (This corresponds to the stage shown in the second panel in **Figure 5.13**.) An RNA whose synthesis has not yet been completed is often called a **nascent RNA** (420).

**Figure 5.14** Transcription units can be visualized in bacteria. Photograph kindly provided by Oscar Miller.

Bacterial mRNAs vary greatly in the number of proteins for which they code. Some mRNAs represent only a single gene: they are **monocistronic**. Others (the majority) carry sequences coding for several proteins: they are **polycistronic**. In these cases, a single mRNA is transcribed from a group of adjacent genes. (Such a cluster of genes constitutes an operon that is controlled as a single genetic unit; see *Molecular Biology 3.10 The operon*.)

All mRNAs contain two types of region. The **coding region** consists of a series of codons representing the amino acid sequence of the protein, starting (usually) with AUG and ending with a termination codon. But the mRNA is always longer than the coding region, extra regions are present at both ends. An additional sequence at the 5' end, preceding the start of the coding region, is described as the **leader** or **5' UTR** (untranslated region). An additional sequence following the termination signal,

forming the 3' end, is called the **trailer** or **3' UTR**. Although part of the transcription unit, these sequences are not used to code for protein.

A polycistronic mRNA also contains **intercistronic regions**, as illustrated in **Figure 5.15**. They vary greatly in size. They may be as long as 30 nucleotides in bacterial mRNAs (and even longer in phage RNAs), but they can also be very short, with as few as 1 or 2 nucleotides separating the termination codon for one protein from the initiation codon for the next. In an extreme case, two genes actually overlap, so that the last base of one coding region is also the first base of the next coding region.

**Figure 5.15** Bacterial mRNA includes non-translated as well as translated regions. Each coding region has its own initiation and termination signals. A typical mRNA may have several coding regions.

The number of ribosomes engaged in translating a particular cistron depends on the efficiency of its initiation site. The initiation site for the first cistron becomes available as soon as the 5' end of the mRNA is synthesized. How are subsequent cistrons translated? Are the several coding regions in a polycistronic mRNA translated independently or is their expression connected? Is the mechanism of initiation the same for all cistrons, or is it different for the first cistron and the internal cistrons?

Translation of a bacterial mRNA proceeds sequentially through its cistrons. At the time when ribosomes attach to the first coding region, the subsequent coding regions have not yet even been transcribed. By the time the second ribosome site is available, translation is well under way through the first cistron. Usually ribosomes terminate translation at the end of the first cistron (and dissociate into subunits), and a new ribosome assembles independently at the start of the next coding region. (We discuss the processes of initiation and termination in *Molecular Biology 2.6 Protein synthesis*.)

**MESSENGER RNA****2.5.8 Eukaryotic mRNA is modified during or after its transcription**

---

**Key Terms**

**Poly(A)** is a stretch of ~200 bases of adenylic acid that is added to the 3' end of mRNA following its synthesis.

**Key Concepts**

- A eukaryotic mRNA transcript is modified in the nucleus during or shortly after transcription.
- The modifications include the addition of a methylated cap at the 5' end and a sequence of poly(A) at the 3' end.
- The mRNA is exported from the nucleus to the cytoplasm only after all modifications have been completed.

---

The production of eukaryotic mRNA involves additional stages after transcription. Transcription occurs in the usual way, initiating a transcript with a 5' triphosphate end. However, the 3' end is generated by cleaving the transcript, rather than by terminating transcription at a fixed site. Those RNAs that are derived from interrupted genes require splicing to remove the introns, generating a smaller mRNA that contains an intact coding sequence.

**Figure 5.16** shows that both ends of the transcript are modified by additions of further nucleotides (involving additional enzyme systems). The 5' end of the RNA is modified by addition of a "cap" virtually as soon as it appears. This replaces the triphosphate of the initial transcript with a nucleotide in reverse (3' → 5') orientation, thus "sealing" the end. The 3' end is modified by addition of a series of adenylic acid nucleotides [polyadenylic acid or **poly(A)**] immediately after its cleavage. Only after the completion of all modification and processing events can the mRNA be exported from the nucleus to the cytoplasm. The average delay in leaving for the cytoplasm is ~20 minutes. Once the mRNA has entered the cytoplasm, it is recognized by ribosomes and translated.

**Figure 5.16** Eukaryotic mRNA is modified by addition of a cap to the 5' end and poly(A) to the 3' end.

**Figure 5.17** shows that the life cycle of eukaryotic mRNA is more protracted than that of bacterial mRNA. Transcription in animal cells occurs at about the same speed as in bacteria, ~40 nucleotides per second. Many eukaryotic genes are large; a gene of 10,000 bp takes ~5 minutes to transcribe. Transcription of mRNA is not terminated by the release of enzyme from the DNA; instead the enzyme continues past the end of the gene. A coordinated series of events generates the 3' end of the mRNA by cleavage, and adds a length of poly(A) to the newly generated 3' end.

**Figure 5.17** Overview: expression of mRNA in animal cells requires transcription, modification, processing, nucleocytoplasmic transport, and translation.

Eukaryotic mRNA constitutes only a small proportion of the total cellular RNA (~3% of the mass). Half-lives are relatively short in yeast, ranging from 1-60 minutes. There is a substantial increase in stability in higher eukaryotes; animal cell mRNA is relatively stable, with half-lives ranging from 4-24 hours.

Eukaryotic polysomes are reasonably stable. The modifications at both ends of the mRNA contribute to the stability.

*This content is available online at <http://www.ergito.com/main.jsp?bcs=MBIO.2.5.8>*

**MESSENGER RNA****2.5.9 The 5' end of eukaryotic mRNA is capped****Key Terms**

A **cap** is the structure at the 5' end of eukaryotic mRNA, introduced after transcription by linking the terminal phosphate of 5' GTP to the terminal base of the mRNA. The added G (and sometimes some other bases) are methylated, giving a structure of the form  ${}^7\text{MeG}5' \text{ ppp}5' \text{ Np} \dots$

A **cap 0** at the 5' end of mRNA has only a methyl group on 7-guanine.

A **cap 1** at the 5' end of mRNA has methyl groups on the terminal 7-guanine and the 2' -O position of the next base.

A **cap 2** has three methyl groups (7-guanine, 2' -O position of next base, and N<sup>6</sup> adenine) at the 5' end of mRNA.

**Key Concepts**

- A 5' cap is formed by adding a G to the terminal base of the transcript via a 5'–5' link. 1-3 methyl groups are added to the base or ribose of the new terminal guanosine.

Transcription starts with a nucleoside triphosphate (usually a purine, A or G). The first nucleotide retains its 5' triphosphate group and makes the usual phosphodiester bond from its 3' position to the 5' position of the next nucleotide. The initial sequence of the transcript can be represented as:

But when the mature mRNA is treated *in vitro* with enzymes that should degrade it into individual nucleotides, the 5' end does not give rise to the expected nucleoside triphosphate. Instead it contains two nucleotides, connected by a 5'–5' triphosphate linkage and also bearing methyl groups. The terminal base is always a guanine that is added to the original RNA molecule after transcription.

Addition of the 5' terminal G is catalyzed by a nuclear enzyme, guanylyl transferase. The reaction occurs so soon after transcription has started that it is not possible to detect more than trace amounts of the original 5' triphosphate end in the nuclear RNA. The overall reaction can be represented as a condensation between GTP and the original 5' triphosphate terminus of the RNA. Thus

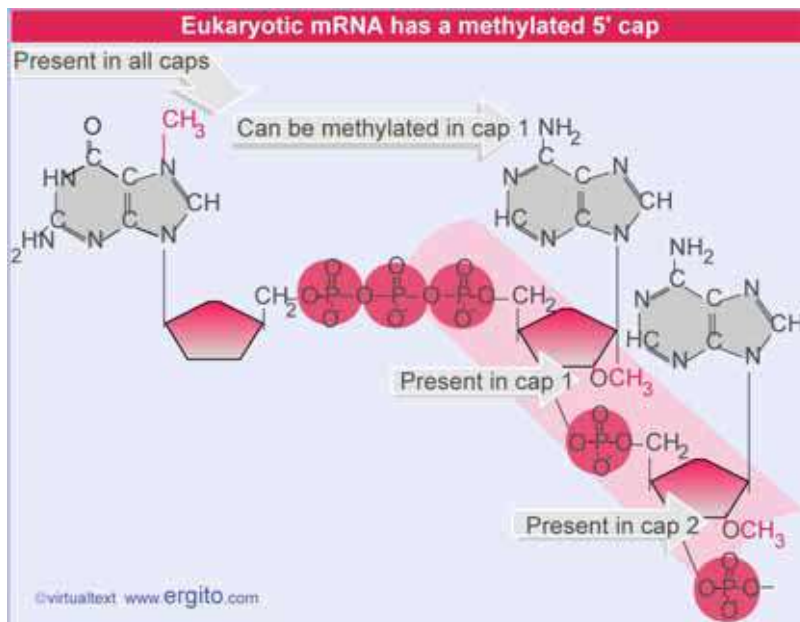

↓

5' — 5'

GpppApNpNp... + pp + p

The new G residue added to the end of the RNA is in the reverse orientation from all the other nucleotides.

This structure is called a **cap**. It is a substrate for several methylation events. **Figure 5.18** shows the full structure of a cap after all possible methyl groups have been added. Types of caps are distinguished by how many of these methylations have occurred:

**Figure 5.18** The cap blocks the 5' end of mRNA and may be methylated at several positions.

- The first methylation occurs in all eukaryotes, and consists of the addition of a methyl group to the 7 position of the terminal guanine. A cap that possesses this single methyl group is known as a **cap 0**. This is as far as the reaction proceeds in unicellular eukaryotes. The enzyme responsible for this modification is called guanine-7-methyltransferase.
- The next step is to add another methyl group, to the 2' -O position of the penultimate base (which was actually the original first base of the transcript before any modifications were made). This reaction is catalyzed by another enzyme (2' -O-methyl-transferase). A cap with the two methyl groups is called **cap 1**. This is the predominant type of cap in all eukaryotes except unicellular organisms.
- In a small minority of cases in higher eukaryotes, another methyl group is added to the second base. This happens only when the position is occupied by adenine; the reaction involves addition of a methyl group at the N<sup>6</sup> position. The enzyme

responsible acts only on an adenosine substrate that already has the methyl group in the 2' -O position.

- In some species, a methyl group is added to the third base of the capped mRNA. The substrate for this reaction is the cap 1 mRNA that already possesses two methyl groups. The third-base modification is always a 2' -O ribose methylation. This creates the **cap 2** type. This cap usually represents less than 10-15% of the total capped population.

In a population of eukaryotic mRNAs, every molecule is capped. The proportions of the different types of cap are characteristic for a particular organism. We do not know whether the structure of a particular mRNA is invariant or can have more than one type of cap.

In addition to the methylation involved in capping, a low frequency of internal methylation occurs in the mRNA only of higher eukaryotes. This is accomplished by the generation of N<sup>6</sup> methyladenine residues at a frequency of about one modification per 1000 bases. There are 1-2 methyladenines in a typical higher eukaryotic mRNA, although their presence is not obligatory, since some mRNAs do not have any (for review see 25).

---

**MESSENGER RNA****2.5.10 The 3' terminus is polyadenylated**

---

**Key Terms**

**poly(A)<sup>+</sup>** mRNA is mRNA that has a 3' terminal stretch of poly(A).

**Poly(A) polymerase** is the enzyme that adds the stretch of polyadenylic acid to the 3' of eukaryotic mRNA. It does not use a template.

**Poly(A)-binding protein (PABP)** is the protein that binds to the 3' stretch of poly(A) on a eukaryotic mRNA.

**cDNA** is a single-stranded DNA complementary to an RNA, synthesized from it by reverse transcription *in vitro*.

**poly(A)<sup>-</sup>** mRNA is mRNA that does not have a 3' terminal stretch of poly(A).

**Key Concepts**

- A length of poly(A) ~200 nucleotides long is added to a nuclear transcript after transcription.
- The poly(A) is bound by a specific protein (PABP).
- The poly(A) stabilizes the mRNA against degradation.

---

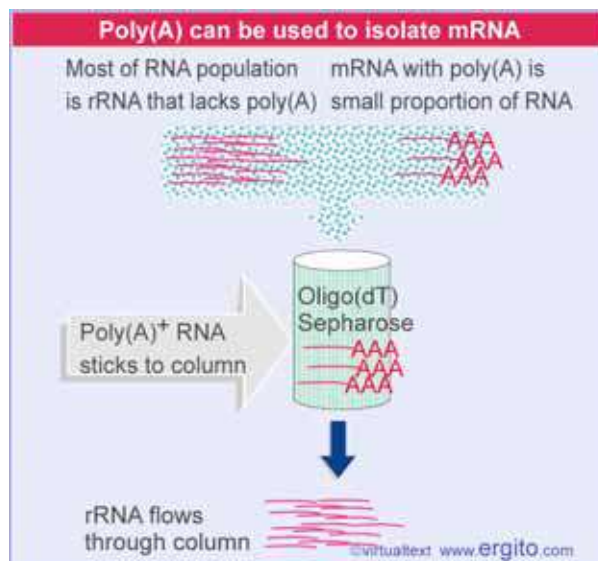

The 3' terminal stretch of A residues is often described as the poly(A) tail; and mRNA with this feature is denoted **poly(A)<sup>+</sup>**.

The poly(A) sequence is not coded in the DNA, but is added to the RNA in the nucleus after transcription. The addition of poly(A) is catalyzed by the enzyme **poly(A) polymerase**, which adds ~200 A residues to the free 3' -OH end of the mRNA. The poly(A) tract of both nuclear RNA and mRNA is associated with a protein, the **poly(A)-binding protein (PABP)**. Related forms of this protein are found in many eukaryotes. One PABP monomer of ~70 kD is bound every 10-20 bases of the poly(A) tail. So a common feature in many or most eukaryotes is that the 3' end of the mRNA consists of a stretch of poly(A) bound to a large mass of protein. Addition of poly(A) occurs as part of a reaction in which the 3' end of the mRNA is generated and modified by a complex of enzymes (see *Molecular Biology 5.24.19 The 3' ends of mRNAs are generated by cleavage and polyadenylation*) (424).

Binding of the PABP to the initiation factor eIF4G generates a closed loop, in which the 5' and 3' ends of the mRNA find themselves held in the same protein complex (see **Figure 6.20** in *Molecular Biology 2.6.9 Eukaryotes use a complex of many initiation factors*). The formation of this complex may be responsible for some of the effects of poly(A) on the properties of mRNA. Poly(A) usually stabilizes mRNA. The ability of the poly(A) to protect mRNA against degradation requires binding of the PABP.

Removal of poly(A) inhibits the initiation of translation *in vitro*, and depletion of PABP has the same effect in yeast *in vivo*. These effects could depend on the binding of PABP to the initiation complex at the 5' end of mRNA. There are many examples in early embryonic development where polyadenylation of a particular mRNA is correlated with its translation. In some cases, mRNAs are stored in a nonpolyadenylated form, and poly(A) is added when their translation is required; in other cases, poly(A)<sup>+</sup> mRNAs are de-adenylated, and their translation is reduced.

The presence of poly(A) has an important practical consequence. The poly(A) region of mRNA can base pair with oligo(U) or oligo(dT); and this reaction can be used to isolate poly(A)<sup>+</sup> mRNA. The most convenient technique is to immobilize the oligo(U) or dT) on a solid support material. Then when an RNA population is applied to the column, as illustrated in **Figure 5.19**, only the poly(A)<sup>+</sup> RNA is retained. It can be retrieved by treating the column with a solution that breaks the bonding to release the RNA.

**Figure 5.19** Poly(A)<sup>+</sup> RNA can be separated from other RNAs by fractionation on Sepharose-oligo(dT).

The only drawback to this procedure is that it isolates all the RNA that contains poly(A). If RNA of the whole cell is used, for example, both nuclear and cytoplasmic poly(A)<sup>+</sup> RNA will be retained. If preparations of polysomes are used (a common procedure), most of the isolated poly(A)<sup>+</sup> RNA will be active mRNA. However, in addition to mRNA in polysomes, there are also ribonucleoprotein particles in the cytosol that contain poly(A)<sup>+</sup> mRNA, but which are not translated. This RNA may be "stored" for use at some other time. Isolation of total poly(A)<sup>+</sup> mRNA therefore does not correspond exactly with the active mRNA population.

The "cloning" approach for purifying mRNA uses a procedure in which the mRNA is copied to make a complementary DNA strand (known as **cDNA**). Then the cDNA can be used as a template to synthesize a DNA strand that is identical with the original mRNA sequence. The product of these reactions is a double-stranded DNA corresponding to the sequence of the mRNA. This DNA can be reproduced in large amounts.

The availability of a cloned DNA makes it easy to isolate the corresponding mRNA by hybridization techniques. Even mRNAs that are present in only very few copies per cell can be isolated by this approach. Indeed, only mRNAs that are present in relatively large amounts can be isolated directly without using a cloning step.

Almost all cellular mRNAs possess poly(A). A significant exception is provided by the mRNAs that code for the histone proteins (a major structural component of chromosomal material). These mRNAs comprise most or all of the **poly(A)**<sup>-</sup> fraction. The significance of the absence of poly(A) from histone mRNAs is not clear, and there is no particular aspect of their function for which this appears to be necessary (for review see 26).

**MESSENGER RNA****2.5.11 Bacterial mRNA degradation involves multiple enzymes**

---

**Key Terms**

The **degradosome** is a complex of bacterial enzymes, including RNAase and helicase activities, which may be involved in degrading mRNA.

**Key Concepts**

- The overall direction of degradation of bacterial mRNA is 5'–3'.
  - Degradation results from the combination of exonucleolytic cleavages followed by endonucleolytic degradation of the fragment from 3'–5'.
- 

Bacterial mRNA is constantly degraded by a combination of endonucleases and exonucleases (for review see 972). Endonucleases cleave an RNA at an internal site. Exonucleases are involved in trimming reactions in which the extra residues are whittled away, base by base from the end. Bacterial exonucleases that act on single-stranded RNA proceed along the nucleic acid chain from the 3' end.

The way the two types of enzymes work together to degrade an mRNA is shown in **Figure 5.20**. Degradation of a bacterial mRNA is initiated by an endonucleolytic attack. Several 3' ends may be generated by endonucleolytic cleavages within the mRNA. The overall direction of degradation (as measured by loss of ability to synthesize proteins) is 5'–3'. This probably results from a succession of endonucleolytic cleavages following the last ribosome. Degradation of the released fragments of mRNA into nucleotides then proceeds by exonucleolytic attack from the free 3'–OH end toward the 5' terminus (that is, in the opposite direction from transcription). Endonucleolytic attack releases fragments that may have different susceptibilities to exonucleases. A region of secondary structure within the mRNA may provide an obstacle to the exonuclease, thus protecting the regions on its 5' side. The stability of each mRNA is therefore determined by the susceptibility of its particular sequence to both endo- and exonucleolytic cleavages.

**Figure 5.20** Degradation of bacterial mRNA is a two-stage process. Endonucleolytic cleavages proceed 5' -3' behind the ribosomes. The released fragments are degraded by exonucleases that move 3' -5'.  
*This is a static version of an interactive figure; see <http://www.ergito.com/main.jsp?bcs=MBIO.2.5.11> to view properly.*

There are ~12 ribonucleases in *E. coli*. Mutants in the endoribonucleases (except ribonuclease I, which is without effect) accumulate unprocessed precursors to rRNA and tRNA, but are viable. Mutants in the exonucleases often have apparently unaltered phenotypes, which suggests that one enzyme can substitute for the absence of another. Mutants lacking multiple enzymes sometimes are inviable (for review see 29).

RNAase E is the key enzyme in initiating cleavage of mRNA. It may be the enzyme that makes the first cleavage for many mRNAs. Bacterial mutants that have a defective ribonuclease E have increased stability (2-3 fold) of mRNA. However, this is not its only function. RNAase E was originally discovered as the enzyme that is responsible for processing 5' rRNA from the primary transcript by a specific endonucleolytic processing event.

The process of degradation may be catalyzed by a multienzyme complex (sometimes

called the **degradosome**) that includes ribonuclease E, PNPase, and a helicase (970). RNAase E plays dual roles. Its N-terminal domain provides an endonuclease activity. The C-terminal domain provides a scaffold that holds together the other components (971). The helicase unwinds the substrate RNA to make it available to PNPase. According to this model, RNAase E makes the initial cut and then passes the fragments to the other components of the complex for processing.

Polyadenylation may play a role in initiating degradation of some mRNAs in bacteria. Poly(A) polymerase is associated with ribosomes in *E. coli*, and short (10-40 nucleotide) stretches of poly(A) are added to at least some mRNAs. Triple mutations that remove poly(A) polymerase, ribonuclease E, and polynucleotide phosphorylase (PNPase is a 3'–5' exonuclease) have a strong effect on stability. (Mutations in individual genes or pairs of genes have only a weak effect.) Poly(A) polymerase may create a poly(A) tail that acts as a binding site for the nucleases. The role of poly(A) in bacteria would therefore be different from that in eukaryotic cells (425).

## MESSENGER RNA

### 2.5.12 mRNA stability depends on its structure and sequence

#### Key Concepts

- The modifications at both ends of mRNA protect it against degradation by exonucleases.
- Specific sequences within an mRNA may have stabilizing or destabilizing effects.
- Destabilization may be triggered by loss of poly(A)

The major features of mRNA that affect its stability are summarized in **Figure 5.21**. Both structure and sequence are important. The 5' and 3' terminal structures protect against degradation, and specific sequences within the mRNA may either serve as targets to trigger degradation or may protect against degradation:

**Figure 5.21** The terminal modifications of mRNA protect it against degradation. Internal sequences may activate degradation systems.

- The modifications at the 5' and 3' ends of mRNA play an important role in preventing exonuclease attack. The cap prevents 5'–3' exonucleases from attacking the 5' end, and the poly(A) prevents 3'–5' exonucleases from attacking the 3' end.
- Specific sequence elements within the mRNA may stabilize or destabilize it. The most common location for destabilizing elements is within the 3' untranslated region. The presence of such an element shortens the lifetime of the mRNA.
- Within the coding region, mutations that create termination codons trigger a surveillance system that degrades the mRNA (see *Molecular Biology 2.5.14 Nonsense mutations trigger a surveillance system*).

Destabilizing elements have been found in several yeast mRNAs, although as yet we do not see any common sequences or know how they destabilize the mRNA. They do not necessarily act directly (by providing targets for endonucleases), but may function indirectly, perhaps by encouraging deadenylation. The criterion for defining a destabilizing sequence element is that its introduction into a new mRNA may cause it to be degraded. The removal of an element from an mRNA does not necessarily stabilize it, suggesting that an individual mRNA can have more than one destabilizing element.

A common feature in some unstable mRNAs is the presence of an AU-rich sequence of ~50 bases (called the ARE) that is found in the 3' trailer region. The consensus sequence in the ARE is the pentanucleotide AUUUA, repeated several times. **Figure 5.22** shows that the ARE triggers destabilization by a two stage process: first the mRNA is deadenylated; then it decays. The deadenylation is probably needed because it causes loss of the poly(A)-binding protein, whose presence stabilizes the 3' region (see *Molecular Biology 2.5.13 mRNA degradation involves multiple activities*).

**Figure 5.22** An ARE in a 3' nontranslated region initiates degradation of mRNA.

In some cases, an mRNA can be stabilized by specifically inhibiting the function of a destabilizing element. Transferrin mRNA contains a sequence called the IRE, which controls the response of the mRNA to changes in iron concentration. The IRE is located in the 3' nontranslated region, and contains stem-loop structures that bind a protein whose affinity for the mRNA is controlled by iron. **Figure 5.23** shows that binding of the protein to the IRE stabilizes the mRNA by inhibiting the function of (unidentified) destabilizing sequences in the vicinity. This is a general model for the stabilization of mRNA, that is, stability is conferred by inhibiting the function of destabilizing sequences (for review see 27; 28).

**Figure 5.23** An IRE in a 3' nontranslated region controls mRNA stability.

---

**MESSENGER RNA****2.5.13 mRNA degradation involves multiple activities**

---

**Key Concepts**

- Degradation of yeast mRNA requires removal of the 5' cap and the 3' poly(A).
  - One yeast pathway involves exonucleolytic degradation from 5'–3'.
  - Another yeast pathway uses a complex of several exonucleases that work in the 3'–5' direction.
  - The deadenylase of animal cells may bind directly to the 5' cap.
- 

We know most about the degradation of mRNA in yeast. There are basically two pathways. Both start with removal of the poly(A) tail (for review see 1934). This is catalyzed by a specific deadenylase which probably functions as part of a large protein complex (1933). (The catalytic subunit is the exonuclease Ccr4 in yeast, and is the exonuclease PARN in vertebrates, which is related to RNAase D.) The enzyme action is processive—once it has started to degrade a particular mRNA substrate, it continues to whittle away that mRNA, base by base.

The major degradation pathway is summarized in **Figure 5.24**. Deadenylation at the 3' end triggers decapping at the 5' end. The basis for this relationship is that the presence of the PABP (poly(A)-binding protein) on the poly(A) prevents the decapping enzyme from binding to the 5' end. PABP is released when the length of poly(A) falls below 10-15 residues. The decapping reaction occurs by cleavage 1-2 bases from the 5' end.

**Figure 5.24** Deadenylation allows decapping to occur, which leads to endonucleolytic cleavage from the 5' end. This is a static version of an interactive figure; see <http://www.ergito.com/main.jsp?bcs=MBIO.2.5.13> to view properly.

Each end of the mRNA influences events that occur at the other end. This is explained by the fact that the two ends of the mRNA are held together by the factors involved in protein synthesis (see *Molecular Biology 2.6.9 Eukaryotes use a complex of many initiation factors*). The effect of PABP on decapping allows the 3' end to have an effect in stabilizing the 5' end. There is also a connection between the structure at the 5' end and degradation at the 3' end. The deadenylase directly binds to the 5' cap, and this interaction is in fact needed for its exonucleolytic attack on the poly(A) (1435).

What is the rationale for the connection between events occurring at both ends of an mRNA? Perhaps it is necessary to ensure that the mRNA is not left in a state (having the structure of one end but not the other) that might compete with active mRNA for the proteins that bind to the ends.

Removal of the cap triggers the 5'–3' degradation pathway in which the mRNA is degraded rapidly from the 5' end, by the 5'–3' exonuclease XRN1 (1935). The decapping enzyme is concentrated in discrete cytoplasmic foci, which may be “processing bodies” where the mRNA is deadenylated and then degraded after it has been decapped (3999).

In the second pathway, deadenylated yeast mRNAs can be degraded by the 3'–5' exonuclease activity of the exosome, a complex of >9 exonucleases (426, 1936). The exosome is also involved in processing precursors for rRNAs. The aggregation of the individual exonucleases into the exosome complex may enable 3'–5' exonucleolytic activities to be coordinately controlled. The exosome may also degrade fragments of mRNA released by endonucleolytic cleavage. **Figure 5.25**

shows that the 3'–5' degradation pathway may actually involve combinations of endonucleolytic and exonucleolytic action. The exosome is also found in the nucleus, where it degrades unspliced precursors to mRNA (2190).

**Figure 5.25** Deadenylation may lead directly to exonucleolytic cleavage and endonucleolytic cleavage from 3' end(s). This is a static version of an interactive figure; see <http://www.ergito.com/main.jsp?bcs=MBIO.2.5.13> to view properly.

Yeast mutants lacking either exonucleolytic pathway degrade their mRNAs more slowly, but the loss of both pathways is lethal (426; for review see 30).

## MESSENGER RNA

### 2.5.14 Nonsense mutations trigger a surveillance system

---

#### Key Terms

**Nonsense-mediated mRNA decay** is a pathway that degrades an mRNA that has a nonsense mutation prior to the last exon.

**Surveillance** systems check nucleic acids for errors. The term is used in several different contexts. One example is the system that degrades mRNAs that have nonsense mutations. Another is the set of systems that react to damage in the double helix. The common feature is that the system recognizes an invalid sequence or structure and triggers a response.

#### Key Concepts

- Nonsense mutations cause mRNA to be degraded.
  - Genes coding for the degradation system have been found in yeast and worm.
- 

Another pathway for degradation is identified by **nonsense-mediated mRNA decay**. **Figure 5.26** shows that the introduction of a nonsense mutation often leads to increased degradation of the mRNA. As may be expected from dependence on a termination codon, the degradation occurs in the cytoplasm. It may represent a quality control or **surveillance** system for removing nonfunctional mRNAs (for review see 973).

**Figure 5.26** Nonsense mutations may cause mRNA to be degraded.

The surveillance system has been studied best in yeast and *C. elegans*, but may also be important in animal cells. For example, during the formation of immunoglobulins and T cell receptors in cells of the immune system, genes are modified by somatic recombination and mutation (see *Molecular Biology 5.25 Immune diversity*). This generates a significant number of nonfunctional genes, whose RNA products are disposed of by a surveillance system.

In yeast, the degradation requires sequence elements (called *DSE*) that are downstream of the nonsense mutation (974; 975). The simplest possibility would be that these are destabilizing elements, and that translation suppresses their use. However, when translation is blocked, the mRNA is stabilized. This suggests that the process of degradation is linked to translation of the mRNA, or to the termination event in some direct way.

Genes that are required for the process have been identified in *S. cerevisiae* (*upf* loci) and *C. elegans* (*smg* loci) by identifying suppressors of nonsense-mediated degradation (976; 977). Mutations in these genes stabilize aberrant mRNAs, but do not affect the stability of most wild-type transcripts. One of these genes is conserved in eukaryotes (*upf1/smg2*). It codes for an ATP-dependent helicase (an enzyme that unwinds double-stranded nucleic acids into single strands). This implies that recognition of the mRNA as an appropriate target for degradation requires a change in its structure (978; 979).

Upf1 interacts with the release factors (eRF1 and eRF3) that catalyze termination, which is probably how it recognizes the termination event (2232). It may then "scan" the mRNA by moving toward the 3' end to look for the downstream sequence elements.

In mammalian cells, the surveillance system appears to work only on mutations located prior to the last exon – in other words, there must be an intron after the site of mutation. This suggests that the system requires some event to occur in the nucleus, before the introns are removed by splicing. One possibility is that proteins attach to the mRNA in the nucleus at the exon-exon boundary when a splicing event occurs (1906). **Figure 5.27** shows a general model for the operation of such a system. This is similar to the way in which an mRNA may be marked for export from the nucleus (see *Molecular Biology 5.24.10 Splicing is connected to export of mRNA*). Attachment of a protein to the exon-exon junction creates a mark of the event that persists into the cytoplasm. Human homologues of the yeast Upf2,3 proteins may be involved in such a system (1907). They bind specifically to mRNA that has been spliced.

**Figure 5.27** A surveillance system could have two types of components. Protein(s) must bind in the nucleus to mark the result of a splicing event. Other proteins could bind to the mark either in the nucleus or cytoplasm. They are triggered to act to degrade the mRNA when ribosomes terminate prematurely.

## MESSENGER RNA

### 2.5.15 Eukaryotic RNAs are transported

#### Key Concepts

- RNA is transported through a membrane as a ribonucleoprotein particle.
- All eukaryotic RNAs that function in the cytoplasm must be exported from the nucleus.
- tRNAs and the RNA component of a ribonuclease are imported into mitochondria.
- mRNAs can travel long distances between plant cells.

A bacterium consists of only a single compartment, so all the RNAs function in the same environment in which they are synthesized. This is most striking in the case of mRNA, where translation occurs simultaneously with transcription (see *Molecular Biology 2.5.7 The life cycle of bacterial messenger RNA* ).

RNA is transported through membranes in the variety of instances summarized in **Figure 5.28**. It poses a significant thermodynamic problem to transport a highly negative RNA through a hydrophobic membrane, and the solution is to transport the RNA packaged with proteins.

RNA can be transported between cell compartments			
RNA	Transport	Location	
All RNA	Nucleus→cytoplasm	All cells	
tRNA	Nucleus→mitochondrion	Many cells	
mRNA	Nurse cell→oocyte	Fly embryogenesis	
mRNA	Anterior→posterior oocyte	ditto	
mRNA	Cell→cell	Plant phloem	

**Figure 5.28** RNAs are transported through membranes in a variety of systems.

In eukaryotic cells, RNAs are transcribed in the nucleus, but translation occurs in the cytoplasm. Each type of RNA must be transported into the cytoplasm to assemble the apparatus for translation. The rRNA assembles with ribosomal proteins into immature ribosome subunits that are the substrates for the transport system. tRNA is transported by a specific protein system (see *Molecular Biology 2.8.28 Transport*

*receptors carry cargo proteins through the pore*). mRNA is transported as a ribonucleoprotein, which forms on the RNA transcript in the nucleus (see *Molecular Biology 5.24 RNA splicing and processing*). These processes are common to all eukaryotic cells. Many mRNAs are translated in the cytosol, but some are localized within the cell, by means of attachment to a cytoskeletal element. One situation in which localization occurs is when it is important for a protein product to be produced near to the site of its incorporation into some macromolecular structure (1921).

Some RNAs are made in the nucleus, exported to the cytosol, and then imported into mitochondria. The mitochondria of some organisms do not code for all of the tRNAs that are required for protein synthesis (see *Molecular Biology 1.3.20 Organelle genomes are circular DNAs that code for organelle proteins*). In these cases, the additional tRNAs must be imported from the cytosol. The enzyme ribonuclease P, which contains both RNA and protein subunits, is coded by nuclear genes, but is found in mitochondria as well as the nucleus (1915). This means that the RNA must be imported into the mitochondria.

We know of some situations in which mRNA is even transported between cells. During development of the oocyte in *Drosophila*, certain mRNAs are transported into the egg from the nurse cells that surround it. The nurse cells have specialized junctions with the oocyte that allow passage of material needed for early development. This material includes certain mRNAs. Once in the egg, these mRNAs take up specific locations. Some simply diffuse from the anterior end where they enter, but others are transported the full length of the egg to the posterior end by a motor attached to microtubules (see *Molecular Biology 6.31.7 How are mRNAs and proteins transported and localized?*).

The most striking case of transport of mRNA has been found in plants. Movement of individual nucleic acids over long distances was first discovered in plants, where viral movement proteins help propagate the viral infection by transporting an RNA virus genome through the plasmodesmata (connections between cells) (see 1919; 1920). Plants also have a defense system, that causes cells to silence an infecting virus, and this too may involve the spread of components including RNA over long distance between cells (see 1918). Now it has turned out that similar systems may transport mRNAs between plant cells. Although the existence of the systems has been known for some time, it is only recently that their functional importance has been demonstrated (1916). This was shown by grafting wild-type tomato plants onto plants that had the dominant mutation *Me* (which causes a change in the shape of the leaf). mRNA from the mutant stock was transported into the leaves of the wild-type graft, where it changed their shape.

---

**MESSENGER RNA****2.5.16 mRNA can be specifically localized**

---

**Key Concepts**

- Yeast Ash1 mRNA forms a ribonucleoprotein that binds to a myosin motor.
  - A motor transports it along actin filaments into the daughter bud.
  - It is anchored and translated in the bud, so that the protein is found only in the bud.
- 

An mRNA is synthesized in the nucleus but translated in the cytoplasm of a eukaryotic cell. It passes into the cytoplasm in the form of a ribonucleoprotein particle that is transported through the nuclear pore. Once in the cytosol, it may associate with ribosomes and be translated. The cytosol is a crowded place, occupied by a high concentration of proteins. It is not clear how freely a polysome can diffuse within the cytosol, and most mRNAs are probably translated in random locations, determined by their point of entry into the cytosol, and the distance that they may have moved away from it. However, some mRNAs are translated at specific sites. This may be accomplished by several mechanisms (for review see 2304; 2423):

- An mRNA may be specifically transported to a site where it is translated.
- It may be universally distributed but degraded at all sites except the site of translation.
- It may be freely diffusible but become trapped at the site of translation.

One of the best characterized cases of localization within a cell is that of Ash1 in yeast (for review see 2302). Ash1 represses expression of the HO endonuclease in the budding daughter cell, with the result that HO is expressed only in the mother cell. The consequence is that mating type is changed only in the mother cell (see *Molecular Biology 4.18.9 Regulation of HO expression controls switching*). The cause of the restriction to the daughter cell is that all the Ash1 mRNA is transported from the mother cell, where it is made, into the budding daughter cell (2348).

Mutations in any one of 5 genes, called *SHE1-5*, prevent the specific localization and cause Ash1 mRNA to be symmetrically distributed in both mother and daughter compartments. The proteins She1,2,3 bind Ash1 mRNA into a ribonucleoprotein particle that transports the mRNA into the daughter cell. **Figure 5.29** shows the functions of the proteins. She1p is a myosin (previously identified as Myo4), and She3 and She2 are proteins that connect the myosin to the mRNA. The myosin is a motor that moves the mRNA along actin filaments (2349).

**Figure 5.29** Ash1 mRNA forms a ribonucleoprotein containing a myosin motor that moves it along an actin filament.

**Figure 5.30** summarizes the overall process. Ash1 mRNA is exported from the nucleus in the form of a ribonucleoprotein. In the cytoplasm it is first bound by She2, which recognizes some stem-loop secondary structures within the mRNA. Then She3 binds to She2, after which the myosin She1 binds. Then the particle hooks on to an actin filament and moves to the bud. When Ash1 mRNA reaches the bud, it is anchored there, probably by proteins that bind specifically to the mRNA.

**Figure 5.30** Ash1 mRNA is exported from the nucleus into the cytoplasm where it is assembled into a complex with the She proteins. The complex transports it along actin filaments to the bud.

Similar principles govern other cases where mRNAs are transported to specific sites. The mRNA is recognized by means of *cis*-acting sequences, which usually are regions of secondary structure in the 3' untranslated region. (Ash1 mRNA is unusual in that the *cis*-acting regions are in the coding frame.) The mRNA is packaged into a ribonucleoprotein particle. In some cases, the transported mRNA can be visualized in very large particles, called mRNA granules. The particles are large enough (several times the size of a ribosome) to contain many protein and RNA components (for review see 1921).

A transported mRNP must be connected to a motor that moves it along a system of tracks. The tracks can be either actin filaments or microtubules. Whereas Ash1 uses a

myosin motor on actin tracks, *oscar* mRNA in the *Drosophila* egg uses a kinesin motor to move along microtubules (see *Molecular Biology* 6.31.7 *How are mRNAs and proteins transported and localized?*). Once the mRNA reaches its destination, it needs to be anchored in order to prevent it from diffusing away. Less is known about this, but the process appears to be independent of transport. An mRNA that is transported along microtubules may anchored to actin filaments at its destination.

**MESSENGER RNA****2.5.17 Summary**

---

Genetic information carried by DNA is expressed in two stages: transcription of DNA into mRNA; and translation of the mRNA into protein. Messenger RNA is transcribed from one strand of DNA and is complementary to this (noncoding) strand and identical with the other (coding) strand. The sequence of mRNA, in triplet codons 5'–3', is related to the amino acid sequence of protein, N- to C-terminal.

The adaptor that interprets the meaning of a codon is transfer RNA, which has a compact L-shaped tertiary structure; one end of the tRNA has an anticodon that is complementary to the codon, and the other end can be covalently linked to the specific amino acid that corresponds to the target codon. A tRNA carrying an amino acid is called an aminoacyl-tRNA.

The ribosome provides the apparatus that allows aminoacyl-tRNAs to bind to their codons on mRNA. The small subunit of the ribosome is bound to mRNA; the large subunit carries the nascent polypeptide. A ribosome moves along mRNA from an initiation site in the 5' region to a termination site in the 3' region, and the appropriate aminoacyl-tRNAs respond to their codons, unloading their amino acids, so that the growing polypeptide chain extends by one residue for each codon traversed.

The translational apparatus is not specific for tissue or organism; an mRNA from one source can be translated by the ribosomes and tRNAs from another source. The number of times any mRNA is translated is a function of the affinity of its initiation site(s) for ribosomes and its stability. There are some cases in which translation of groups of mRNA or individual mRNAs is specifically prevented: this is called translational control.

A typical mRNA contains both a nontranslated 5' leader and 3' trailer as well as coding region(s). Bacterial mRNA is usually polycistronic, with nontranslated regions between the cistrons. Each cistron is represented by a coding region that starts with a specific initiation site and ends with a termination site. Ribosome subunits associate at the initiation site and dissociate at the termination site of each coding region.

A growing *E. coli* bacterium has ~20,000 ribosomes and ~200,000 tRNAs, mostly in the form of aminoacyl-tRNA. There are ~1500 mRNA molecules, representing 2-3 copies of each of 600 different messengers.

A single mRNA can be translated by many ribosomes simultaneously, generating a polyribosome (or polysome). Bacterial polysomes are large, typically with tens of ribosomes bound to a single mRNA. Eukaryotic polysomes are smaller, typically with fewer than 10 ribosomes; each mRNA carries only a single coding sequence.

Bacterial mRNA has an extremely short half-life, only a few minutes. The 5' end starts translation even while the downstream sequences are being transcribed.

Degradation is initiated by endonucleases that cut at discrete sites, following the ribosomes in the 5'–3' direction, after which exonucleases reduce the fragments to nucleotides by degrading them from the released 3' end toward the 5' end. Individual sequences may promote or retard degradation in bacterial mRNAs.

Eukaryotic mRNA must be processed in the nucleus before it is transported to the cytoplasm for translation. A methylated cap is added to the 5' end. It consists of a nucleotide added to the original end by a 5'–5' bond, after which methyl groups are added. Most eukaryotic mRNA has an ~200 base sequence of poly(A) added to its 3' terminus in the nucleus after transcription, but poly(A)<sup>-</sup> mRNAs appear to be translated and degraded with the same kinetics as poly(A)<sup>+</sup> mRNAs. Eukaryotic mRNA exists as a ribonucleoprotein particle; in some cases mRNPs are stored that fail to be translated. Eukaryotic mRNAs are usually stable for several hours. They may have multiple sequences that initiate degradation; examples are known in which the process is regulated.

Yeast mRNA is degraded by (at least) two pathways. Both start with removal of poly(A) from the 3' end, causing loss of poly(A)-binding protein, which in turn leads to removal of the methylated cap from the 5' end. One pathway degrades the mRNA from the 5' end by an exonuclease. Another pathway degrades from the 3' end by the exosome, a complex containing several exonucleases.

Nonsense-mediated degradation leads to the destruction of mRNAs that have a termination (nonsense) codon prior to the last exon. The *upf* loci in yeast and the *smg* loci in worms are required for the process. They include a helicase activity to unwind mRNA and a protein that interacts with the factors that terminate protein synthesis. The features of the process in mammalian cells suggest that some of the proteins attach to the mRNA in the nucleus when RNA splicing occurs to remove introns.

mRNAs can be transported to specific locations within a cell (especially in embryonic development). In the Ash1 system in yeast, mRNA is transported from the mother cell into the daughter cell by a myosin motor that moves on actin filaments. In plants, mRNAs can be transported long distances between cells.

## PROTEIN SYNTHESIS

### 2.6.1 Introduction

An mRNA contains a series of codons that interact with the anticodons of aminoacyl-tRNAs so that a corresponding series of amino acids is incorporated into a polypeptide chain. The ribosome provides the environment for controlling the interaction between mRNA and aminoacyl-tRNA. The ribosome behaves like a small migrating factory that travels along the template engaging in rapid cycles of peptide bond synthesis. Aminoacyl-tRNAs shoot in and out of the particle at a fearsome rate, depositing amino acids; and elongation factors cyclically associate with and dissociate from the ribosome. Together with its accessory factors, the ribosome provides the full range of activities required for all the steps of protein synthesis.

**Figure 6.1** shows the relative dimensions of the components of the protein synthetic apparatus. The ribosome consists of two subunits that have specific roles in protein synthesis. Messenger RNA is associated with the small subunit; ~30 bases of the mRNA are bound at any time. The mRNA threads its way along the surface close to the junction of the subunits. Two tRNA molecules are active in protein synthesis at any moment; so polypeptide elongation involves reactions taking place at just two of the (roughly) 10 codons covered by the ribosome. The two tRNAs are inserted into internal sites that stretch across the subunits. A third tRNA may remain present on the ribosome after it has been used in protein synthesis, before being recycled.

**Figure 6.1** Size comparisons show that the ribosome is large enough to bind tRNAs and mRNA.

The basic form of the ribosome has been conserved in evolution, but there are appreciable variations in the overall size and proportions of RNA and protein in the ribosomes of bacteria, eukaryotic cytoplasm, and organelles. **Figure 6.2** compares the components of bacterial and mammalian ribosomes. Both are ribonucleoprotein particles that contain more RNA than protein. The ribosomal proteins are known as *r-proteins*.

Ribosomes are ribonucleoprotein particles			
Ribosomes		rRNAs	r-proteins
<b>Bacterial (70S)</b> mass: 2.5 MDa 66% RNA	 50S	23S = 2904 bases 5S = 120 bases	31
	 30S	16S = 1542 bases	21
<b>Mammalian (80S)</b> mass: 4.2 MDa 60% RNA	 60S	28S = 4718 bases 5.8S = 160 bases 5S = 120 bases	49
	 40S	18S = 1874 bases	33

©virtualtext www.ergito.com

**Figure 6.2** Ribosomes are large ribonucleoprotein particles that contain more RNA than protein and dissociate into large and small subunits.

Each of the ribosome subunits contains a major rRNA and a number of small proteins. The large subunit may also contain smaller RNA(s). In *E. coli*, the small (30S) subunit consists of the 16S rRNA and 21 r-proteins. The large (50S) subunit contains 23S rRNA, the small 5S RNA, and 31 proteins. With the exception of one protein present at four copies per ribosome, there is one copy of each protein. The major RNAs constitute the major part of the mass of the bacterial ribosome. Their presence is pervasive, and probably most or all of the ribosomal proteins actually contact rRNA. So the major rRNAs form what is sometimes thought of as the backbone of each subunit, a continuous thread whose presence dominates the structure, and which determines the positions of the ribosomal proteins.

The ribosomes of higher eukaryotic cytoplasm are larger than those of bacteria. The total content of both RNA and protein is greater; the major RNA molecules are longer (called 18S and 28S rRNAs), and there are more proteins. Probably most or all of the proteins are present in stoichiometric amounts. RNA is still the predominant component by mass.

Organelle ribosomes are distinct from the ribosomes of the cytosol, and take varied forms. In some cases, they are almost the size of bacterial ribosomes and have 70% RNA; in other cases, they are only 60S and have <30% RNA.

The ribosome possesses several active centers, each of which is constructed from a group of proteins associated with a region of ribosomal RNA. The active centers require the direct participation of rRNA in a structural or even catalytic role. Some catalytic functions require individual proteins, but none of the activities can be reproduced by isolated proteins or groups of proteins; they function only in the context of the ribosome.

Two types of information are important in analyzing the ribosome. Mutations implicate particular ribosomal proteins or bases in rRNA in participating in particular reactions. Structural analysis, including direct modification of components of the ribosome and comparisons to identify conserved features in rRNA, identifies the physical locations of components involved in particular functions.

## PROTEIN SYNTHESIS

### 2.6.2 Protein synthesis occurs by initiation, elongation, and termination

---

#### Key Terms

The **A site** of the ribosome is the site that an aminoacyl-tRNA enters to base pair with the codon.

The **P site** of the ribosome is the site that is occupied by peptidyl-tRNA, the tRNA carrying the nascent polypeptide chain, still paired with the codon to which it bound in the A site.

**Peptidyl-tRNA** is the tRNA to which the nascent polypeptide chain has been transferred following peptide bond synthesis during protein synthesis.

**Deacylated tRNA** has no amino acid or polypeptide chain attached because it has completed its role in protein synthesis and is ready to be released from the ribosome.

**Translocation** is the movement of the ribosome one codon along mRNA after the addition of each amino acid to the polypeptide chain.

**Elongation** is the stage in a macromolecular synthesis reaction (replication, transcription, or translation) when the nucleotide or polypeptide chain is being extended by the addition of individual subunits.

**Termination** is a separate reaction that ends a macromolecular synthesis reaction (replication, transcription, or translation), by stopping the addition of subunits, and (typically) causing disassembly of the synthetic apparatus.

#### Key Concepts

- The ribosome has 3 tRNA-binding sites.
- An aminoacyl-tRNA enters the A site.
- Peptidyl-tRNA is bound in the P site.
- Deacylated tRNA exits via the E site.
- An amino acid is added to the polypeptide chain by transferring the polypeptide from peptidyl-tRNA in the P site to aminoacyl-tRNA in the A site.

---

An amino acid is brought to the ribosome by an aminoacyl-tRNA. Its addition to the growing protein chain occurs by an interaction with the tRNA that brought the previous amino acid. Each of these tRNA lies in a distinct site on the ribosome. **Figure 6.3** shows that the two sites have different features:

**Figure 6.3** The ribosome has two sites for binding charged tRNA.

- An incoming aminoacyl-tRNA binds to the **A site**. Prior to the entry of aminoacyl-tRNA, the site exposes the codon representing the next amino acid due to be added to the chain.
- The codon representing the most recent amino acid to have been added to the nascent polypeptide chain lies in the **P site**. This site is occupied by **peptidyl-tRNA**, a tRNA carrying the nascent polypeptide chain.

**Figure 6.4** shows that the aminoacyl end of the tRNA is located on the large subunit,

while the anticodon at the other end interacts with the mRNA bound by the small subunit. So the P and A sites each extend across both ribosomal subunits.

**Figure 6.4** The P and A sites position the two interacting tRNAs across both ribosome subunits.

For a ribosome to synthesize a peptide bond, it must be in the state shown in step 1 in **Figure 6.3**, when peptidyl-tRNA is in the P site and aminoacyl-tRNA is in the A site. Then peptide bond formation occurs when the polypeptide carried by the peptidyl-tRNA is transferred to the amino acid carried by the aminoacyl-tRNA. This reaction is catalyzed by the large subunit of the ribosome.

Transfer of the polypeptide generates the ribosome shown in step 2, in which the **deacylated tRNA**, lacking any amino acid, lies in the P site, while a new peptidyl-tRNA has been created in the A site. This peptidyl-tRNA is one amino acid residue longer than the peptidyl-tRNA that had been in the P site in step 1.

Then the ribosome moves one triplet along the messenger. This stage is called **translocation**. The movement transfers the deacylated tRNA out of the P site, and moves the peptidyl-tRNA into the P site (see step 3). The next codon to be translated now lies in the A site, ready for a new aminoacyl-tRNA to enter, when the cycle will be repeated. **Figure 6.5** summarizes the interaction between tRNAs and the ribosome.

**Figure 6.5** Aminoacyl-tRNA enters the A site, receives the polypeptide chain from peptidyl-tRNA, and is transferred into the P site for the next cycle of elongation.

*This is a static version of an interactive figure; see <http://www.ergito.com/main.jsp?bcs=MBIO.2.6.2> to view properly.*

The deacylated tRNA leaves the ribosome via another tRNA-binding site, the E site. This site is transiently occupied by the tRNA en route between leaving the P site and being released from the ribosome into the cytosol. So the flow of tRNA is into the A site, through the P site, and out through the E site (see also **Figure 6.28**). **Figure 6.6** compares the movement of tRNA and mRNA, which may be thought of as a sort of ratchet in which the reaction is driven by the codon-anticodon interaction.

**Figure 6.6** tRNA and mRNA move through the ribosome in the same direction.

Protein synthesis falls into the three stages shown in **Figure 6.7**:

**Figure 6.7** Protein synthesis falls into three stages.

- **Initiation** involves the reactions that precede formation of the peptide bond between the first two amino acids of the protein. It requires the ribosome to bind to the mRNA, forming an initiation complex that contains the first aminoacyl-tRNA. This is a relatively slow step in protein synthesis, and usually determines the rate at which an mRNA is translated.
- **Elongation** includes all the reactions from synthesis of the first peptide bond to addition of the last amino acid. Amino acids are added to the chain one at a time; the addition of an amino acid is the most rapid step in protein synthesis.
- **Termination** encompasses the steps that are needed to release the completed polypeptide chain; at the same time, the ribosome dissociates from the mRNA.

Different sets of accessory factors assist the ribosome at each stage. Energy is provided at various stages by the hydrolysis of GTP.

During initiation, the small ribosomal subunit binds to mRNA and then is joined by the 50S subunit. During elongation, the mRNA moves through the ribosome and is translated in triplets. (Although we usually talk about the ribosome moving along mRNA, it is more realistic to think in terms of the mRNA being pulled through the ribosome.) At termination, the protein is released, mRNA is released, and the

individual ribosomal subunits dissociate in order to be used again.

---

## PROTEIN SYNTHESIS

### 2.6.3 Special mechanisms control the accuracy of protein synthesis

---

#### Key Concepts

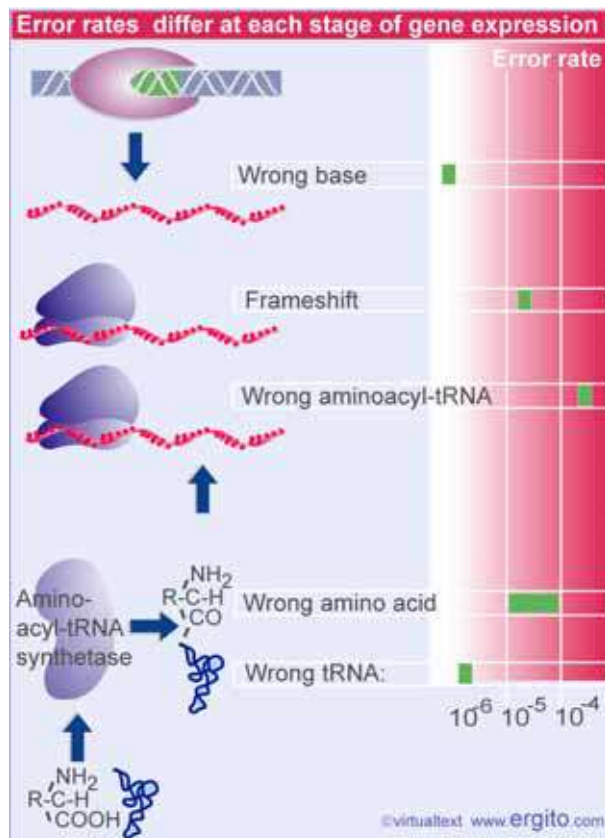

- The accuracy of protein synthesis is controlled by specific mechanisms at each stage.
- 

We know that protein synthesis is generally accurate, because of the consistency that is found when we determine the sequence of a protein. There are few detailed measurements of the error rate *in vivo*, but it is generally thought to lie in the range of 1 error for every  $10^4$  -  $10^5$  amino acids incorporated. Considering that most proteins are produced in large quantities, this means that the error rate is too low to have any effect on the phenotype of the cell.

It is not immediately obvious how such a low error rate is achieved. In fact, the nature of discriminatory events is a general issue raised by several steps in gene expression. How do synthetases recognize just the corresponding tRNAs and amino acids? How does a ribosome recognize only the tRNA corresponding to the codon in the A site? How do the enzymes that synthesize DNA or RNA recognize only the base complementary to the template? Each case poses a similar problem: how to distinguish one particular member from the entire set, all of which share the same general features.

Probably any member initially can contact the active center by a random-hit process, but then the wrong members are rejected and only the appropriate one is accepted. The appropriate member is always in a minority (1 of 20 amino acids, 1 of ~40 tRNAs, 1 of 4 bases), so the criteria for discrimination must be strict. The point is that the enzyme must have some mechanism for increasing discrimination from the level that would be achieved merely by making contacts with the available surfaces of the substrates.

**Figure 6.8** summarizes the error rates at the steps that can affect the accuracy of protein synthesis.

**Figure 6.8** Errors occur at rates from  $10^{-6}$  to  $5 \times 10^{-4}$  at different stages of protein synthesis.

Errors in transcribing mRNA are rare – probably  $< 10^{-6}$ . This is an important stage to control, because a single mRNA molecule is translated into many protein copies. We do not know very much about the mechanisms.

The ribosome can make two types of errors in protein synthesis. It may cause a frameshift by skipping a base when it reads the mRNA (or in the reverse direction by reading a base twice, once as the last base of one codon and then again as the first base of the next codon). These errors are rare,  $\sim 10^{-5}$ . Or it may allow an incorrect aminoacyl-tRNA to (mis)pair with a codon, so that the wrong amino acid is incorporated. This is probably the most common error in protein synthesis,  $\sim 5 \times 10^{-4}$ . It is controlled by ribosome structure and velocity (see *Molecular Biology 2.7.15 The ribosome influences the accuracy of translation*).

A tRNA synthetase can make two types of error. It can place the wrong amino acid on its tRNA; or it can charge its amino acid with the wrong tRNA. The incorporation of the wrong amino acid is more common, probably because the tRNA offers a larger surface with which the enzyme can make many more contacts to ensure specificity. Aminoacyl-tRNA synthetases have specific mechanisms to correct errors before a mischarged tRNA is released (see *Molecular Biology 2.7.11 Synthetases use proofreading to improve accuracy*).

## PROTEIN SYNTHESIS

### 2.6.4 Initiation in bacteria needs 30S subunits and accessory factors

---

#### Key Terms

A **ribosome-binding site** is a sequence on bacterial mRNA that includes an initiation codon that is bound by a 30S subunit in the initiation phase of protein synthesis.

An **initiation complex** in bacterial protein synthesis contains a small ribosome subunit, initiation factors, and initiator aminoacyl-tRNA bound to mRNA at an AUG initiation codon.

**Initiation factors (IF)** (IF in prokaryotes, eIF in eukaryotes) are proteins that associate with the small subunit of the ribosome specifically at the stage of initiation of protein synthesis.

**IF-1** is a bacterial initiation factor that stabilizes the initiation complex.

**IF-2** is a bacterial initiation factor that binds the initiator tRNA to the initiation complex.

**IF-3** is a bacterial initiation factor required for 30S subunits to bind to initiation sites in mRNA. It also prevents 30S subunits from binding to 50S subunits.

#### Key Concepts

- Initiation of protein synthesis requires separate 30S and 50S ribosome subunits.
- Initiation factors (IF-1,2,3), which bind to 30S subunits, are also required.
- A 30S subunit carrying initiation factors binds to an initiation site on mRNA to form an initiation complex.
- IF-3 must be released to allow 50S subunits to join the 30S-mRNA complex.

---

Bacterial ribosomes engaged in elongating a polypeptide chain exist as 70S particles. At termination, they are released from the mRNA as free ribosomes. In growing bacteria, the majority of ribosomes are synthesizing proteins; the free pool is likely to contain ~20% of the ribosomes.

Ribosomes in the free pool can dissociate into separate subunits; so 70S ribosomes are in dynamic equilibrium with 30S and 50S subunits. *Initiation of protein synthesis is not a function of intact ribosomes, but is undertaken by the separate subunits, which reassociate during the initiation reaction.* **Figure 6.9** summarizes the ribosomal subunit cycle during protein synthesis in bacteria.

**Figure 6.9** Initiation requires free ribosome subunits. When ribosomes are released at termination, the 30S subunits bind initiation factors, and dissociate to generate free subunits. When subunits reassociate to give a functional ribosome at initiation, they release the factors.

*This is a static version of an interactive figure; see <http://www.ergito.com/main.jsp?bcs=MBIO.2.6.4> to view properly.*

Initiation occurs at a special sequence on mRNA called the **ribosome-binding site**. This is a short sequence of bases that precedes the coding region (see **Figure 6.16**). The small and large subunits associate at the ribosome-binding site to form an intact ribosome. The reaction occurs in two steps:

- Recognition of mRNA occurs when a small subunit binds to form an **initiation complex** at the ribosome-binding site.
- Then a large subunit joins the complex to generate a complete ribosome.

Although the 30S subunit is involved in initiation, it is not by itself competent to undertake the reactions of binding mRNA and tRNA. It requires additional proteins called **initiation factors (IF)**. These factors are found only on 30S subunits, and they are released when the 30S subunits associate with 50S subunits to generate 70S ribosomes. This behavior distinguishes initiation factors from the structural proteins of the ribosome. The initiation factors are concerned solely with formation of the initiation complex, they are absent from 70S ribosomes, and they play no part in the stages of elongation (for review see 428). **Figure 6.10** summarizes the stages of initiation.

**Figure 6.10** Initiation factors stabilize free 30S subunits and bind initiator tRNA to the 30S-mRNA complex.

This is a static version of an interactive figure; see <http://www.ergito.com/main.jsp?bcs=MBIO.2.6.4> to view properly.

Bacteria use three initiation factors, numbered **IF-1**, **IF-2**, and **IF-3**. They are needed for both mRNA and tRNA to enter the initiation complex:

- IF-3 is needed for 30S subunits to bind specifically to initiation sites in mRNA.
- IF-2 binds a special initiator tRNA and controls its entry into the ribosome.
- IF-1 binds to 30S subunits only as a part of the complete initiation complex. It binds to the A site and prevents aminoacyl-tRNA from entering (3053). Its location also may impede the 30S subunit from binding to the 50S subunit (2391).

IF-3 has multiple functions: it is needed first to stabilize (free) 30S subunits; then it enables them to bind to mRNA; and as part of the 30S-mRNA complex it checks the accuracy of recognition of the first aminoacyl-tRNA (see *Molecular Biology 2.6.6 Use of  $fMet$ -tRNA<sub>f</sub> is controlled by IF-2 and the ribosome.*

The first function of IF-3 controls the equilibrium between ribosomal states, as shown in **Figure 6.11**. IF-3 binds to free 30S subunits that are released from the pool of 70S ribosomes. The presence of IF-3 prevents the 30S subunit from reassociating with a 50S subunit. The reaction between IF-3 and the 30S subunit is stoichiometric: one molecule of IF-3 binds per subunit. There is a relatively small amount of IF-3, so its availability determines the number of free 30S subunits.

**Figure 6.11** Initiation requires 30S subunits that carry IF-3.

IF-3 binds to the surface of the 30S subunit in the vicinity of the A site. There is significant overlap between the bases in 16S rRNA protected by IF-3 and those protected by binding of the 50S subunit, suggesting that it physically prevents junction of the subunits (3054). IF-3 therefore behaves as an anti-association factor that causes a 30S subunit to remain in the pool of free subunits.

The second function of IF-3 controls the ability of 30S subunits to bind to mRNA. Small subunits must have IF-3 in order to form initiation complexes with mRNA. IF-3 must be released from the 30S-mRNA complex in order to enable the 50S subunit to join. On its release, IF-3 immediately recycles by finding another 30S subunit.

IF-2 has a ribosome-dependent GTPase activity: it sponsors the hydrolysis of GTP in the presence of ribosomes, releasing the energy stored in the high-energy bond. The GTP is hydrolyzed when the 50S subunit joins to generate a complete ribosome. The GTP cleavage could be involved in changing the conformation of the ribosome, so that the joined subunits are converted into an active 70S ribosome.

## PROTEIN SYNTHESIS

### 2.6.5 A special initiator tRNA starts the polypeptide chain

---

#### Key Terms

The **initiation codon** is a special codon (usually AUG) used to start synthesis of a protein.

**N-formyl-methionyl-tRNA** ( $\text{tRNA}_f^{\text{Met}}$ ) is the aminoacyl-tRNA that initiates bacterial protein synthesis. The amino group of the methionine is formylated.

$\text{tRNA}_f^{\text{Met}}$  is the special RNA that is to initiate protein synthesis in bacteria. It mostly uses AUG, but can also respond to GUG and CUG.

$\text{tRNA}_m^{\text{Met}}$  inserts methionine at internal AUG codons.

#### Key Concepts

- Protein synthesis starts with a methionine amino acid usually coded by AUG.
- Different methionine tRNAs are involved in initiation and elongation.
- The initiator tRNA has unique structural features that distinguish it from all other tRNAs.
- The  $\text{NH}_2$  group of the methionine bound to bacterial initiator tRNA is formylated.

---

Synthesis of all proteins starts with the same amino acid: methionine. The signal for initiating a polypeptide chain is a special **initiation codon** that marks the start of the reading frame. Usually the initiation codon is the triplet AUG, but in bacteria, GUG or UUG are also used.

The AUG codon represents methionine, and two types of tRNA can carry this amino acid. One is used for initiation, the other for recognizing AUG codons during elongation.

In bacteria and in eukaryotic organelles, the initiator tRNA carries a methionine residue that has been formylated on its amino group, forming a molecule of **N-formyl-methionyl-tRNA**. The tRNA is known as  $\text{tRNA}_f^{\text{Met}}$ . The name of the aminoacyl-tRNA is usually abbreviated to fMet-tRNA<sub>f</sub> (3057).

The initiator tRNA gains its modified amino acid in a two stage reaction. First, it is charged with the amino acid to generate Met-tRNA<sub>f</sub>; then the formylation reaction shown in **Figure 6.12** blocks the free  $\text{NH}_2$  group. Although the blocked amino acid group would prevent the initiator from participating in chain elongation, it does not interfere with the ability to initiate a protein.

**Figure 6.12** The initiator N-formyl-methionyl-tRNA (fMet-tRNA<sub>f</sub>) is generated by formylation of methionyl-tRNA, using formyl-tetrahydrofolate as cofactor.

This tRNA is used only for initiation. It recognizes the codons AUG or GUG (occasionally UUG). The codons are not recognized equally well: the extent of initiation declines about half when AUG is replaced by GUG, and declines by about half again when UUG is employed.

The species responsible for recognizing AUG codons in internal locations is **tRNA<sub>Met</sub><sup>m</sup>**. This tRNA responds only to internal AUG codons. Its methionine cannot be formylated.

What features distinguish the fMet-tRNA<sub>f</sub> initiator and the Met-tRNA<sub>m</sub> elongator? Some characteristic features of the tRNA<sub>f</sub> sequence are important, as summarized in **Figure 6.13**. Some of these features are needed to prevent the initiator from being used in elongation, others are necessary for it to function in initiation:

**Figure 6.13** fMet-tRNA<sub>f</sub> has unique features that distinguish it as the initiator tRNA.

- Formylation is not strictly necessary, because nonformylated Met-tRNA<sub>f</sub> can function as an initiator, but it improves the efficiency with which the Met-tRNA<sub>f</sub> is used, because it is one of the features recognized by the factor IF-2 that binds the initiator tRNA (3056).
- The bases that face one another at the last position of the stem to which the amino acid is connected are paired in all tRNAs except tRNA<sub>f</sub><sup>Met</sup>. Mutations that create a base pair in this position of tRNA<sub>f</sub><sup>Met</sup> allow it to function in elongation. The absence of this pair is therefore important in preventing tRNA<sub>f</sub><sup>Met</sup> from being used in elongation. It is also needed for the formylation reaction (3058).
- A series of 3 G-C pairs in the stem that precedes the loop containing the anticodon is unique to tRNA<sub>f</sub><sup>Met</sup>. These base pairs are required to allow the fMet-tRNA<sub>f</sub> to be inserted directly into the P site.

In bacteria and mitochondria, the formyl residue on the initiator methionine is removed by a specific deformylase enzyme to generate a normal NH<sub>2</sub> terminus. If methionine is to be the N-terminal amino acid of the protein, this is the only necessary step. In about half the proteins, the methionine at the terminus is removed by an aminopeptidase, creating a new terminus from R<sub>2</sub> (originally the second amino acid incorporated into the chain). When both steps are necessary, they occur sequentially. The removal reaction(s) occur rather rapidly, probably when the nascent polypeptide chain has reached a length of 15 amino acids.

**PROTEIN SYNTHESIS****2.6.6 Use of fMet-tRNA<sub>f</sub> is controlled by IF-2 and the ribosome**

---

**Key Terms**

The **context** of a codon in mRNA refers to the fact that neighboring sequences may change the efficiency with which a codon is recognized by its aminoacyl-tRNA or is used to terminate protein synthesis.

**Key Concepts**

- IF-2 binds the initiator fMet-tRNA<sub>f</sub> and allows it to enter the partial P site on the 30S subunit.

---

The meaning of the AUG and GUG codons depends on their **context**. When the AUG codon is used for initiation, it is read as formyl-methionine; when used within the coding region, it represents methionine. The meaning of the GUG codon is even more dependent on its location. When present as the first codon, it is read via the initiation reaction as formyl-methionine. Yet when present within a gene, it is read by Val-tRNA, one of the regular members of the tRNA set, to provide valine as required by the genetic code.

How is the context of AUG and GUG codons interpreted? **Figure 6.14** illustrates the decisive role of the ribosome, in conjunction with accessory factors.

**Figure 6.14** Only fMet-tRNA<sub>f</sub> can be used for initiation by 30S subunits; only other aminoacyl-tRNAs (α-tRNA) can be used for elongation by 70S ribosomes.

In an initiation complex, the small subunit alone is bound to mRNA. The initiation codon lies within the part of the P site carried by the small subunit. The only aminoacyl-tRNA that can become part of the initiation complex is the initiator, which has the unique property of being able to enter directly into the partial P site to recognize its codon.

When the large subunit joins the complex, the partial tRNA-binding sites are converted into the intact P and A sites. The initiator fMet-tRNA<sub>f</sub> occupies the P site, and the A site is available for entry of the aminoacyl-tRNA complementary to the second codon of the gene. The first peptide bond forms between the initiator and the next aminoacyl-tRNA.

Initiation prevails when an AUG (or GUG) codon lies within a ribosome-binding site, because only the initiator tRNA can enter the partial P site generated when the 30S subunit binds *de novo* to the mRNA. Internal reading prevails subsequently, when the codons are encountered by a ribosome that is continuing to translate an mRNA, because only the regular aminoacyl-tRNAs can enter the (complete) A site.

Accessory factors are critical in controlling the usage of aminoacyl-tRNAs. All aminoacyl-tRNAs associate with the ribosome by binding to an accessory factor. The factor used in initiation is IF-2 (see *Molecular Biology 2.6.4 Initiation in bacteria needs 30S subunits and accessory factors*), and the corresponding factor used at elongation is EF-Tu (see *Molecular Biology 2.6.10 Elongation factor Tu loads*

*aminoacyl-tRNA into the A site).*

The initiation factor IF-2 places the initiator tRNA into the P site. By forming a complex specifically with fMet-tRNA<sub>f</sub>, IF-2 ensures that only the initiator tRNA, and none of the regular aminoacyl-tRNAs, participates in the initiation reaction. Conversely, EF-Tu, which places aminoacyl-tRNAs in the A site cannot bind fMet-tRNA<sub>f</sub>, which is therefore excluded from use during elongation.

An additional check on accuracy is made by IF-3, which stabilizes binding of the initiator tRNA by recognizing correct base pairing with the second and third bases of the AUG initiation codon.

**Figure 6.15** details the series of events by which IF-2 places the fMet-tRNA<sub>f</sub> initiator in the P site. IF-2, bound to GTP, associates with the P site of the 30S subunit. At this point, the 30S subunit carries all the initiation factors. fMet-tRNA<sub>f</sub> then binds to the IF-2 on the 30S subunit. IF-2 then transfers the tRNA into the partial P site.

**Figure 6.15** IF-2 is needed to bind fMet-tRNA<sub>f</sub> to the 30S-mRNA complex. After 50S binding, all IF factors are released and GTP is cleaved.

## PROTEIN SYNTHESIS

### 2.6.7 Initiation involves base pairing between mRNA and rRNA

---

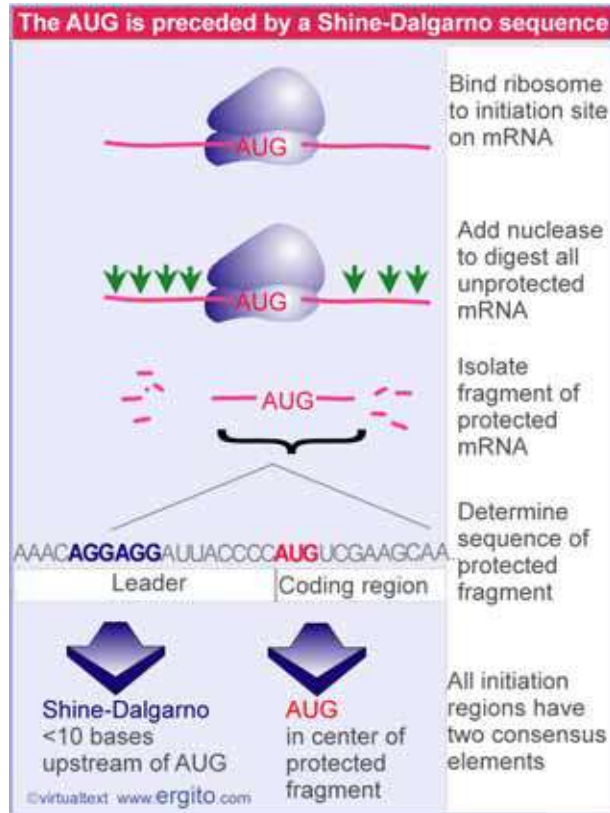

#### Key Terms

The **Shine-Dalgarno** sequence is the polypurine sequence AGGAGG centered about 10 bp before the AUG initiation codon on bacterial mRNA. It is complementary to the sequence at the 3' end of 16S rRNA.

#### Key Concepts

- An initiation site on bacterial mRNA consists of the AUG initiation codon preceded with a gap of ~10 bases by the Shine-Dalgarno polypurine hexamer.
  - The rRNA of the 30S bacterial ribosomal subunit has a complementary sequence that base pairs with the Shine-Dalgarno sequence during initiation.
- 

An mRNA contains many AUG triplets: how is the initiation codon recognized as providing the starting point for translation? The sites on mRNA where protein synthesis is initiated can be identified by binding the ribosome to mRNA under conditions that block elongation. Then the ribosome remains at the initiation site. When ribonuclease is added to the blocked initiation complex, all the regions of mRNA outside the ribosome are degraded, but those actually bound to it are protected, as illustrated in **Figure 6.16**. The protected fragments can be recovered and characterized.

**Figure 6.16** Ribosome-binding sites on mRNA can be recovered from initiation complexes. They include the upstream Shine-Dalgarno sequence and the initiation codon.

The initiation sequences protected by bacterial ribosomes are ~30 bases long. The ribosome-binding sites of different bacterial mRNAs display two common features:

- The AUG (or less often, GUG or UUG) initiation codon is always included within the protected sequence.
- Within 10 bases upstream of the AUG is a sequence that corresponds to part or all of the hexamer.

5' ... A G G A G G ... 3'

This polypurine stretch is known as the **Shine-Dalgarno** sequence. It is complementary to a highly conserved sequence close to the 3' end of 16S rRNA. (The extent of complementarity differs with individual mRNAs, and may extend from a 4-base core sequence GAGG to a 9-base sequence extending beyond each end of the hexamer.) Written in reverse direction, the rRNA sequence is the hexamer:

3' ... U C C U C C ... 5'

Does the Shine-Dalgarno sequence pair with its complement in rRNA during mRNA-ribosome binding? Mutations of both partners in this reaction demonstrate its

importance in initiation. Point mutations in the Shine-Dalgarno sequence can prevent an mRNA from being translated. And the introduction of mutations into the complementary sequence in rRNA is deleterious to the cell and changes the pattern of protein synthesis. The decisive confirmation of the base pairing reaction is that a mutation in the Shine-Dalgarno sequence of an mRNA can be suppressed by a mutation in the rRNA that restores base pairing (see *Great Experiments 4.8 rRNA-mRNA base pairing selects translational initiator regions in bacteria*).

The sequence at the 3' end of rRNA is conserved between prokaryotes and eukaryotes except that in all eukaryotes there is a deletion of the five-base sequence CCUCC that is the principal complement to the Shine-Dalgarno sequence. There does not appear to be base pairing between eukaryotic mRNA and 18S rRNA. This is a significant difference in the mechanism of initiation.

In bacteria, a 30S subunit binds directly to a ribosome-binding site. As a result, the initiation complex forms at a sequence surrounding the AUG initiation codon. When the mRNA is polycistronic, each coding region starts with a ribosome-binding site.

The nature of bacterial gene expression means that translation of a bacterial mRNA proceeds sequentially through its cistrons. At the time when ribosomes attach to the first coding region, the subsequent coding regions have not yet even been transcribed. By the time the second ribosome site is available, translation is well under way through the first cistron.

What happens between the coding regions depends on the individual mRNA. Probably in most cases the ribosomes bind independently at the beginning of each cistron. The most common series of events is illustrated in **Figure 6.17**. When synthesis of the first protein terminates, the ribosomes leave the mRNA and dissociate into subunits. Then a new ribosome must assemble at the next coding region, and set out to translate the next cistron.

**Figure 6.17** Initiation occurs independently at each cistron in a polycistronic mRNA. When the intercistronic region is longer than the span of the ribosome, dissociation at the termination site is followed by independent reinitiation at the next cistron.

This is a static version of an interactive figure; see <http://www.ergito.com/main.jsp?bcs=MBIO.2.6.7> to view properly.

In some bacterial mRNAs, translation between adjacent cistrons is directly linked, because ribosomes gain access to the initiation codon of the second cistron as they complete translation of the first cistron. This effect requires the space between the two coding regions to be small. It may depend on the high local density of ribosomes; or the juxtaposition of termination and initiation sites could allow some of the usual intercistronic events to be bypassed. A ribosome physically spans ~30 bases of mRNA, so that it could simultaneously contact a termination codon and the next initiation site if they are separated by only a few bases.

## PROTEIN SYNTHESIS

### 2.6.8 Small subunits scan for initiation sites on eukaryotic mRNA

---

#### Key Concepts

- Eukaryotic 40S ribosomal subunits bind to the 5' end of mRNA and scan the mRNA until they reach an initiation site.
  - A eukaryotic initiation site consists of a 10 nucleotide sequence that includes an AUG codon.
  - 60S ribosomal subunits join the complex at the initiation site.
- 

Initiation of protein synthesis in eukaryotic cytoplasm resembles the process in bacteria, but the order of events is different, and the number of accessory factors is greater. Some of the differences in initiation are related to a difference in the way that bacterial 30S and eukaryotic 40S subunits find their binding sites for initiating protein synthesis on mRNA. In eukaryotes, small subunits first recognize the 5' end of the mRNA, and then move to the initiation site, where they are joined by large subunits. (In prokaryotes, small subunits bind directly to the initiation site.)

Virtually all eukaryotic mRNAs are monocistronic, but each mRNA usually is substantially longer than necessary just to code for its protein. The average mRNA in eukaryotic cytoplasm is 1000-2000 bases long, has a methylated cap at the 5' terminus, and carries 100-200 bases of poly(A) at the 3' terminus.

The nontranslated 5' leader is relatively short, usually <100 bases. The length of the coding region is determined by the size of the protein. The nontranslated 3' trailer is often rather long, sometimes ~1000 bases.

The first feature to be recognized during translation of a eukaryotic mRNA is the methylated cap that marks the 5' end. Messengers whose caps have been removed are not translated efficiently *in vitro*. Binding of 40S subunits to mRNA requires several initiation factors, including proteins that recognize the structure of the cap.

Modification at the 5' end occurs to almost all cellular or viral mRNAs, and is essential for their translation in eukaryotic cytoplasm (although it is not needed in organelles). The sole exception to this rule is provided by a few viral mRNAs (such as poliovirus) that are not capped; only these exceptional viral mRNAs can be translated *in vitro* without caps. They use an alternative pathway that bypasses the need for the cap.

Some viruses take advantage of this difference. Poliovirus infection inhibits the translation of host mRNAs. This is accomplished by interfering with the cap binding proteins that are needed for initiation of cellular mRNAs, but that are superfluous for the noncapped poliovirus mRNA.

We have dealt with the process of initiation as though the ribosome-binding site is always freely available. However, its availability may be impeded by secondary structure. The recognition of mRNA requires several additional factors; an important part of their function is to remove any secondary structure in the mRNA (see **Figure 6.20**).

Sometimes the AUG initiation codon lies within 40 bases of the 5' terminus of the mRNA, so that both the cap and AUG lie within the span of ribosome binding. But in many mRNAs the cap and AUG are farther apart, in extreme cases ~1000 bases distant. Yet the presence of the cap still is necessary for a stable complex to be formed at the initiation codon. How can the ribosome rely on two sites so far apart?

**Figure 6.18** illustrates the "scanning" model, which supposes that the 40S subunit initially recognizes the 5' cap and then "migrates" along the mRNA. Scanning from the 5' end is a linear process. When 40S subunits scan the leader region, they can melt secondary structure hairpins with stabilities <-30 kcal, but hairpins of greater stability impede or prevent migration.

**Figure 6.18** Eukaryotic ribosomes migrate from the 5' end of mRNA to the ribosome binding site, which includes an AUG initiation codon.

*This is a static version of an interactive figure; see <http://www.ergito.com/main.jsp?bcs=MBIO.2.6.8> to view properly.*

Migration stops when the 40S subunit encounters the AUG initiation codon. Usually, although not always, the first AUG triplet sequence to be encountered will be the

initiation codon. However, the AUG triplet by itself is not sufficient to halt migration; it is recognized efficiently as an initiation codon only when it is in the right context. The most important determinants of context are the bases in positions -4 and +1. An initiation codon may be recognized in the sequence NNNPuNNAUGG. The purine (A or G) 3 bases before the AUG codon, and the G immediately following it, can influence the efficiency of translation by 10×. When the leader sequence is long, further 40S subunits can recognize the 5' end before the first has left the initiation site, creating a queue of subunits proceeding along the leader to the initiation site (427; for review see 429).

It is probably true that the initiation codon is the first AUG to be encountered in the most efficiently translated mRNAs. But what happens when there is an AUG triplet in the 5' nontranslated region? There are two possible escape mechanisms for a ribosome that starts scanning at the 5' end. The most common is that scanning is leaky, that is, a ribosome may continue past a non-initiation AUG because it is not in the right context. In the rare case that it does recognize the AUG, it may initiate translation but terminate before the proper initiation codon, after which it resumes scanning.

The vast majority of eukaryotic initiation events involve scanning from the 5' cap, but there is an alternative means of initiation, used especially by certain viral RNAs, in which a 40S subunit associates directly with an internal site called an IRES (for review see 2242). (This entirely bypasses any AUG codons that may be in the 5' nontranslated region.) There are few sequence homologies between known IRES elements. We can distinguish three types on the basis of their interaction with the 40S subunit:

- One type of IRES includes the AUG initiation codon at its upstream boundary. The 40S subunit binds directly to it, using a subset of the same factors that are required for initiation at 5' ends (2244; 2245).
- Another is located as much as 100 nucleotides upstream of the AUG, requiring a 40S subunit to migrate, again probably by a scanning mechanism.
- An exceptional type of IRES in hepatitis C virus can bind a 40S subunit directly, without requiring any initiation factors (2243). The order of events is different from all other eukaryotic initiation. Following 40S - mRNA binding, a complex containing initiator factors and the initiator tRNA binds.

Use of the IRES is especially important in picornavirus infection, where it was first discovered, because the virus inhibits host protein synthesis by destroying cap structures and inhibiting the initiation factors that bind them (see *Molecular Biology 2.6.9 Eukaryotes use a complex of many initiation factors*)(995).

Binding is stabilized at the initiation site. When the 40S subunit is joined by a 60S subunit, the intact ribosome is located at the site identified by the protection assay. A 40S subunit protects a region of up to 60 bases; when the 60S subunits join the complex, the protected region contracts to about the same length of 30-40 bases seen in prokaryotes.

**PROTEIN SYNTHESIS****2.6.9 Eukaryotes use a complex of many initiation factors**

---

**Key Terms**

**tRNA<sub>i</sub><sup>Met</sup>** is the special tRNA used to respond to initiation codons in eukaryotes.

**Key Concepts**

- Initiation factors are required for all stages of initiation, including binding the initiator tRNA, 40S subunit attachment to mRNA, movement along the mRNA, and joining of the 60S subunit.
- Eukaryotic initiator tRNA is a Met-tRNA that is different from the Met-tRNA used in elongation, but the methionine is not formylated.
- eIF2 binds the initiator Met-tRNA<sub>i</sub> and GTP, and the complex binds to the 40S subunit before it associates with mRNA.

---

Initiation in eukaryotes has the same general features as in bacteria in using a specific initiation codon and initiator tRNA. Initiation in eukaryotic cytoplasm uses AUG as the initiator. The initiator tRNA is a distinct species, but its methionine does not become formylated. It is called **tRNA<sub>i</sub><sup>Met</sup>**. So the difference between the initiating and elongating Met-tRNAs lies solely in the tRNA moiety, with Met-tRNA<sub>i</sub> used for initiation and Met-tRNA<sub>m</sub> used for elongation.

At least two features are unique to the initiator tRNA<sub>i</sub><sup>Met</sup> in yeast; it has an unusual tertiary structure; and it is modified by phosphorylation of the 2' ribose position on base 64 (if this modification is prevented, the initiator can be used in elongation). So the principle of a distinction between initiator and elongator Met-tRNAs is maintained in eukaryotes, but its structural basis is different from that in bacteria (for comparison see **Figure 6.13**).

Eukaryotic cells have more initiation factors than bacteria – the current list includes 12 factors that are directly or indirectly required for initiation (for review see 2393). The factors are named similarly to those in bacteria, sometimes by analogy with the bacterial factors, and are given the prefix "e" to indicate their eukaryotic origin. They act at all stages of the process, including:

- forming an initiation complex with the 5' end of mRNA
- forming a complex with Met-tRNA<sub>i</sub>
- binding the mRNA-factor complex to the Met-tRNA<sub>i</sub>-factor complex
- enabling the ribosome to scan mRNA from the 5' end to the first AUG

- detecting binding of initiator tRNA to AUG at the start site
- mediating joining of the 60S subunit.

**Figure 6.19** summarizes the stages of initiation, and shows which initiation factors are involved at each stage. eIF2 and eIF3 bind to the 40S ribosome subunit. eIF4A, eIF4B, eIF4F bind to the mRNA. eIF1 and eIF1A bind to the ribosome subunit-mRNA complex (for review see 2840).

**Figure 6.19** Some initiation factors bind to the 40S ribosome subunit to form the 43S complex; others bind to mRNA. When the 43S complex binds to mRNA, it scans for the initiation codon and can be isolated as the 48S complex.

**Figure 6.20** shows the group of factors that bind to the 5' end of mRNA. The factor eIF4F is a protein complex that contains three of the initiation factors (for review see 994). It is not clear whether it preassembles as a complex before binding to mRNA or whether the individual subunits are added individually to form the complex on mRNA. It includes the cap-binding subunit eIF4E, the helicase eIF4A, and the "scaffolding" subunit eIF4G. After eIF4E binds the cap, eIF4A unwinds any secondary structure that exists in the first 15 bases of the mRNA. Energy for the unwinding is provided by hydrolysis of ATP. Unwinding of structure farther along the mRNA is accomplished by eIF4A together with another factor, eIF4B. The main role of eIF4G is to link other components of the initiation complex.

**Figure 6.20** The heterotrimer eIF4F binds the 5' end of mRNA and also binds further factors.

eIF4E is a focus for regulation. Its activity is increased by phosphorylation, which is triggered by stimuli that increase protein synthesis, and reversed by stimuli that repress protein synthesis. eIF4F has a kinase activity that phosphorylates eIF4E. The availability of eIF4E is also controlled by proteins that bind to it (called 4E-BP1,2,3), to prevent it from functioning in initiation. eIF4G is also a target for degradation during picornavirus infection, as part of the destruction of the capacity to initiate at 5' cap structures (see *Molecular Biology 2.6.8 Small subunits scan for initiation sites on eukaryotic mRNA*).

The presence of poly(A) on the 3' tail of an mRNA stimulates the formation of an initiation complex at the 5' end. The poly(A)-binding protein (Pab1p in yeast) is required for this effect. Pab1p binds to the eIF4G scaffolding protein(2309). This implies that the mRNA will have a circular organization so long as eIF4G is bound, with both the 5' and 3' ends held in this complex (see **Figure 6.20**) (for review see 439). The significance of the formation of this closed loop is not clear, although it could have several effects, such as:

- stimulating initiation of translation;
- promoting reinitiation of ribosomes, so that when they terminate at the 3' end, the released subunits are already in the vicinity of the 5' end;
- stabilizing the mRNA against degradation;
- allowing factors that bind to the 3' end to regulate the initiation of translation.

eIF2 is the key factor in binding Met-tRNA<sub>i</sub>. It is a typical monomeric GTP-binding protein that is active when bound to GTP, and inactive when bound to GDP (see *Molecular Biology Supplement 32.10 G proteins*). **Figure 6.21** shows that the eIF2-GTP binds to Met-tRNA<sub>i</sub> (1865). The product is sometimes called the ternary complex (after its three components, eIF2, GTP, Met-tRNA<sub>i</sub>).

**Figure 6.21** In eukaryotic initiation, eIF-2 forms a ternary complex with Met-tRNA. The ternary complex binds to free 40S subunits, which attach to the 5' end of mRNA. Later in the reaction, GTP is hydrolyzed when eIF-2 is released in the form of eIF-2-GDP. eIF-2B regenerates the active form.

**Figure 6.22** shows that the ternary complex places Met-tRNA<sub>i</sub> onto the 40S subunit. This generates the 43S initiation complex. The reaction is independent of the presence of mRNA. In fact, the Met-tRNA<sub>i</sub> initiator must be present in order for the 40S subunit to bind to mRNA (for review<sup>1</sup> see 435; 438). One of the factors in this complex is eIF3, which is required to maintain 40S subunits in their dissociated state. eIF3 is a very large factor, with 8-10 subunits.

**Figure 6.22** Initiation factors bind the initiator Met-tRNA to the 40S subunit to form a 43S complex. Later in the reaction, GTP is hydrolyzed when eIF-2 is released in the form of eIF2-GDP. eIF-2B regenerates the active form.

The next step is for the 43S complex to bind to the 5' end of the mRNA. **Figure 6.23** shows that the interactions involved at this stage are not completely defined, but probably involve eIF4G and eIF3 as well as the mRNA and 40S subunit. eIF4G binds to eIF3. This provides the means by which the 40S ribosomal subunit binds to eIF4F, and thus is recruited to the complex. In effect, eIF4F functions to get eIF4G in place so that it can attract the small ribosomal subunit.

**Figure 6.23** Interactions involving initiation factors are important when mRNA binds to the 43S complex.

When the small subunit has bound mRNA, it migrates to (usually) the first AUG codon. This requires expenditure of energy in the form of ATP. It is assisted by the factors eIF1 and eIF1A. **Figure 6.24** shows that the small subunit stops when it reaches the initiation site, forming a 48S complex.

**Figure 6.24** eIF1 and eIF1A help the 43S initiation complex to scan the mRNA until it reaches an AUG codon. eIF2 hydrolyzes its GTP to enable its release together with eIF3. eIF5B mediates 60S-40S joining.

Junction of the 60S subunits with the initiation complex cannot occur until eIF2 and eIF3 have been released from the initiation complex. This is mediated by eIF5, and causes eIF2 to hydrolyze its GTP. The reaction occurs on the small ribosome subunit, and requires the initiator tRNA to be base paired with the AUG initiation codon (2839). Probably all of the remaining factors are released when the complete 80S ribosome is formed.

Finally the factor eIF5B enables the 60S subunit to join the complex, forming an intact ribosome that is ready to start elongation (2241). eIF5B has a similar sequence to the prokaryotic factor IF2, which has a similar role in hydrolyzing GTP (in addition to its role in binding the initiator tRNA).

Once the factors have been released, they can associate with the initiator tRNA and ribosomal subunits in another initiation cycle. Because eIF2 has hydrolyzed its GTP, the active form must be regenerated. This is accomplished by another factor, eIF2B, which displaces the GDP so that it can be replaced by GTP.

eIF2 is a target for regulation. Several regulatory kinases act on the  $\alpha$  subunit of eIF2. Phosphorylation prevents eIF2B from regenerating the active form. This limits the action of eIF2B to one cycle of initiation, and thereby inhibits protein synthesis (for review see 2393).

## PROTEIN SYNTHESIS

### 2.6.10 Elongation factor Tu loads aminoacyl-tRNA into the A site

---

#### Key Terms

**Elongation factors** (EF in prokaryotes, eEF in eukaryotes) are proteins that associate with ribosomes cyclically, during addition of each amino acid to the polypeptide chain.

**EF-Tu** is the elongation factor that binds aminoacyl-tRNA and places it into the A site of a bacterial ribosome.

**GMP-PCP** is an analog of GTP that cannot be hydrolyzed. It is used to test which stage in a reaction requires hydrolysis of GTP.

**Kirromycin** is an antibiotic that inhibits protein synthesis by acting on EF-Tu.

#### Key Concepts

- EF-Tu is a monomeric G protein whose active form (bound to GTP) binds aminoacyl-tRNA.
- The EF-Tu·GTP·aminoacyl-tRNA complex binds to the ribosome A site.

---

Once the complete ribosome is formed at the initiation codon, the stage is set for a cycle in which aminoacyl-tRNA enters the A site of a ribosome whose P site is occupied by peptidyl-tRNA. Any aminoacyl-tRNA except the initiator can enter the A site. Its entry is mediated by an **elongation factor (EF-Tu in bacteria)**. The process is similar in eukaryotes. EF-Tu is a highly conserved protein throughout bacteria and mitochondria, and is homologous to its eukaryotic counterpart.

Just like its counterpart in initiation (IF-2), EF-Tu is associated with the ribosome only during the process of aminoacyl-tRNA entry. Once the aminoacyl-tRNA is in place, EF-Tu leaves the ribosome, to work again with another aminoacyl-tRNA. So it displays the cyclic association with, and dissociation from, the ribosome that is the hallmark of the accessory factors.

The pathway for aminoacyl-tRNA entry to the A site is illustrated in **Figure 6.25**. EF-Tu carries a guanine nucleotide. The factor is a monomeric G protein whose activity is controlled by the state of the guanine nucleotide (see introduction on *Molecular Biology Supplement 32.10 G proteins*):

**Figure 6.25** EF-Tu-GTP places aminoacyl-tRNA on the ribosome and then is released as EF-Tu-GDP. EF-Ts is required to mediate the replacement of GDP by GTP. The reaction consumes GTP and releases GDP. The only aminoacyl-tRNA that cannot be recognized by EF-Tu-GTP is fMet-tRNA<sub>f</sub>, whose failure to bind prevents it from responding to internal AUG or GUG codons.

- When GTP is present, the factor is in its active state.
- When the GTP is hydrolyzed to GDP, the factor becomes inactive.
- Activity is restored when the GDP is replaced by GTP.

The binary complex of EF-Tu-GTP binds aminoacyl-tRNA to form a ternary complex of aminoacyl-tRNA·EF-Tu-GTP. The ternary complex binds only to the A site of ribosomes whose P site is already occupied by peptidyl-tRNA. This is the critical reaction in ensuring that the aminoacyl-tRNA and peptidyl-tRNA are correctly positioned for peptide bond formation.

Aminoacyl-tRNA is loaded into the A site in two stages. First the anticodon end binds to the A site of the 30S subunit. Then codon-anticodon recognition triggers a change in the conformation of the ribosome. This stabilizes tRNA binding and causes EF-Tu to hydrolyze its GTP. The CCA end of the tRNA now moves into the A site on the 50S subunit. The binary complex EF-Tu-GDP is released. This form of EF-Tu is inactive and does not bind aminoacyl-tRNA effectively.

Another factor, EF-Ts, mediates the regeneration of the used form, EF-Tu-GDP, into the active form, EF-Tu-GTP. First, EF-Ts displaces the GDP from EF-Tu, forming the combined factor EF-Tu-EF-Ts. Then the EF-Ts is in turn displaced by GTP,

reforming EF-Tu-GTP. The active binary complex binds aminoacyl-tRNA; and the released EF-Ts can recycle.

There are ~70,000 molecules of EF-Tu per bacterium (~5% of the total bacterial protein), which approaches the number of aminoacyl-tRNA molecules. This implies that most aminoacyl-tRNAs are likely to be present in ternary complexes. There are only ~10,000 molecules of EF-Ts per cell (about the same as the number of ribosomes). The kinetics of the interaction between EF-Tu and EF-Ts suggest that the EF-Tu·EF-Ts complex exists only transiently, so that the EF-Tu is very rapidly converted to the GTP-bound form, and then to a ternary complex.

The role of GTP in the ternary complex has been studied by substituting an analog that cannot be hydrolyzed. The compound **GMP-PCP** has a methylene bridge in place of the oxygen that links the  $\beta$  and  $\gamma$  phosphates in GTP. In the presence of GMP-PCP, a ternary complex can be formed that binds aminoacyl-tRNA to the ribosome. But the peptide bond cannot be formed. So the presence of GTP is needed for aminoacyl-tRNA to be bound at the A site; but the hydrolysis is not required until later.

**Kirromycin** is an antibiotic that inhibits the function of EF-Tu. When EF-Tu is bound by kirromycin, it remains able to bind aminoacyl-tRNA to the A site. But the EF-Tu-GDP complex cannot be released from the ribosome. Its continued presence prevents formation of the peptide bond between the peptidyl-tRNA and the aminoacyl-tRNA. As a result, the ribosome becomes "stalled" on mRNA, bringing protein synthesis to a halt.

This effect of kirromycin demonstrates that inhibiting one step in protein synthesis blocks the next step. The reason is that the continued presence of EF-Tu prevents the aminoacyl end of aminoacyl-tRNA from entering the A site on the 50S subunit (see **Figure 6.31**). So the release of EF-Tu-GDP is needed for the ribosome to undertake peptide bond formation. The same principle is seen at other stages of protein synthesis: one reaction must be completed properly before the next can occur.

The interaction with EF-Tu also plays a role in quality control. Aminoacyl-tRNAs are brought into the A site without knowing whether their anticodons will fit the codon. The hydrolysis of EF-Tu-GTP is relatively slow: because it takes longer than the time required for an incorrect aminoacyl-tRNA to dissociate from the A site, most incorrect species are removed at this stage. The release of EF-Tu-GDP after hydrolysis also is slow, so any surviving incorrect aminoacyl-tRNAs may dissociate at this stage. The basic principle is that the reactions involving EF-Tu occur slowly enough to allow incorrect aminoacyl-tRNAs to dissociate before they become trapped in protein synthesis.

In eukaryotes, the factor *eEF1*  $\alpha$  is responsible for bringing aminoacyl-tRNA to the ribosome, again in a reaction that involves cleavage of a high-energy bond in GTP. Like its prokaryotic homologue (EF-Tu), it is an abundant protein. After hydrolysis of GTP, the active form is regenerated by the factor *eEF1*  $\beta \gamma$ , a counterpart to EF-Ts.

## PROTEIN SYNTHESIS

### 2.6.11 The polypeptide chain is transferred to aminoacyl-tRNA

---

#### Key Terms

**Peptidyl transferase** is the activity of the ribosomal 50S subunit that synthesizes a peptide bond when an amino acid is added to a growing polypeptide chain. The actual catalytic activity is a property of the rRNA.

**Puromycin** is an antibiotic that terminates protein synthesis by mimicking a tRNA and becoming linked to the nascent protein chain.

#### Key Concepts

- The 50S subunit has peptidyl transferase activity.
  - The nascent polypeptide chain is transferred from peptidyl-tRNA in the P site to aminoacyl-tRNA in the A site.
  - Peptide bond synthesis generates deacylated tRNA in the P site and peptidyl-tRNA in the A site.
- 

The ribosome remains in place while the polypeptide chain is elongated by transferring the polypeptide attached to the tRNA in the P site to the aminoacyl-tRNA in the A site. The reaction is shown in **Figure 6.26**. The activity responsible for synthesis of the peptide bond is called **peptidyl transferase**.

**Figure 6.26** Peptide bond formation takes place by reaction between the polypeptide of peptidyl-tRNA in the P site and the amino acid of aminoacyl-tRNA in the A site.

*This is a static version of an interactive figure; see <http://www.ergito.com/main.jsp?bcs=MBIO.2.6.11> to view properly.*

The nature of the transfer reaction is revealed by the ability of the antibiotic **puromycin** to inhibit protein synthesis. Puromycin resembles an amino acid attached to the terminal adenosine of tRNA. **Figure 6.27** shows that puromycin has an N instead of the O that joins an amino acid to tRNA. The antibiotic is treated by the ribosome as though it were an incoming aminoacyl-tRNA. Then the polypeptide attached to peptidyl-tRNA is transferred to the  $\text{NH}_2$  group of the puromycin.

**Figure 6.27** Puromycin mimics aminoacyl-tRNA because it resembles an aromatic amino acid linked to a sugar-base moiety.

Because the puromycin moiety is not anchored to the A site of the ribosome, the polypeptidyl-puromycin adduct is released from the ribosome in the form of polypeptidyl-puromycin. This premature termination of protein synthesis is responsible for the lethal action of the antibiotic.

Peptidyl transferase is a function of the large (50S or 60S) ribosomal subunit. The reaction is triggered when EF-Tu releases the aminoacyl end of its tRNA. The aminoacyl end then swings into a location close to the end of the peptidyl-tRNA. This site has a peptidyl transferase activity that essentially ensures a rapid transfer of the peptide chain to the aminoacyl-tRNA. Both rRNA and 50S subunit proteins are necessary for this activity, but the actual act of catalysis is a property of the ribosomal RNA of the 50S subunit (see *Molecular Biology 2.6.19 23S rRNA has peptidyl transferase activity*).

## PROTEIN SYNTHESIS

### 2.6.12 Translocation moves the ribosome

---

#### Key Terms

**Translocation** is the movement of the ribosome one codon along mRNA after the addition of each amino acid to the polypeptide chain.

#### Key Concepts

- Ribosomal translocation moves the mRNA through the ribosome by 3 bases.
- Translocation moves deacylated tRNA into the E site, peptidyl-tRNA into the P site, and empties the A site.
- The hybrid state model proposes that translocation occurs in two stages, in which the 50S moves relative to the 30S, and then the 30S moves along mRNA to restore the original conformation.

---

The cycle of addition of amino acids to the growing polypeptide chain is completed by **translocation**, when the ribosome advances three nucleotides along the mRNA. **Figure 6.28** shows that translocation expels the uncharged tRNA from the P site, so that the new peptidyl-tRNA can enter. The ribosome then has an empty A site ready for entry of the aminoacyl-tRNA corresponding to the next codon. As the figure shows, in bacteria the discharged tRNA is transferred from the P site to the E site (from which it is then expelled into the cytoplasm). In eukaryotes it is expelled directly into the cytosol. The A and P sites straddle both the large and small subunits; the E site (in bacteria) is located largely on the 50S subunit, but has some contacts in the 30S subunit.

**Figure 6.28** A bacterial ribosome has 3 tRNA-binding sites. Aminoacyl-tRNA enters the A site of a ribosome that has peptidyl-tRNA in the P site. Peptide bond synthesis deacylates the P site tRNA and generates peptidyl-tRNA in the A site. Translocation moves the deacylated tRNA into the E site and moves peptidyl-tRNA into the P site.

*This is a static version of an interactive figure; see <http://www.ergito.com/main.jsp?bcs=MBIO.2.6.12> to view properly.*

Most thinking about translocation follows the hybrid state model, which proposes that translocation occurs in two stages (for review see 2390). **Figure 6.29** shows that first there is a shift of the 50S subunit relative to the 30S subunit; then a second shift occurs when the 30S subunit moves along mRNA to restore the original conformation. The basis for this model was the observation that the pattern of contacts that tRNA makes with the ribosome (measured by chemical footprinting) changes in two stages (934). When puromycin is added to a ribosome that has an aminoacylated tRNA in the P site, the contacts of tRNA on the 50S subunit change

from the P site to the E site, but the contacts on the 30S subunit do not change. This suggests that the 50S subunit has moved to a post-transfer state, but the 30S subunit has not changed.

**Figure 6.29** Models for translocation involve two stages. First, at peptide bond formation the aminoacyl end of the tRNA in the A site becomes located in the P site. Second, the anticodon end of the tRNA becomes located in the P site.

The interpretation of these results is that first the aminoacyl ends of the tRNAs (located in the 50S subunit) move into the new sites (while the anticodon ends remain bound to their anticodons in the 30S subunit). At this stage, the tRNAs are effectively bound in hybrid sites, consisting of the 50S E/ 30S P and the 50S P/ 30S A sites. Then movement is extended to the 30S subunits, so that the anticodon-codon pairing region finds itself in the right site. The most likely means of creating the hybrid state is by a movement of one ribosomal subunit relative to the other, so that translocation in effect involves two stages, the normal structure of the ribosome being restored by the second stage (444).

The ribosome faces an interesting dilemma at translocation. It needs to break many of its contacts with tRNA in order to allow movement. But at the same time it must maintain pairing between tRNA and the anticodon (breaking the pairing of the deacylated tRNA only at the right moment). One possibility is that the ribosome switches between alternative, discrete conformations. The switch could consist of changes in rRNA base pairing. The accuracy of translation is influenced by certain mutations that influence alternative base pairing arrangements. The most likely

interpretation is that the effect is mediated by the tightness of binding to tRNA of the alternative conformations (440).

## PROTEIN SYNTHESIS

### 2.6.13 Elongation factors bind alternately to the ribosome

---

#### Key Concepts

- Translocation requires EF-G, whose structure resembles the aminoacyl-tRNA·EF-Tu·GTP complex.
  - Binding of EF-Tu and EF-G to the ribosome is mutually exclusive.
  - Translocation requires GTP hydrolysis, which triggers a change in EF-G, which in turn triggers a change in ribosome structure.
- 

Translocation requires GTP and another elongation factor, EF-G. This factor is a major constituent of the cell; it is present at a level of ~1 copy per ribosome (20,000 molecules per cell).

Ribosomes cannot bind EF-Tu and EF-G simultaneously, so protein synthesis follows the cycle illustrated in Figure 151 in which the factors are alternately bound to, and released from, the ribosome. So EF-Tu·GDP must be released before EF-G can bind; and then EF-G must be released before aminoacyl-tRNA·EF-Tu·GTP can bind.

Does the ability of each elongation factor to exclude the other rely on an allosteric effect on the overall conformation of the ribosome or on direct competition for overlapping binding sites? **Figure 6.30** shows an extraordinary similarity between the structures of the ternary complex of aminoacyl-tRNA·EF-Tu·GDP and EF-G (928). The structure of EF-G mimics the overall structure of EF-Tu bound to the amino acceptor stem of aminoacyl-tRNA. This creates the immediate assumption that they compete for the same binding site (presumably in the vicinity of the A site). The need for each factor to be released before the other can bind ensures that the events of protein synthesis proceed in an orderly manner (928).

**Figure 6.30** The structure of the ternary complex of aminoacyl-tRNA-EF-Tu-GTP (left) resembles the structure of EF-G (right). Structurally conserved domains of EF-Tu and EF-G are in red and green; the tRNA and the domain resembling it in EF-G are in purple. Photograph kindly provided by Poul Nissen.

Both elongation factors are monomeric GTP-binding proteins that are active when bound to GTP but inactive when bound to GDP. The triphosphate form is required for binding to the ribosome, which ensures that each factor obtains access to the ribosome only in the company of the GTP that it needs to fulfill its function.

EF-G binds to the ribosome to sponsor translocation; and then is released following ribosome movement. EF-G can still bind to the ribosome when GMP-PCP is substituted for GTP; thus the presence of a guanine nucleotide is needed for binding, but its hydrolysis is not absolutely essential for translocation (although translocation is much slower in the absence of GTP hydrolysis). The hydrolysis of GTP is needed to release EF-G.

The need for EF-G release was discovered by the effects of the steroid antibiotic fusidic acid, which "jams" the ribosome in its post-translocation state (see **Figure 6.31**). In the presence of fusidic acid, one round of translocation occurs: EF-G binds to the ribosome, GTP is hydrolyzed, and the ribosome moves three nucleotides. But fusidic acid stabilizes the ribosome-EF-G-GDP complex, so that EF-G and GDP remain on the ribosome instead of being released. Because the ribosome then cannot bind aminoacyl-tRNA, no further amino acids can be added to the chain.

**Figure 6.31** Binding of factors EF-Tu and EF-G alternates as ribosomes accept new aminoacyl-tRNA, form peptide bonds, and translocate.

Translocation is an intrinsic property of the ribosome that requires a major change in structure (see *Molecular Biology 2.6.17 Ribosomes have several active centers*). However, its activated by EF-G in conjunction with GTP hydrolysis, which occurs before translocation and accelerates the ribosome movement. The most likely mechanism is that GTP hydrolysis causes a change in the structure of EF-G, which in turn forces a change in the ribosome structure. An extensive reorientation of EF-G occurs at translocation (947). Before translocation, it is bound across the two ribosomal subunits. Most of its contacts with the 30S subunit are made by a region called domain 4, which is inserted into the A site. This domain could be responsible for displacing the tRNA. After translocation, domain 4 is instead oriented toward the 50S subunit.

The eukaryotic counterpart to EF-G is the protein eEF2, which functions in a similar manner, as a translocase dependent on GTP hydrolysis. Its action also is inhibited by

fusidic acid. A stable complex of eEF2 with GTP can be isolated; and the complex can bind to ribosomes with consequent hydrolysis of its GTP.

A unique reaction of eEF2 is its susceptibility to diphtheria toxin. The toxin uses NAD (nicotinamide adenine dinucleotide) as a cofactor to transfer an ADPR moiety (adenosine diphosphate ribosyl) on to the eEF2. The ADPR-eEF2 conjugate is inactive in protein synthesis. The substrate for the attachment is an unusual amino acid, produced by modifying a histidine; it is common to the eEF2 of many species.

The ADP-ribosylation is responsible for the lethal effects of diphtheria toxin. The reaction is extremely effective: a single molecule of toxin can modify sufficient eEF2 molecules to kill a cell.

## PROTEIN SYNTHESIS

### 2.6.14 Three codons terminate protein synthesis

---

#### Key Terms

The **amber** codon is the triplet UAG, one of the three termination codons that end protein synthesis.

The **ochre** codon is the triplet UAA, one of the three termination codons that end protein synthesis.

The **opal** codon is the triplet UGA, one of the three termination codons that end protein synthesis. It has evolved to code for an amino acid in a small number of organisms or organelles.

**Missense** mutations change a single codon so as to cause the replacement of one amino acid by another in a protein sequence.

**Premature termination** describes the termination of protein or of RNA synthesis before the chain has been completed. In protein synthesis it can be caused by mutations that create termination codons within the coding region. In RNA synthesis it is caused by various events that act on RNA polymerase.

A **nonsense mutation** is any change in DNA that replaces a codon specifying an amino acid with a translation-termination codon (UAG, UGA, or UAA).

A **stop codon (Termination codon)** is one of three triplets (UAG, UAA, UGA) that causes protein synthesis to terminate. They are also known historically as *nonsense codons*. The UAA codon is called ochre, and the UAG codon is called amber, after the names of the nonsense mutations by which they were originally identified.

#### Key Concepts

- The codons UAA (ochre), UAG (amber) and UGA terminate protein synthesis.
- In bacteria they are used most often with relative frequencies UAA>UGA>UAG.

---

Only 61 triplets are assigned to amino acids. The other three triplets are **termination codons** (or stop codons) that end protein synthesis. They have casual names from the history of their discovery. The UAG triplet is called the **amber** codon; UAA is the **ochre** codon; and UGA is sometimes called the **opal** codon.

The nature of these triplets was originally shown by a genetic test that distinguished two types of point mutation:

- A point mutation that changes a codon to represent a different amino acid is called a **missense** mutation. One amino acid replaces the other in the protein; the effect on protein function depends on the site of mutation and the nature of the amino acid replacement.

- When a point mutation creates one of the three termination codons, it causes **premature termination** of protein synthesis at the mutant codon. Only the first part of the protein is made in the mutant cell. This is likely to abolish protein function (depending, of course, on how far along the protein the mutant site is located). A change of this sort is called a **nonsense mutation**.

(Sometimes the term *nonsense codon* is used to describe the termination triplets. "Nonsense" is really a misnomer, since the codons do have meaning, albeit a disruptive one in a mutant gene. A better term is **stop codon**.)

In every gene that has been sequenced, one of the termination codons lies immediately after the codon representing the C-terminal amino acid of the wild-type sequence. Nonsense mutations show that any one of the three codons is sufficient to terminate protein synthesis within a gene. The UAG, UAA, and UGA triplet sequences are therefore necessary and sufficient to end protein synthesis, whether occurring naturally at the end of a gene or created by mutation within a coding sequence.

In bacterial genes, UAA is the most commonly used termination codon. UGA is used more heavily than UAG, although there appear to be more errors reading UGA. (An error in reading a termination codon, when an aminoacyl-tRNA improperly responds to it, results in the continuation of protein synthesis until another termination codon is encountered.)

---

## PROTEIN SYNTHESIS

### 2.6.15 Termination codons are recognized by protein factors

---

#### Key Terms

A **release factor (RF)** is required to terminate protein synthesis to cause release of the completed polypeptide chain and the ribosome from mRNA. Individual factors are numbered. Eukaryotic factors are called eRF.

**RF1** is the bacterial release factor that recognizes UAA and UAG as signals to terminate protein synthesis.

**RF2** is the bacterial release factor that recognizes UAA and UGA as signals to terminate protein synthesis.

**RF3** is a protein synthesis termination factor related to the elongation factor EF-G. It functions to release the factors RF1 or RF2 from the ribosome when they act to terminate protein synthesis.

#### Key Concepts

- Termination codons are recognized by protein release factors, not by aminoacyl-tRNAs.
- The structures of the class 1 release factors resemble aminoacyl-tRNA·EF-Tu and EF-G.
- The class 1 release factors respond to specific termination codons and hydrolyze the polypeptide-tRNA linkage.
- The class 1 release factors are assisted by class 2 release factors that depend on GTP.
- The mechanism is similar in bacteria (which have two types of class 1 release factors) and eukaryotes (which have only one class 1 release factor).

---

Two stages are involved in ending translation. The *termination reaction* itself involves release of the protein chain from the last tRNA. The *post-termination reaction* involves release of the tRNA and mRNA, and dissociation of the ribosome into its subunits.

None of the termination codons is represented by a tRNA. They function in an entirely different manner from other codons, and are recognized directly by protein factors. (Since the reaction does not depend on codon-anticodon recognition, there seems to be no particular reason why it should require a triplet sequence. Presumably this reflects the evolution of the genetic code.)

Termination codons are recognized by class 1 **release factors (RF)**. In *E. coli* two class 1 release factors are specific for different sequences (927). **RF1** recognizes UAA and UAG; **RF2** recognizes UGA and UAA. The factors act at the ribosomal A

site and require polypeptidyl-tRNA in the P site. The release factors are present at much lower levels than initiation or elongation factors; there are ~600 molecules of each per cell, equivalent to 1 RF per 10 ribosomes. Probably at one time there was only a single release factor, recognizing all termination codons, and later it evolved into two factors with specificities for particular codons. In eukaryotes, there is only a single class 1 release factor, called eRF. The efficiency with which the bacterial factors recognize their target codons is influenced by the bases on the 3' side.

The class 1 release factors are assisted by class 2 release factors, which are not codon-specific. The class 2 factors are GTP-binding proteins. In *E. coli*, the role of the class 2 factor is to release the class 1 factor from the ribosome.

Although the general mechanism of termination is similar in prokaryotes and eukaryotes, the interactions between the class 1 and class 2 factors have some differences.

The class 1 factors RF1 and RF2 recognize the termination codons and activate the ribosome to hydrolyze the peptidyl tRNA. Cleavage of polypeptide from tRNA takes place by a reaction analogous to the usual peptidyl transfer, except that the acceptor is H<sub>2</sub>O instead of aminoacyl-tRNA (see **Figure 6.34**).

Then RF1 or RF2 is released from the ribosome by the class 2 factor **RF3**, which is related to EF-G (1161; 1162). RF3-GDP binds to the ribosome before the termination reaction occurs. The GDP is replaced by GTP. This enables RF3 to contact the ribosome GTPase center, where it causes RF1/2 to be released when the polypeptide chain is terminated (4766).

RF3 resembles the GTP-binding domains of EF-Tu and EF-G, and RF1/2 resemble the C-terminal domain of EF-G, which mimics tRNA. This suggests that the release factors utilize the same site that is used by the elongation factors. **Figure 6.32** illustrates the basic idea that these factors all have the same general shape and bind to the ribosome successively at the same site (basically the A site or a region extensively overlapping with it) (2231; for review see 3050).

**Figure 6.32** Molecular mimicry enables the elongation factor Tu-tRNA complex, the translocation factor EF-G, and the release factors RF1/2-RF3 to bind to the same ribosomal site.

The eukaryotic class 1 release factor, eRF1, is a single protein that recognizes all three termination codons (2229). Its sequence is unrelated to the bacterial factors. It can terminate protein synthesis *in vitro* without the class 3 factor, eRF3, although eRF3 is essential in yeast *in vivo*. The structure of eRF1 follows a familiar theme: **Figure 6.33** shows that it consists of three domains that mimic the structure of tRNA (2230).

**Figure 6.33** The eukaryotic termination factor eRF1 has a structure that mimics tRNA. The motif GGQ at the tip of domain 2 is essential for hydrolyzing the polypeptide chain from tRNA. Photograph kindly provided by David Barford (see 2230).

An essential motif of three amino acids, GGQ, is exposed at the top of domain 2. Its position in the A site corresponds to the usual location of an amino acid on an aminoacyl-tRNA. This positions it to use the glutamine (Q) to position a water molecule to substitute for the amino acid of aminoacyl-tRNA in the peptidyl transfer reaction. **Figure 6.34** compares the termination reaction with the usual peptide transfer reaction. Termination transfers a hydroxyl group from the water, thus effectively hydrolyzing the peptide-tRNA bond (and see **Figure 6.48** for discussion of how the peptidyl transferase center works).

**Figure 6.34** Peptide transfer and termination are similar reactions in which a base in the peptidyl transfer center triggers a transesterification reaction by attacking an N-H or O-H bond, releasing the N or O to attack the link to tRNA.

Mutations in the RF genes reduce the efficiency of termination, as seen by an increased ability to continue protein synthesis past the termination codon. Overexpression of RF1 or RF2 increases the efficiency of termination at the codons on which it acts. This suggests that codon recognition by RF1 or RF2 competes with aminoacyl-tRNAs that erroneously recognize the termination codons (for review see 36). The release factors recognize their target sequences very efficiently (1163).

The termination reaction involves release of the completed polypeptide, but leaves a deacylated tRNA and the mRNA still associated with the ribosome. **Figure 6.35** shows that the dissociation of the remaining components (tRNA, mRNA, 30S and 50S subunits) requires the factor RRF, ribosome recycling factor. This acts together with EF-G in a reaction that uses hydrolysis of GTP. Like the other factors involved in release, RRF has a structure that mimics tRNA, except that it lacks an equivalent for the 3' amino acid-binding region (926). IF-3 is also required, which brings the wheel full circle to its original discovery, when it was proposed to be a dissociation factor! RRF acts on the 50S subunit, and IF-3 acts to remove deacylated tRNA from the 30S subunit. Once the subunits have separated, IF-3 remains necessary, of course, to prevent their reassociation.

**Figure 6.35** The RF (release factor) terminates protein synthesis by releasing the protein chain. The RRF (ribosome recycling factor) releases the last tRNA, and EF-G releases RRF, causing the ribosome to dissociate.

## PROTEIN SYNTHESIS

### 2.6.16 Ribosomal RNA pervades both ribosomal subunits

---

#### Key Terms

**5S RNA** is a 120 base RNA that is a component of the large subunit of the ribosome.

**5.8S RNA** is an independent small RNA present on the large subunit of eukaryotic ribosomes. It is homologous to the 5' end of bacterial 23S rRNA.

#### Key Concepts

- Each rRNA has several distinct domains that fold independently.
- Virtually all ribosomal proteins are in contact with rRNA.
- Most of the contacts between ribosomal subunits are made between the 16S and 23S rRNAs.

---

Two thirds of the mass of the bacterial ribosome is made up of rRNA. The most penetrating approach to analyzing secondary structure of large RNAs is to compare the sequences of corresponding rRNAs in related organisms. Those regions that are important in the secondary structure retain the ability to interact by base pairing. So if a base pair is required, it can form at the same relative position in each rRNA. This approach has enabled detailed models to be constructed for both 16S and 23S rRNA.

Each of the major rRNAs can be drawn in a secondary structure with several discrete domains. 16S rRNA forms four general domains, in which just under half of the sequence is base paired (see **Figure 6.45**). 23S rRNA forms six general domains. The individual double-helical regions tend to be short (<8 bp). Often the duplex regions are not perfect, but contain bulges of unpaired bases. Comparable models have been drawn for mitochondrial rRNAs (which are shorter and have fewer domains) and for eukaryotic cytosolic rRNAs (which are longer and have more domains). The increase in length in eukaryotic rRNAs is due largely to the acquisition of sequences representing additional domains (for review see 431). The crystal structure of the ribosome shows that in each subunit the domains of the major rRNA fold independently and have a discrete location in the subunit (1670).

Differences in the ability of 16S rRNA to react with chemical agents are found when 30S subunits are compared with 70S ribosomes; also there are differences between free ribosomes and those engaged in protein synthesis. Changes in the reactivity of the rRNA occur when mRNA is bound, when the subunits associate, or when tRNA is bound. Some changes reflect a direct interaction of the rRNA with mRNA or tRNA, while others are caused indirectly by other changes in ribosome structure. The main point is that ribosome conformation is flexible during protein synthesis.

A feature of the primary structure of rRNA is the presence of methylated residues. There are ~10 methyl groups in 16S rRNA (located mostly toward the 3' end of the

molecule) and ~20 in 23S rRNA. In mammalian cells, the 18S and 28S rRNAs carry 43 and 74 methyl groups, respectively, so ~2% of the nucleotides are methylated (about three times the proportion methylated in bacteria).

The large ribosomal subunit also contains a molecule of a 120 base **5S RNA** (in all ribosomes except those of mitochondria). The sequence of 5S RNA is less well conserved than those of the major rRNAs. All 5S RNA molecules display a highly base-paired structure.

In eukaryotic cytosolic ribosomes, another small RNA is present in the large subunit. This is the **5.8S RNA**. Its sequence corresponds to the 5' end of the prokaryotic 23S rRNA.

Some ribosomal proteins bind strongly to isolated rRNA. Some do not bind to free rRNA, but can bind after other proteins have bound. This suggests that the conformation of the rRNA is important in determining whether binding sites exist for some proteins. As each protein binds, it induces conformational changes in the rRNA that make it possible for other proteins to bind. In *E. coli*, virtually all the 30S ribosomal proteins interact (albeit to varying degrees) with 16S rRNA. The binding sites on the proteins show a wide variety of structural features, suggesting that protein-RNA recognition mechanisms may be diverse.

The 70S ribosome has an asymmetric construction. **Figure 6.36** shows a schematic of the structure of the 30S subunit, which is divided into four regions: the head, neck, body, and platform. **Figure 6.37** shows a similar representation of the 50S subunit, where two prominent features are the central protuberance (where 5S rRNA is located) and the stalk (made of multiple copies of protein L7). **Figure 6.38** shows that the platform of the small subunit fits into the notch of the large subunit. There is a cavity between the subunits which contains some of the important sites (for review see 430; 433; 434).

**Figure 6.36** The 30S subunit has a head separated by a neck from the body, with a protruding platform.

**Figure 6.37** The 50S subunit has a central protuberance where 5S rRNA is located, separated by a notch from a stalk made of copies of the protein L7.

**Figure 6.38** The platform of the 30S subunit fits into the notch of the 50S subunit to form the 70S ribosome.

The structure of the 30S subunit follows the organization of 16S rRNA, with each structural feature corresponding to a domain of the rRNA. The body is based on the 5' domain, the platform on the central domain, and the head on the 3' region. **Figure 6.39** shows that the 30S subunit has an asymmetrical distribution of RNA and protein (931; 1184). One important feature is that the platform of the 30S subunit that provides the interface with the 50S subunit is composed almost entirely of RNA. Only two proteins (a small part of S7 and possibly part of S12) lie near the interface. This means that the association and dissociation of ribosomal subunits must depend on interactions with the 16S rRNA. Subunit association is affected by a mutation in a loop of 16S rRNA (at position 791) that is located at the subunit interface, and other nucleotides in 16S rRNA have been shown to be involved by modification/interference experiments. This behavior supports the idea that the evolutionary origin of the ribosome may have been as a particle consisting of RNA rather than protein.

**Figure 6.39** The 30S ribosomal subunit is a ribonucleoprotein particle. Proteins are in yellow. Photograph kindly provided by Venkitaraman Ramakrishnan.

The 50S subunit has a more even distribution of components than the 30S, with long rods of double-stranded RNA crisscrossing the structure (932; 1086). The RNA forms a mass of tightly packed helices. The exterior surface largely consists of protein, except for the peptidyl transferase center (see *Molecular Biology 2.6.19 23S rRNA has peptidyl transferase activity*). Almost all segments of the 23S rRNA interact with protein, but many of the proteins are relatively unstructured.

The junction of subunits in the 70S ribosome involves contacts between 16S rRNA (many in the platform region) with 23S rRNA. There are also some interactions between rRNA of each subunit with proteins in the other, and a few protein-protein contacts. **Figure 6.40** identifies the contact points on the rRNA structures. **Figure 6.41** opens out the structure (imagine the 50S subunit rotated counterclockwise and the 30S subunit rotated clockwise around the axis shown in the figure) to show the locations of the contact points on the face of each subunit.

**Figure 6.40** Contact points between the rRNAs are located in two domains of 16S rRNA and one domain of 23S rRNA. Photograph kindly provided by Harry Noller (see 1670).

**Figure 6.41** Contacts between the ribosomal subunits are mostly made by RNA (shown in purple). Contacts involving proteins are shown in yellow. The two subunits are rotated away from one another to show the faces where contacts are made; from a plane of contact perpendicular to the screen, the 50S subunit is rotated 90° counter-clockwise, and the 30S is rotated 90° clockwise (this shows it in the reverse of the usual orientation). Photograph kindly provided by Harry Noller (see 1670).

**PROTEIN SYNTHESIS****2.6.17 Ribosomes have several active centers**

---

**Key Concepts**

- Interactions involving rRNA are a key part of ribosome function.
  - The environment of the tRNA-binding sites is largely determined by rRNA.
- 

The basic message to remember about the ribosome is that it is a cooperative structure that depends on changes in the relationships among its active sites during protein synthesis. The active sites are not small, discrete regions like the active centers of enzymes. They are large regions whose construction and activities may depend just as much on the rRNA as on the ribosomal proteins. The crystal structures of the individual subunits and bacterial ribosomes give us a good impression of the overall organization and emphasize the role of the rRNA. The most recent structure, at 5.5 Å resolution, clearly identifies the locations of the tRNAs and the functional sites (1670; for review see 2390). We can now account for many ribosomal functions in terms of its structure (for review see 3447, 4529).

Ribosomal functions are centered around the interaction with tRNAs. **Figure 6.42** shows the 70S ribosome with the positions of tRNAs in the three binding sites (933). The tRNAs in the A and P sites are nearly parallel to one another. All three tRNAs are aligned with their anticodon loops bound to the mRNA in the groove on the 30S subunit. The rest of each tRNA is bound to the 50S subunit. The environment surrounding each tRNA is mostly provided by rRNA. In each site, the rRNA contacts the tRNA at parts of the structure that are universally conserved.

**Figure 6.42** The 70S ribosome consists of the 50S subunit (blue) and the 30S subunit (purple) with three tRNAs located superficially: yellow in the A site, blue in the P site, and green in the E site. Photograph kindly provided by Harry Noller (see 933)

It has always been a big puzzle to understand how two bulky tRNAs can fit next to one another in reading adjacent codons. The crystal structure shows a  $45^\circ$  kink in the mRNA between the P and A sites, which allows the tRNAs to fit as shown in the expansion of **Figure 6.43**. The tRNAs in the P and A sites are angled at  $26^\circ$  relative to each other at their anticodons. The closest approach between the backbones of the tRNAs occurs at the 3' ends, where they converge to within  $5 \text{ \AA}$  (perpendicular to the plane of the screen). This allows the peptide chain to be transferred from the peptidyl-tRNA in the A site to the aminoacyl-tRNA in the A site.

**Figure 6.43** Three tRNAs have different orientations on the ribosome. mRNA turns between the P and A sites to allow aminoacyl-tRNAs to bind adjacent codons. Photograph kindly provided by Harry Noller (see 1670).

Aminoacyl-tRNA is inserted into the A site by EF-Tu, and its pairing with the codon is necessary for EF-Tu to hydrolyze GTP and be released from the ribosome (see *Molecular Biology 2.6.10 Elongation factor Tu loads aminoacyl-tRNA into the A site*). EF-Tu initially places the aminoacyl-tRNA into the small subunit, where the anticodon pairs with the codon. Movement of the tRNA is required to bring it fully into the A site, when its 3' end enters the peptidyl transferase center on the large subunit. There are different models for how this process may occur. One calls for the entire tRNA to swivel, so that the elbow in the L-shaped structure made by the D and T  $\Psi$  C arms moves into the ribosome, enabling the T  $\Psi$  C arm to pair with rRNA (2846). Another calls for the internal structure of the tRNA to change, using the anticodon loop as a hinge, with the rest of the tRNA rotating from a position in which it is stacked on the 3' side of the anticodon loop to one in which it is stacked on the 5' side (3060). Following the transition, EF-Tu hydrolyzes GTP, allowing peptide synthesis to proceed.

Translocation involves large movements in the positions of the tRNAs within the ribosome. The anticodon end of tRNA moves  $\sim 28 \text{ \AA}$  from the A site to the P site, and then a further  $20 \text{ \AA}$  from the P site to the E site. Because of the angle of each tRNA relative to the anticodon, the bulk of the tRNA moves much larger distances,  $40 \text{ \AA}$  from A to P site, and  $55 \text{ \AA}$  from P site to E site. This suggests that translocation requires a major reorganization of structure.

For many years, it was thought that translocation could occur only in the presence of the factor EF-G. However, the antibiotic sparsomycin (which inhibits the peptidyl transferase activity) triggers translocation (3998). This suggests that the energy to drive translocation actually is stored in the ribosome after peptide bond formation has occurred. Usually EF-G acts on the ribosome to release this energy and enable it to drive translocation, but sparsomycin can have the same role. Sparsomycin inhibits peptidyl transferase by binding to the peptidyl-tRNA, blocking its interaction with aminoacyl-tRNA. It probably creates a conformation that resembles the usual post-translocation conformation, which in turn promotes movement of the peptidyl-tRNA. The important point is that translocation is an intrinsic property of the ribosome.

The hybrid states model suggests that translocation may take place in two stages, with one ribosomal subunit moving relative to the other to create an intermediate stage in which there are hybrid tRNA-binding sites (50S E/30S P and 50S P/30S A) (see **Figure 6.29**). Comparisons of the ribosome structure between pre- and post-translocation states, and comparisons in 16S rRNA conformation between free 30S subunits and 70S ribosomes, suggest that mobility of structure is especially marked in the head and platform regions of the 30S subunit. An interesting insight on the hybrid states model is cast by the fact that many bases in rRNA involved in subunit association are close to bases involved in interacting with tRNA. This suggests that tRNA-binding sites are close to the interface between subunits, and carries the implication that changes in subunit interaction could be connected with movement of tRNA.

Much of the structure of the ribosome is occupied by its active centers. The schematic view of the ribosomal sites in **Figure 6.44** shows they comprise about two thirds of the ribosomal structure. A tRNA enters the A site, is transferred by translocation into the P site, and then leaves the (bacterial) ribosome by the E site. The A and P sites extend across both ribosome subunits; tRNA is paired with mRNA

in the 30S subunit, but peptide transfer takes place in the 50S subunit. The A and P sites are adjacent, enabling translocation to move the tRNA from one site into the other. The E site is located near the P site (representing a position en route to the surface of the 50S subunit). The peptidyl transferase center is located on the 50S subunit, close to the aminoacyl ends of the tRNAs in the A and P sites (see *Molecular Biology 2.6.18 16S rRNA plays an active role in protein synthesis*).

**Figure 6.44** The ribosome has several active centers. It may be associated with a membrane. mRNA takes a turn as it passes through the A and P sites, which are angled with regard to each other. The E site lies beyond the P site. The peptidyl transferase site (not shown) stretches across the tops of the A and P sites. Part of the site bound by EF-Tu/G lies at the base of the A and P sites.

All of the GTP-binding proteins that function in protein synthesis (EF-Tu, EF-G, IF-2, RF1,2,3) bind to the same factor-binding site (sometimes called the GTPase center), which probably triggers their hydrolysis of GTP. It is located at the base of the stalk of the large subunit, which consists of the proteins L7/L12. (L7 is a modification of L12, and has an acetyl group on the N-terminus.) In addition to this region, the complex of protein L11 with a 58 base stretch of 23S rRNA provides the binding site for some antibiotics that affect GTPase activity. Neither of these ribosomal structures actually possesses GTPase activity, but they are both necessary for it. The role of the ribosome is to trigger GTP hydrolysis by factors bound in the factor-binding site.

Initial binding of 30S subunits to mRNA requires protein S1, which has a strong affinity for single-stranded nucleic acid. It is responsible for maintaining the single-stranded state in mRNA that is bound to the 30S subunit (2200). This action is necessary to prevent the mRNA from taking up a base-paired conformation that would be unsuitable for translation. S1 has an extremely elongated structure and associates with S18 and S21. The three proteins constitute a domain that is involved in the initial binding of mRNA and in binding initiator tRNA. This locates the mRNA-binding site in the vicinity of the cleft of the small subunit (see **Figure 6.38**). The 3' end of rRNA, which pairs with the mRNA initiation site, is located in this region.

The initiation factors bind in the same region of the ribosome. IF-3 can be crosslinked to the 3' end of the rRNA, as well as to several ribosomal proteins, including those probably involved in binding mRNA. The role of IF-3 could be to

stabilize mRNA·30S subunit binding; then it would be displaced when the 50S subunit joins.

The incorporation of 5S RNA into 50S subunits that are assembled in vitro depends on the ability of three proteins, L5, L8, and L25, to form a stoichiometric complex with it. The complex can bind to 23S rRNA, although none of the isolated components can do so. It lies in the vicinity of the P and A sites.

A nascent protein debouches through the ribosome, away from the active sites, into the region in which ribosomes may be attached to membranes (see *Molecular Biology 2.8 Protein localization*). A polypeptide chain emerges from the ribosome through an exit channel, which leads from the peptidyl transferase site to the surface of the 50S subunit. The tunnel is composed mostly of rRNA. It is quite narrow, only 1-2 nm wide, and ~10 nm long. The nascent polypeptide emerges from the ribosome ~15 Å away from the peptidyl transferase site. The tunnel can hold ~50 amino acids, and probably constrains the polypeptide chain so that it cannot fold until it leaves the exit domain.

**PROTEIN SYNTHESIS****2.6.18 16S rRNA plays an active role in protein synthesis**

---

**Key Concepts**

- 16S rRNA plays an active role in the functions of the 30S subunit. It interacts directly with mRNA, with the 50S subunit, and with the anticodons of tRNAs in the P and A sites.
- 

The ribosome was originally viewed as a collection of proteins with various catalytic activities, held together by protein-protein interactions and by binding to rRNA. But the discovery of RNA molecules with catalytic activities (see *Molecular Biology 5.24 RNA splicing and processing*) immediately suggests that rRNA might play a more active role in ribosome function. There is now evidence that rRNA interacts with mRNA or tRNA at each stage of translation, and that the proteins are necessary to maintain the rRNA in a structure in which it can perform the catalytic functions. Several interactions involve specific regions of rRNA:

- The 3' terminus of the rRNA interacts directly with mRNA at initiation.
- Specific regions of 16S rRNA interact directly with the anticodon regions of tRNAs in both the A site and the P site. Similarly, 23S rRNA interacts with the CCA terminus of peptidyl-tRNA in both the P site and A site.
- Subunit interaction involves interactions between 16S and 23S rRNAs (see *Molecular Biology 2.6.16 Ribosomal RNA pervades both ribosomal subunits*).

Much information about the individual steps of bacterial protein synthesis has been obtained by using antibiotics that inhibit the process at particular stages. The target for the antibiotic can be identified by the component in which resistant mutations occur. Some antibiotics act on individual ribosomal proteins, but several act on rRNA, which suggests that the rRNA is involved with many or even all of the functions of the ribosome.

The functions of rRNA have been investigated by two types of approach. Structural studies show that particular regions of rRNA are located in important sites of the ribosome, and that chemical modifications of these bases impede particular ribosomal functions. And mutations identify bases in rRNA that are required for particular ribosomal functions. **Figure 6.45** summarizes the sites in 16S rRNA that have been identified by these means (for review see 436).

**Figure 6.45** Some sites in 16S rRNA are protected from chemical probes when 50S subunits join 30S subunits or when aminoacyl-tRNA binds to the A site. Others are the sites of mutations that affect protein synthesis. TERM suppression sites may affect termination at some or several termination codons. The large colored blocks indicate the four domains of the rRNA.

An indication of the importance of the 3' end of 16S rRNA is given by its susceptibility to the lethal agent colicin E3. Produced by some bacteria, the colicin cleaves ~50 nucleotides from the 3' end of the 16S rRNA of *E. coli*. The cleavage entirely abolishes initiation of protein synthesis. Several important functions require the region that is cleaved: binding the factor IF-3; recognition of mRNA; and binding of tRNA.

The 3' end of the 16S rRNA is directly involved in the initiation reaction by pairing with the Shine-Dalgarno sequence in the ribosome-binding site of mRNA (see **Figure 6.16** and *Great Experiments 4.8 rRNA-mRNA base pairing selects translational initiator regions in bacteria*). Another direct role for the 3' end of 16S rRNA in protein synthesis is shown by the properties of kasugamycin-resistant mutants, which lack certain modifications in 16S rRNA. Kasugamycin blocks initiation of protein synthesis. Resistant mutants of the type *ksgA* lack a methylase

enzyme that introduces four methyl groups into two adjacent adenines at a site near the 3' terminus of the 16S rRNA. The methylation generates the highly conserved sequence G-m<sub>2</sub><sup>6</sup>A-m<sub>2</sub><sup>6</sup>A, found in both prokaryotic and eukaryotic small rRNA. The methylated sequence is involved in the joining of the 30S and 50S subunits, which in turn is connected also with the retention of initiator tRNA in the complete ribosome. Kasugamycin causes fMet-tRNA<sub>f</sub> to be released from the sensitive (methylated) ribosomes, but the resistant ribosomes are able to retain the initiator.

Changes in the structure of 16S rRNA occur when ribosomes are engaged in protein synthesis, as seen by protection of particular bases against chemical attack. The individual sites fall into a few groups, concentrated in the 3' minor and central domains. Although the locations are dispersed in the linear sequence of 16S rRNA, it seems likely that base positions involved in the same function are actually close together in the tertiary structure.

Some of the changes in 16S rRNA are triggered by joining with 50S subunits, binding of mRNA, or binding of tRNA. They indicate that these events are associated with changes in ribosome conformation that affect the exposure of rRNA. They do not necessarily indicate direct participation of rRNA in these functions. One change that occurs during protein synthesis is shown in **Figure 6.46**; it involves a local movement to change the nature of a short duplex sequence.

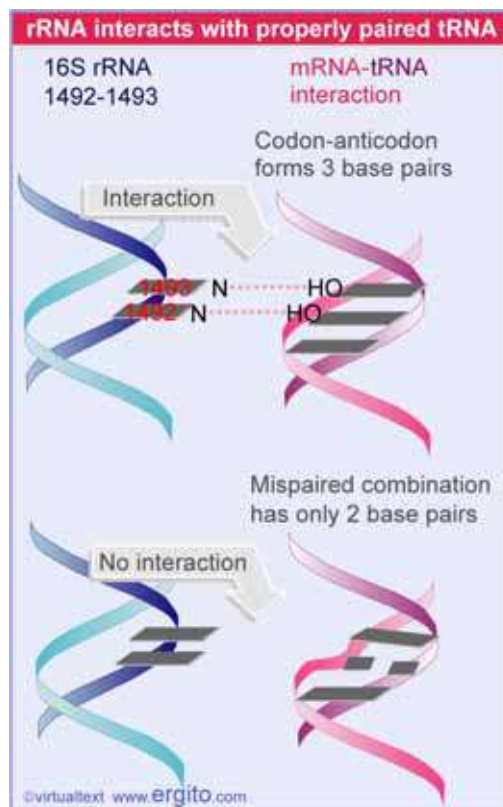

**Figure 6.46** A change in conformation of 16S rRNA may occur during protein synthesis.

The 16S rRNA is involved in both A site and P site function, and significant changes in its structure occur when these sites are occupied (934). Certain distinct regions are protected by tRNA bound in the A site (see **Figure 6.45**). One is the 530 loop (which is also the site of a mutation that prevents termination at the UAA, UAG, and UGA codons). The other is the 1400-1500 region (so-called because bases 1399-1492 and the adenines at 1492-1493 are two single-stranded stretches that are connected by a long hairpin). All of the effects that tRNA binding has on 16S rRNA can be produced by the isolated oligonucleotide of the anticodon stem-loop, so that tRNA-30S subunit binding must involve this region (443).

The adenines at 1492-1493 provide a mechanism for detecting properly paired codon-anticodon complexes (935). The principle of the interaction is that the structure of the 16S rRNA responds to the structure of the first two base pairs in the minor groove of the duplex formed by the codon-anticodon interaction. Modification

of the N1 position of either base 1492 or 1493 in rRNA prevents tRNA from binding in the A site. However, mutations at 1492 or 1493 can be suppressed by the introduction of fluorine at the 2' position of the corresponding bases in mRNA (which restores the interaction). **Figure 6.47** shows that codon-anticodon pairing allows the N1 of each adenine to interact with the 2' -OH in the mRNA backbone. When an incorrect tRNA enters the A site, the structure of the codon-anticodon complex is distorted, and this interaction cannot occur. The interaction stabilizes the association of tRNA with the A site.

**Figure 6.47** Codon-anticodon pairing supports interaction with adenines 1492-1493 of 16S rRNA, but mispaired tRNA-mRNA cannot interact.

A variety of bases in different positions of 16S rRNA are protected by tRNA in the P site; probably the bases lie near one another in the tertiary structure. In fact, there are more contacts with tRNA when it is in the P site than when it is in the A site. This may be responsible for the increased stability of peptidyl-tRNA compared with aminoacyl-tRNA. This makes sense, because once the tRNA has reached the P site, the ribosome has decided that it is correctly bound, whereas in the A site, the assessment of binding is being made. The 1400 region can be directly cross-linked to peptidyl-tRNA, which suggests that this region is a structural component of the P site.

The basic conclusion to be drawn from these results is that rRNA has many interactions with both tRNA and mRNA, and that these interactions recur in each cycle of peptide bond formation.

**PROTEIN SYNTHESIS****2.6.19 23S rRNA has peptidyl transferase activity**

---

**Key Concepts**

- Peptidyl transferase activity resides exclusively in the 23S rRNA.
- 

The sites involved in the functions of 23S rRNA are less well identified than those of 16S rRNA, but the same general pattern is observed: bases at certain positions affect specific functions. Bases at some positions in 23S rRNA are affected by the conformation of the A site or P site. In particular, oligonucleotides derived from the 3' CCA terminus of tRNA protect a set of bases in 23S rRNA which essentially are the same as those protected by peptidyl-tRNA. This suggests that the major interaction of 23S rRNA with peptidyl-tRNA in the P site involves the 3' end of the tRNA.

The tRNA makes contacts with the 23S rRNA in both the P and A sites. At the P site, G2552 of 23S rRNA base pairs with C74 of the peptidyl tRNA. A mutation in the G in the rRNA prevents interaction with tRNA, but interaction is restored by a compensating mutation in the C of the amino acceptor end of the tRNA. At the A site, G2553 of the 23S rRNA base pairs with C75 of the aminoacyl-tRNA. So there is a close role for rRNA in both the tRNA-binding sites. Indeed, when we have a clearer structural view of the region, we should be able to understand the movements of tRNA between the A and P sites in terms of making and breaking contacts with rRNA (442).

Another site that binds tRNA is the E site, which is localized almost exclusively on the 50S subunit. Bases affected by its conformation can be identified in 23S rRNA.

What is the nature of the site on the 50S subunit that provides peptidyl transferase function? The involvement of rRNA was first indicated because a region of the 23S rRNA is the site of mutations that confer resistance to antibiotics that inhibit peptidyl transferase.

A long search for ribosomal proteins that might possess the catalytic activity has been unsuccessful. More recent results suggest that the ribosomal RNA of the large subunit has the catalytic activity. Extraction of almost all the protein content of 50S subunits leaves the 23S rRNA associated largely with fragments of proteins, amounting to <5% of the mass of the ribosomal proteins. This preparation retains peptidyl transferase activity. Treatments that damage the RNA abolish the catalytic activity (441).

Following from these results, 23S rRNA prepared by transcription *in vitro* can catalyze the formation of a peptide bond between Ac-Phe-tRNA and Phe-tRNA. The yield of Ac-Phe-Phe is very low, suggesting that the 23S rRNA requires proteins in order to function at a high efficiency. But since the rRNA has the basic catalytic activity, the role of the proteins must be indirect, serving to fold the rRNA properly or to present the substrates to it. The reaction also works, although less effectively, if

the domains of 23S rRNA are synthesized separately and then combined. In fact, some activity is shown by domain V alone, which has the catalytic center. Activity is abolished by mutations in position 2252 of domain V that lies in the P site.

The crystal structure of an archaeal 50S subunit shows that the peptidyl transferase site basically consists of 23S rRNA (1086). There is no protein within 18Å of the active site where the transfer reaction occurs between peptidyl-tRNA and aminoacyl-tRNA!

Peptide bond synthesis requires an attack by the amino group of one amino acid on the carboxyl group of another amino acid. Catalysis requires a basic residue to accept the hydrogen atom that is released from the amino group, as shown in **Figure 6.48**. If rRNA is the catalyst, it must provide this residue, but we do not know how this happens. The purine and pyrimidine bases are not basic at physiological pH. A highly conserved base (at position 2451 in *E. coli*) had been implicated, but appears now neither to have the right properties nor to be crucial for peptidyl transferase activity (2001; 2002).

**Figure 6.48** Peptide bond formation requires acid-base catalysis in which an H atom is transferred to a basic residue.

Proteins that are bound to the 23S rRNA outside of the peptidyl transfer region are

almost certainly required to enable the rRNA to form the proper structure *in vivo*. The idea that rRNA is the catalytic component is consistent with the results discussed in *Molecular Biology 5.24 RNA splicing and processing* that identify catalytic properties in RNA that are involved with several RNA processing reactions. It fits with the notion that the ribosome evolved from functions originally possessed by RNA.

## PROTEIN SYNTHESIS

### 2.6.20 Summary

---

Ribosomes are ribonucleoprotein particles in which a majority of the mass is provided by rRNA. The shapes of all ribosomes are generally similar, but only those of bacteria (70S) have been characterized in detail. The small (30S) subunit has a squashed shape, with a "body" containing about two-thirds of the mass divided from the "head" by a cleft. The large (50S) subunit is more spherical, with a prominent "stalk" on the right and a "central protuberance." Locations of all proteins are known approximately in the small subunit.

Each subunit contains a single major rRNA, 16S and 23S in prokaryotes, 18S and 28S in eukaryotic cytosol. There are also minor rRNAs, most notably 5S rRNA in the large subunit. Both major rRNAs have extensive base pairing, mostly in the form of short, imperfectly paired duplex stems with single-stranded loops. Conserved features in the rRNA can be identified by comparing sequences and the secondary structures that can be drawn for rRNA of a variety of organisms. The 16S rRNA has four distinct domains; the 23S rRNA has six distinct domains. Eukaryotic rRNAs have additional domains.

The crystal structure shows that the 30S subunit has an asymmetrical distribution of RNA and protein. RNA is concentrated at the interface with the 50S subunit. The 50S subunit has a surface of protein, with long rods of double-stranded RNA crisscrossing the structure. 30S-50S joining involves contacts between 16S rRNA and 23S rRNA.

Each subunit has several active centers, concentrated in the translational domain of the ribosome where proteins are synthesized. Proteins leave the ribosome through the exit domain, which can associate with a membrane. The major active sites are the P and A sites, the E site, the EF-Tu and EF-G binding sites, peptidyl transferase, and mRNA-binding site. Ribosome conformation may change at stages during protein synthesis; differences in the accessibility of particular regions of the major rRNAs have been detected.

The tRNAs in the A and P sites are parallel to one another. The anticodon loops are bound to mRNA in a groove on the 30S subunit. The rest of each tRNA is bound to the 50S subunit. A conformational shift of tRNA within the A site is required to bring its aminoacyl end into juxtaposition with the end of the peptidyl-tRNA in the P site. The peptidyl transferase site that links the P and A binding sites is made of 23S rRNA, which has the peptidyl transferase catalytic activity, although proteins are probably needed to acquire the right structure.

An active role for the rRNAs in protein synthesis is indicated by mutations that affect ribosomal function, interactions with mRNA or tRNA that can be detected by chemical crosslinking, and the requirement to maintain individual base pairing interactions with the tRNA or mRNA. The 3' terminal region of the rRNA base pairs with mRNA at initiation. Internal regions make individual contacts with the tRNAs in both the P and A sites. Ribosomal RNA is the target for some antibiotics or other agents that inhibit protein synthesis

A codon in mRNA is recognized by an aminoacyl-tRNA, which has an anticodon complementary to the codon and carries the amino acid corresponding to the codon. A special initiator tRNA (fMet-tRNA<sub>f</sub> in prokaryotes or Met-tRNA<sub>i</sub> in eukaryotes) recognizes the AUG codon, which is used to start all coding sequences. In prokaryotes, GUG is also used. Only the termination (nonsense) codons UAA, UAG, and UGA are not recognized by aminoacyl-tRNAs.

Ribosomes are released from protein synthesis to enter a pool of free ribosomes that are in equilibrium with separate small and large subunits. Small subunits bind to mRNA and then are joined by large subunits to generate an intact ribosome that undertakes protein synthesis. Recognition of a prokaryotic initiation site involves binding of a sequence at the 3' end of rRNA to the Shine-Dalgarno motif which precedes the AUG (or GUG) codon in the mRNA. Recognition of a eukaryotic mRNA involves binding to the 5' cap; the small subunit then migrates to the initiation site by scanning for AUG codons. When it recognizes an appropriate AUG codon (usually but not always the first it encounters), it is joined by a large subunit.

A ribosome can carry two aminoacyl-tRNAs simultaneously: its P site is occupied by a polypeptidyl-tRNA, which carries the polypeptide chain synthesized so far, while the A site is used for entry by an aminoacyl-tRNA carrying the next amino acid to be added to the chain. Bacterial ribosomes also have an E site, through which deacylated tRNA passes before it is released after being used in protein synthesis. The polypeptide chain in the P site is transferred to the aminoacyl-tRNA in the A site, creating a deacylated tRNA in the P site and a peptidyl-tRNA in the A site.

Following peptide bond synthesis, the ribosome translocates one codon along the mRNA, moving deacylated tRNA into the E site, and peptidyl tRNA from the A site into the P site. Translocation is catalyzed by the elongation factor EF-G, and like several other stages of ribosome function, requires hydrolysis of GTP. During translocation, the ribosome passes through a hybrid stage in which the 50S subunit moves relative to the 30S subunit.

Protein synthesis is an expensive process. ATP is used to provide energy at several stages, including the charging of tRNA with its amino acid, and the unwinding of mRNA. It has been estimated that up to 90% of all the ATP molecules synthesized in a rapidly growing bacterium are consumed in assembling amino acids into protein!

Additional factors are required at each stage of protein synthesis. They are defined by their cyclic association with, and dissociation from, the ribosome. IF factors are involved in prokaryotic initiation. IF-3 is needed for 30S subunits to bind to mRNA and also is responsible for maintaining the 30S subunit in a free form. IF-2 is needed for fMet-tRNA<sub>f</sub> to bind to the 30S subunit and is responsible for excluding other aminoacyl-tRNAs from the initiation reaction. GTP is hydrolyzed after the initiator tRNA has been bound to the initiation complex. The initiation factors must be released in order to allow a large subunit to join the initiation complex.

Eukaryotic initiation involves a greater number of factors. Some of them are involved in the initial binding of the 40S subunit to the capped 5' end of the mRNA. Then the initiator tRNA is bound by another group of factors. After this initial binding, the small subunit scans the mRNA until it recognizes the correct AUG codon. At this point, initiation factors are released and the 60S subunit joins the

complex.

Prokaryotic EF factors are involved in elongation. EF-Tu binds aminoacyl-tRNA to the 70S ribosome. GTP is hydrolyzed when EF-Tu is released, and EF-Ts is required to regenerate the active form of EF-Tu. EF-G is required for translocation. Binding of the EF-Tu and EF-G factors to ribosomes is mutually exclusive, which ensures that each step must be completed before the next can be started.

Termination occurs at any one of the three special codons, UAA, UAG, UGA. Class 1 RF factors that specifically recognize the termination codons activate the ribosome to hydrolyze the peptidyl-tRNA. A class 2 RF factor is required to release the class 1 RF factor from the ribosome. The GTP-binding factors IF-2, EF-Tu, EF-G, RF3 all have similar structures, with the latter two mimicking the RNA-protein structure of the first two when they are bound to tRNA; they all bind to the same ribosomal site, the G-factor binding site.

## USING THE GENETIC CODE

### 2.7.1 Introduction

---

The sequence of a coding strand of DNA, read in the direction from 5' to 3', consists of nucleotide triplets (codons) corresponding to the amino acid sequence of a protein read from N-terminus to C-terminus. Sequencing of DNA and proteins makes it possible to compare corresponding nucleotide and amino acid sequences directly. There are 64 codons (each of 4 possible nucleotides can occupy each of the three positions of the codon, making  $4^3 = 64$  possible trinucleotide sequences). Each of these codons has a specific meaning in protein synthesis: 61 codons represent amino acids; 3 codons cause the termination of protein synthesis.

The meaning of a codon that represents an amino acid is determined by the tRNA that corresponds to it; the meaning of the termination codons is determined directly by protein factors.

The breaking of the genetic code originally showed that genetic information is stored in the form of nucleotide triplets, but did not reveal how each codon specifies its corresponding amino acid. Before the advent of sequencing, codon assignments were deduced on the basis of two types of *in vitro* studies. A system involving the translation of synthetic polynucleotides was introduced in 1961, when Nirenberg showed that polyuridylic acid [poly(U)] directs the assembly of phenylalanine into polyphenylalanine. This result means that UUU must be a codon for phenylalanine. A second system was later introduced in which a trinucleotide was used to mimic a codon, thus causing the corresponding aminoacyl-tRNA to bind to a ribosome. By identifying the amino acid component of the aminoacyl-tRNA, the meaning of the codon can be found. The two techniques together assigned meaning to all of the codons that represent amino acids (418; 423).

61 of the 64 codons represent amino acids. The other three cause termination of protein synthesis. The assignment of amino acids to codons is not random, but shows relationships in which the third base has less effect on codon meaning; also related amino acids are often represented by related codons.

## USING THE GENETIC CODE

### 2.7.2 Related codons represent related amino acids

---

#### Key Terms

**Synonym** codons have the same meaning in the genetic code. Synonym tRNAs bear the same amino acid and respond to the same codon.

**Third base degeneracy** describes the lesser effect on codon meaning of the nucleotide present in the third codon position.

A **stop codon (Termination codon)** is one of three triplets (UAG, UAA, UGA) that causes protein synthesis to terminate. They are also known historically as *nonsense codons*. The UAG codon is called ochre, and the UAA codon is called amber, after the names of the nonsense mutations by which they were originally identified.

#### Key Concepts

- 61 of the 64 possible triplets code for 20 amino acids.
  - 3 codons do not represent amino acids and cause termination.
  - The genetic code was frozen at an early stage of evolution and is universal.
  - Most amino acids are represented by more than one codon.
  - The multiple codons for an amino acid are usually related.
  - Related amino acids often have related codons, minimizing the effects of mutation.
- 

The code is summarized in **Figure 7.1**. Because there are more codons (61) than there are amino acids (20), almost all amino acids are represented by more than one codon. The only exceptions are methionine and tryptophan. Codons that have the same meaning are called **synonyms**. Because the genetic code is actually read on the mRNA, usually it is described in terms of the four bases present in RNA: U, C, A, and G.

**The genetic code is triplet**

	U	C	A	G
<b>U</b>	UUU } Phe UUC } UUA } Leu UUG }	UCU } UCC } Ser UCA } UCG }	UAU } Tyr UAC } UAA } STOP UAG }	UGU } Cys UGC } UGA } STOP UGG } Trp
<b>C</b>	CUU } CUC } Leu CUA } CUG }	CCU } CCC } Pro CCA } CCG }	CAU } His CAC } CAA } Gln CAG }	CGU } CGC } Arg CGA } CGG }
<b>A</b>	AUU } Ile AUC } AUA } AUG } Met	ACU } ACC } Thr ACA } ACG }	AAU } Asn AAC } AAA } Lys AAG }	AGU } Ser AGC } AGA } Arg AGG }

©virtualtext www.ergito.com

**Figure 7.1** All the triplet codons have meaning: 61 represent amino acids, and 3 cause termination (STOP).

Codons representing the same or related amino acids tend to be similar in sequence. Often the base in the third position of a codon is not significant, because the four codons differing only in the third base represent the same amino acid. Sometimes a distinction is made only between a purine versus a pyrimidine in this position. The reduced specificity at the last position is known as **third base degeneracy**.

The interpretation of a codon requires base pairing with the anticodon of the corresponding aminoacyl-tRNA. The reaction occurs within the ribosome: complementary trinucleotides in isolation would usually be too short to pair in a stable manner, but the interaction is stabilized by the environment of the ribosomal A site. Also, base pairing between codon and anticodon is not solely a matter of A·U and G·C base pairing. The ribosome controls the environment in such a way that conventional pairing occurs at the first two positions of the codon, but additional reactions are permitted at the third base. As a result, a single aminoacyl-tRNA may recognize more than one codon, corresponding with the pattern of degeneracy. Furthermore, pairing interactions may also be influenced by the introduction of special bases into tRNA, especially by modification in or close to the anticodon.

The tendency for similar amino acids to be represented by related codons minimizes the effects of mutations. It increases the probability that a single random base change will result in no amino acid substitution or in one involving amino acids of similar character. For example, a mutation of CUC to CUG has no effect, since both codons represent leucine; and a mutation of CUU to AUU results in replacement of leucine with isoleucine, a closely related amino acid.

**Figure 7.2** plots the number of codons representing each amino acid against the

frequency with which the amino acid is used in proteins (in *E. coli*). There is only a slight tendency for amino acids that are more common to be represented by more codons, and therefore it does not seem that the genetic code has been optimized with regard to the utilization of amino acids.

**Figure 7.2** The number of codons for each amino acid does not correlate closely with its frequency of use in proteins.

The three codons (UAA, UAG, and UGA) that do not represent amino acids are used specifically to terminate protein synthesis. One of these **stop codons** marks the end of every gene.

Is the genetic code the same in all living organisms?

Comparisons of DNA sequences with the corresponding protein sequences reveal that the identical set of codon assignments is used in bacteria and in eukaryotic cytoplasm. As a result, mRNA from one species usually can be translated correctly *in vitro* or *in vivo* by the protein synthetic apparatus of another species. So the codons used in the mRNA of one species have the same meaning for the ribosomes and tRNAs of other species.

The universality of the code argues that it must have been established very early in evolution. Perhaps the code started in a primitive form in which a small number of codons were used to represent comparatively few amino acids, possibly even with one codon corresponding to any member of a group of amino acids. More precise codon meanings and additional amino acids could have been introduced later. One possibility is that at first only two of the three bases in each codon were used; discrimination at the third position could have evolved later. (Originally there might have been a stereochemical relationship between amino acids and the codons representing them. Then a more complex system evolved.)

Evolution of the code could have become "frozen" at a point at which the system had become so complex that any changes in codon meaning would disrupt existing proteins by substituting unacceptable amino acids. Its universality implies that this must have happened at such an early stage that all living organisms are descended from a single pool of primitive cells in which this occurred.

Exceptions to the universal genetic code are rare. Changes in meaning in the principal genome of a species usually concern the termination codons. For example, in a mycoplasma, UGA codes for tryptophan; and in certain species of the ciliates *Tetrahymena* and *Paramecium*, UAA and UAG code for glutamine. Systematic alterations of the code have occurred only in mitochondrial DNA (see *Molecular Biology 2.7.7 There are sporadic alterations of the universal code*).

## USING THE GENETIC CODE

### 2.7.3 Codon-anticodon recognition involves wobbling

---

#### Key Terms

The **wobble hypothesis** accounts for the ability of a tRNA to recognize more than one codon by unusual (non-G·C, non-A·T) pairing with the third base of a codon.

#### Key Concepts

- Multiple codons that represent the same amino acid most often differ at the third base position.
  - The wobble in pairing between the first base of the anticodon and the third base of the codon results from the structure of the anticodon loop.
- 

The function of tRNA in protein synthesis is fulfilled when it recognizes the codon in the ribosomal A site. The interaction between anticodon and codon takes place by base pairing, but under rules that extend pairing beyond the usual G·C and A·U partnerships.

We can deduce the rules governing the interaction from the sequences of the anticodons that correspond to particular codons. The ability of any tRNA to respond to a given codon can be measured directly by the trinucleotide binding assay or by its use in an *in vitro* protein synthetic system.

The genetic code itself yields some important clues about the process of codon recognition. The pattern of third-base degeneracy is drawn in **Figure 7.3**, which shows that in almost all cases either the third base is irrelevant or a distinction is made only between purines and pyrimidines.

**Figure 7.3** Third bases have the least influence on codon meanings. Boxes indicate groups of codons within which third-base degeneracy ensures that the meaning is the same.

There are eight codon families in which all four codons sharing the same first two bases have the same meaning, so that the third base has no role at all in specifying the amino acid. There are seven codon pairs in which the meaning is the same whichever pyrimidine is present at the third position; and there are five codon pairs in which either purine may be present without changing the amino acid that is coded.

There are only three cases in which a unique meaning is conferred by the presence of a particular base at the third position: AUG (for methionine), UGG (for tryptophan), and UGA (termination). So C and U never have a unique meaning in the third position, and A never signifies a unique amino acid.

Because the anticodon is complementary to the codon, it is the first base in the anticodon sequence written conventionally in the direction from 5' to 3' that pairs with the third base in the codon sequence written by the same convention. So the combination

Codon 5' A C G 3'

Anticodon 3' U G C 5'

is usually written as codon ACG/anticodon CGU, where the anticodon sequence must be read backward for complementarity with the codon.

To avoid confusion, we shall retain the usual convention in which all sequences are written 5'–3', but indicate anticodon sequences with a backward arrow as a reminder of the relationship with the codon. So the codon/anticodon pair shown above will be written as ACG and CGU<sup>←</sup>, respectively.

Does each triplet codon demand its own tRNA with a complementary anticodon? Or can a single tRNA respond to both members of a codon pair and to all (or at least some) of the four members of a codon family?

Often one tRNA can recognize more than one codon. This means that the base in the first position of the anticodon must be able to partner alternative bases in the corresponding third position of the codon. Base pairing at this position cannot be limited to the usual G-C and A-U partnerships.

The rules governing the recognition patterns are summarized in the **wobble hypothesis**, which states that the pairing between codon and anticodon at the first two codon positions always follows the usual rules, but that exceptional "wobbles" occur at the third position. Wobbling occurs because the conformation of the tRNA anticodon loop permits flexibility at the first base of the anticodon (449). **Figure 7.4** shows that G-U pairs can form in addition to the usual pairs.

**Figure 7.4** Wobble in base pairing allows G-U pairs to form between the third base of the codon and the first base of the anticodon.

This single change creates a pattern of base pairing in which A can no longer have a unique meaning in the codon (because the U that recognizes it must also recognize G). Similarly, C also no longer has a unique meaning (because the G that recognizes it also must recognize U). **Figure 7.5** summarizes the pattern of recognition.

The third codon base wobbles	
Base in first position of anticodon	Base(s) recognized in third position of codon
U	A or G
C	G only
A	U only
G	C or U

©virtualtext www.ergito.com

**Figure 7.5** Codon-anticodon pairing involves wobbling at the third position.

It is therefore possible to recognize unique codons only when the third bases are G or U; this option is not used often, since UGG and AUG are the only examples of the first type, and there is none of the second type.

(G·U pairs are common in RNA duplex structures. But the formation of stable contacts between codon and anticodon, when only 3 base pairs can be formed, is more constrained, and thus G·U pairs can contribute only in the last position of the codon.)

---

**USING THE GENETIC CODE****2.7.4 tRNAs are processed from longer precursors**

---

**Key Concepts**

- A mature tRNA is generated by processing a precursor.
- The 5' end is generated by cleavage by the endonuclease RNAase P.
- The 3' end is generated by cleavage followed by trimming of the last few bases, followed by addition of the common terminal trinucleotide sequence CCA.

---

tRNAs are commonly synthesized as precursor chains with additional material at one or both ends. **Figure 7.6** shows that the extra sequences are removed by combinations of endonucleolytic and exonucleolytic activities. One feature that is common to all tRNAs is that the three nucleotides at the 3' terminus, always the triplet sequence CCA, are not coded in the genome, but are added as part of tRNA processing (for review see 3461).

**Figure 7.6** The tRNA 3' end is generated by cutting and trimming followed by addition of CCA; the 5' end is generated by cutting.

The 5' end of tRNA is generated by a cleavage action catalyzed by the enzyme ribonuclease P.

The enzymes that process the 3' end are best characterized in *E. coli*, where an endonuclease triggers the reaction by cleaving the precursor downstream, and several exonucleases then trim the end by degradation in the 3' -5' direction. The reaction also involves several enzymes in eukaryotes. It generates a tRNA that needs the CCA trinucleotide sequence to be added to the 3' end.

The addition of CCA is the result solely of an enzymatic process, that is, the enzymatic activity carries the specificity for the sequence of the trinucleotide, which is not determined by a template. There are several models for the process, which may be different in different organisms.

In some organisms, the process is catalyzed by a single enzyme. One model for its action proposes that a single enzyme binds to the 3' end, and sequentially adds C, C,

and A, the specificity at each stage being determined by the structure of the 3' end. Other models propose that the enzyme has different active sites for CTP and ATP.

In other organisms, different enzymes are responsible for adding the C and A residues, and they function sequentially.

When a tRNA is not properly processed, it attracts the attention of a quality control system that degrades it. This ensures that the protein synthesis apparatus does not become blocked by nonfunctional tRNAs.

## USING THE GENETIC CODE

### 2.7.5 tRNA contains modified bases

---

#### Key Terms

**Modification** of DNA or RNA includes all changes made to the nucleotides after their initial incorporation into the polynucleotide chain.

#### Key Concepts

- tRNAs contain >50 modified bases.
- Modification usually involves direct alteration of the primary bases in tRNA, but there are some exceptions in which a base is removed and replaced by another base.

---

Transfer RNA is unique among nucleic acids in its content of "unusual" bases. An unusual base is any purine or pyrimidine ring except the usual A, G, C, and U from which all RNAs are synthesized. All other bases are produced by **modification** of one of the four bases after it has been incorporated into the polyribonucleotide chain.

All classes of RNA display some degree of modification, but in all cases except tRNA this is confined to rather simple events, such as the addition of methyl groups. In tRNA, there is a vast range of modifications, ranging from simple methylation to wholesale restructuring of the purine ring. Modifications occur in all parts of the tRNA molecule. There are >50 different types of modified bases in tRNA.

**Figure 7.7** shows some of the more common modified bases. Modifications of pyrimidines (C and U) are less complex than those of purines (A and G). In addition to the modifications of the bases themselves, methylation at the 2' -O position of the ribose ring also occurs.

**Figure 7.7** All of the four bases in tRNA can be modified.

The most common modifications of uridine are straightforward. Methylation at position 5 creates ribothymidine (T). The base is the same commonly found in DNA; but here it is attached to ribose, not deoxyribose. In RNA, thymine constitutes an unusual base, originating by modification of U.

Dihydrouridine (D) is generated by the saturation of a double bond, changing the ring structure. Pseudouridine ( $\psi$ ) interchanges the positions of N and C atoms (see **Figure 24.40**). And 4-thiouridine has sulfur substituted for oxygen.

The nucleoside inosine is found normally in the cell as an intermediate in the purine biosynthetic pathway. However, it is not incorporated directly into RNA, where instead its existence depends on modification of A to create I. Other modifications of A include the addition of complex groups.

Two complex series of nucleotides depend on modification of G. The Q bases, such as queuosine, have an additional pentenyl ring added via an NH linkage to the methyl group of 7-methylguanosine. The pentenyl ring may carry various further groups.

The Y bases, such as wyosine, have an additional ring fused with the purine ring itself; the extra ring carries a long carbon chain, again to which further groups are added in different cases.

The modification reaction usually involves the alteration of, or addition to, existing bases in the tRNA. An exception is the synthesis of Q bases, where a special enzyme exchanges free queuosine with a guanosine residue in the tRNA. The reaction involves breaking and remaking bonds on either side of the nucleoside.

The modified nucleosides are synthesized by specific tRNA-modifying enzymes. The original nucleoside present at each position can be determined either by comparing the sequence of tRNA with that of its gene or (less efficiently) by isolating precursor molecules that lack some or all of the modifications. The sequences of precursors show that different modifications are introduced at different stages during the maturation of tRNA.

Some modifications are constant features of all tRNA molecules – for example, the D residues that give rise to the name of the D arm, and the  $\psi$  found in the T  $\psi$  C sequence. On the 3' side of the anticodon there is always a modified purine, although the modification varies widely.

Other modifications are specific for particular tRNAs or groups of tRNAs. For example, wyosine bases are characteristic of tRNA<sup>Phe</sup> in bacteria, yeast, and mammals. There are also some species-specific patterns.

The many tRNA-modifying enzymes (~60 in yeast) vary greatly in specificity (for review see 3461). In some cases, a single enzyme acts to make a particular modification at a single position. In other cases, an enzyme can modify bases at several different target positions. Some enzymes undertake single reactions with individual tRNAs; others have a range of substrate molecules. The features recognized by the tRNA-modifying enzymes are unknown, but probably involve recognition of structural features surrounding the site of modification. Some modifications require the successive actions of more than one enzyme.

## USING THE GENETIC CODE

**2.7.6 Modified bases affect anticodon-codon pairing****Key Concepts**

- Modifications in the anticodon affect the pattern of wobble pairing and therefore are important in determining tRNA specificity.

The most direct effect of modification is seen in the anticodon, where change of sequence influences the ability to pair with the codon, thus determining the meaning of the tRNA. Modifications elsewhere in the vicinity of the anticodon also influence its pairing.

When bases in the anticodon are modified, further pairing patterns become possible in addition to those predicted by the regular and wobble pairing involving A, C, U, and G. **Figure 7.8** shows the use of inosine (I), which is often present at the first position of the anticodon. Inosine can pair with any one of three bases, U, C, and A.

**Figure 7.8** Inosine can pair with any of U, C, and A.

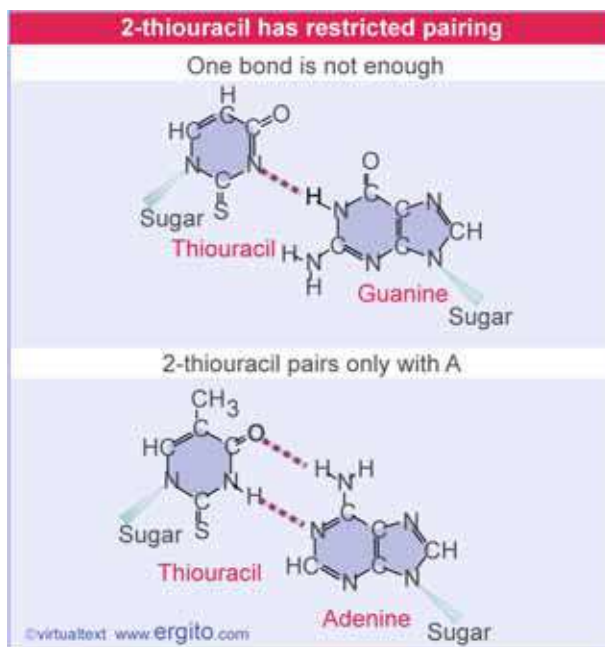

This ability is especially important in the isoleucine codons, where AUA codes for isoleucine, while AUG codes for methionine. Because with the usual bases it is not possible to recognize A alone in the third position, any tRNA with U starting its anticodon would have to recognize AUG as well as AUA. So AUA must be read together with AUU and AUC, a problem that is solved by the existence of tRNA

with I in the anticodon.

Actually, some of the predicted regular combinations do not occur, because some bases are always modified. There seems to be an absolute ban on the employment of A; usually it is converted to I. And U at the first position of the anticodon is usually converted to a modified form that has altered pairing properties.

Some modifications create preferential readings of some codons with respect to others. Anticodons with uridine-5-oxyacetic acid and 5-methoxyuridine in the first position recognize A and G efficiently as third bases of the codon, but recognize U less efficiently. Another case in which multiple pairings can occur, but with some preferred to others, is provided by the series of queuosine and its derivatives. These modified G bases continue to recognize both C and U, but pair with U more readily.

A restriction not allowed by the usual rules can be achieved by the employment of 2-thiouridine in the anticodon. **Figure 7.9** shows that its modification allows the base to continue to pair with A, but prevents it from indulging in wobble pairing with G (for review see 32).

**Figure 7.9** Modification to 2-thiouridine restricts pairing to A alone because only one H-bond can form with G.

These and other pairing relationships make the general point that there are multiple ways to construct a set of tRNAs able to recognize all the 61 codons representing amino acids. No particular pattern predominates in any given organism, although the absence of a certain pathway for modification can prevent the use of some recognition patterns. So a particular codon family is read by tRNAs with different anticodons in different organisms.

Often the tRNAs will have overlapping responses, so that a particular codon is read by more than one tRNA. In such cases there may be differences in the efficiencies of

the alternative recognition reactions. (As a general rule, codons that are commonly used tend to be more efficiently read.) And in addition to the construction of a set of tRNAs able to recognize all the codons, there may be multiple tRNAs that respond to the same codons.

The predictions of wobble pairing accord very well with the observed abilities of almost all tRNAs. But there are exceptions in which the codons recognized by a tRNA differ from those predicted by the wobble rules. Such effects probably result from the influence of neighboring bases and/or the conformation of the anticodon loop in the overall tertiary structure of the tRNA. Indeed, the importance of the structure of the anticodon loop is inherent in the idea of the wobble hypothesis itself. Further support for the influence of the surrounding structure is provided by the isolation of occasional mutants in which a change in a base in some other region of the molecule alters the ability of the anticodon to recognize codons.

Another unexpected pairing reaction is presented by the ability of the bacterial initiator, fMet-tRNA<sub>f</sub>, to recognize both AUG and GUG. This misbehavior involves the third base of the anticodon.

## USING THE GENETIC CODE

### 2.7.7 There are sporadic alterations of the universal code

#### Key Concepts

- Changes in the universal genetic code have occurred in some species.
- They are more common in mitochondrial genomes, where a phylogenetic tree can be constructed for the changes.
- In nuclear genomes, they are sporadic and usually affect only termination codons.

The universality of the genetic code is striking, but some exceptions exist. They tend to affect the codons involved in initiation or termination and result from the production (or absence) of tRNAs representing certain codons. The changes found in principal (bacterial or nuclear) genomes are summarized in **Figure 7.10**.

Changes in the genetic code usually involve Stop/None signals			
UUU Phe	UCU	UAU Tyr	UGU Cys
UUC	UCC Ser	UAC	UGC Cys
UUA Leu	UCA	UAA STOP→Gln	UGA STOP→Trp, Cys, Sel
UUG	UCG	UAG	UGG Trp
CUU	CCU	CAU His	CGU
CUC Leu	CCC Pro	CAC	CGC Arg
CUA	CCA	CAA Gln	CGA Arg
CUG Leu→Ser	CCG	CAG	CGG Arg→NONE
AUU	ACU	AAU Asn	AGU Ser
AUC Ile	ACC Thr	AAC	AGC Ser
AUA Ile→NONE	ACA	AAA Lys	AGA Arg→NONE
AUG Met	ACG	AAG	AGG Arg
GUU	GCU	GAU Asp	GGU
GUC Val	GCC Ala	GAC	GGC Gly
GUA	GCA	GAA	GGA Gly
GUG	GCG	GAG Glu	GGG ©virtualtext www.ergito.com

**Figure 7.10** Changes in the genetic code in bacterial or eukaryotic nuclear genomes usually assign amino acids to stop codons or change a codon so that it no longer specifies an amino acid. A change in meaning from one amino acid to another is unusual.

Almost all of the changes that allow a codon to represent an amino acid affect termination codons:

- In the prokaryote *Mycoplasma capricolum*, UGA is not used for termination, but instead codes for tryptophan. In fact, it is the predominant Trp codon, and UGG is used only rarely. Two Trp-tRNA species exist, with the anticodons UCA ←

(reads UGA and UGG) and CCA<sup>←</sup> (reads only UGG).

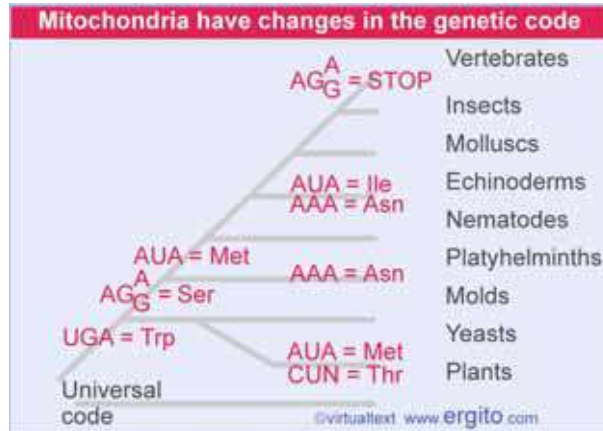

- Some ciliates (unicellular protozoa) read UAA and UAG as glutamine instead of termination signals. *Tetrahymena thermophila*, one of the ciliates, contains three tRNA<sup>Glu</sup> species. One recognizes the usual codons CAA and CAG for glutamine, one recognizes both UAA and UAG (in accordance with the wobble hypothesis), and the last recognizes only UAG. We assume that a further change is that the release factor eRF has a restricted specificity, compared with that of other eukaryotes.
- In another ciliate (*Euplotes octacarinatus*), UGA codes for cysteine. Only UAA is used as a termination codon, and UAG is not found. The change in meaning of UGA might be accomplished by a modification in the anticodon of tRNA<sup>Cys</sup> to allow it to read UGA with the usual codons UGU and UGC.
- The only substitution in coding for amino acids occurs in a yeast (*Candida*), where CUG means serine instead of leucine (and UAG is used as a sense codon).

Acquisition of a coding function by a termination codon requires two types of change: a tRNA must be mutated so as to recognize the codon; and the class I release factor must be mutated so that it does not terminate at this codon.

The other common type of change is loss of the tRNA that responds to a codon, so that the codon no longer specifies any amino acid. What happens at such a codon will depend on whether the termination factor evolves to recognize it.

All of these changes are sporadic, which is to say that they appear to have occurred independently in specific lines of evolution. They may be concentrated on termination codons, because these changes do not involve substitution of one amino acid for another. Once the genetic code was established, early in evolution, any general change in the meaning of a codon would cause a substitution in all the proteins that contain that amino acid. It seems likely that the change would be deleterious in at least some of these proteins, with the result that it would be strongly selected against. The divergent uses of the termination codons could represent their "capture" for normal coding purposes. If some termination codons were used only rarely, they could be recruited to coding purposes by changes that allowed tRNAs to recognize them.

Exceptions to the universal genetic code also occur in the mitochondria from several species. **Figure 7.11** constructs a phylogeny for the changes. It suggests that there was a universal code that was changed at various points in mitochondrial evolution. The earliest change was the employment of UGA to code for tryptophan, which is common to all (non-plant) mitochondria (for review see 41).

**Figure 7.11** Changes in the genetic code in mitochondria can be traced in phylogeny. The minimum number of independent changes is generated by supposing that the AUA=Met and the AAA=Asn changes each occurred independently twice, and that the early AUA=Met change was reversed in echinoderms.

Some of these changes make the code simpler, by replacing two codons that had different meanings with a pair that has a single meaning. Pairs treated like this include UGG and UGA (both Trp instead of one Trp and one termination) and AUG and AUA (both Met instead of one Met and the other Ile).

Why have changes been able to evolve in the mitochondrial code? Because the mitochondrion synthesizes only a small number of proteins (~10), the problem of disruption by changes in meaning is much less severe. Probably the codons that are altered were not used extensively in locations where amino acid substitutions would have been deleterious. The variety of changes found in mitochondria of different species suggests that they have evolved separately, and not by common descent from an ancestral mitochondrial code.

According to the wobble hypothesis, a minimum of 31 tRNAs (excluding the initiator) are required to recognize all 61 codons (at least 2 tRNAs are required for each codon family and 1 tRNA is needed per codon pair or single codon). But an unusual situation exists in (at least) mammalian mitochondria in which there are only 22 different tRNAs. How does this limited set of tRNAs accommodate all the codons?

The critical feature lies in a simplification of codon-anticodon pairing, in which one tRNA recognizes all four members of a codon family. This reduces to 23 the minimum number of tRNAs required to respond to all usual codons. The use of AG<sup>A</sup>G for termination reduces the requirement by one further tRNA, to 22.

In all eight codon families, the sequence of the tRNA contains an unmodified U at the first position of the anticodon. The remaining codons are grouped into pairs in which all the codons ending in pyrimidines are read by G in the anticodon, and all the codons ending in purines are read by a modified U in the anticodon, as predicted by the wobble hypothesis. The complication of the single UGG codon is avoided by the change in the code to read UGA with UGG as tryptophan; and in mammals, AUA ceases to represent isoleucine and instead is read with AUG as methionine.

This allows all the nonfamily codons to be read as 14 pairs.

The 22 identified tRNA genes therefore code for 14 tRNAs representing pairs, and 8 tRNAs representing families. This leaves the two usual termination codons UAG and UAA unrecognized by tRNA, together with the codon pair  $AG^A_G$ . Similar rules are followed in the mitochondria of fungi (for review see 33).

## USING THE GENETIC CODE

### 2.7.8 Novel amino acids can be inserted at certain stop codons

---

#### Key Concepts

- Changes in the reading of specific codons can occur in individual genes.
  - The insertion of seleno-Cys-tRNA at certain UGA codons requires several proteins to modify the Cys-tRNA and insert it into the ribosome.
  - Pyrrolysine can be inserted at certain UAG codons.
- 

Specific changes in reading the code occur in individual genes. The specificity of such changes implies that the reading of the particular codon must be influenced by the surrounding bases.

A striking example is the incorporation of the modified amino acid seleno-cysteine at certain UGA codons within the genes that code for selenoproteins in both prokaryotes and eukaryotes. Usually these proteins catalyze oxidation-reduction reactions, and contain a single seleno-cysteine residue, which forms part of the active site. The most is known about the use of the UGA codons in three *E. coli* genes coding for formate dehydrogenase isozymes. The internal UGA codon is read by a seleno-Cys-tRNA. This unusual reaction is determined by the local secondary structure of mRNA, in particular by the presence of a hairpin loop downstream of the UGA.

Mutations in 4 *sel* genes create a deficiency in selenoprotein synthesis. *selC* codes for tRNA (with the anticodon ACU<sup>←</sup>) that is charged with serine. *selA* and *selD* are required to modify the serine to seleno-cysteine. SelB is an alternative elongation factor. It is a guanine nucleotide-binding protein that acts as a specific translation factor for entry of seleno-Cys-tRNA into the A site; it thus provides (for this single tRNA) a replacement for factor EF-Tu. The sequence of SelB is related to both EF-Tu and IF-2 (for review see 39).

Why is seleno-Cys-tRNA inserted only at certain UGA codons? These codons are followed by a stem-loop structure in the mRNA. **Figure 7.12** shows that the stem of this structure is recognized by an additional domain in SelB (one that is not present in EF-Tu or IF-2). A similar mechanism interprets some UGA codons in mammalian cells, except that two proteins are required to identify the appropriate UGA codons. One protein (SBP2) binds a stem-loop structure far downstream from the UGA codon, while the counterpart of SelB (called SECIS) binds to SBP2 and simultaneously binds the tRNA to the UGA codon (1186).

**Figure 7.12** SelB is an elongation factor that specifically binds Seleno-Cys-tRNA to a UGA codon that is followed by a stem-loop structure in mRNA.

Another example of the insertion of a special amino acid is the placement of pyrrolysine at a UAG codon. This happens in both an archaea and a bacterium (2492; 2493). The mechanism is probably similar to the insertion of seleno-cysteine. An unusual tRNA is charged with lysine, which is presumably then modified. The tRNA has a CUA anticodon, which responds to UAG. There must be other components of the system that restricts its response to the appropriate UAG codons.

## USING THE GENETIC CODE

### 2.7.9 tRNAs are charged with amino acids by synthetases

---

#### Key Terms

**Cognate tRNAs (Isoaccepting tRNA)** are those recognized by a particular aminoacyl-tRNA synthetase. They all are charged with the same amino acid.

#### Key Concepts

- Aminoacyl-tRNA synthetases are enzymes that charge tRNA with an amino acid to generate aminoacyl-tRNA in a two-stage reaction that uses energy from ATP.
- There are 20 aminoacyl-tRNA synthetases in each cell. Each charges all the tRNAs that represent a particular amino acid.
- Recognition of a tRNA is based on a small number of points of contact in the tRNA sequence.

---

It is necessary for tRNAs to have certain characteristics in common, yet be distinguished by others. The crucial feature that confers this capacity is the ability of tRNA to fold into a specific tertiary structure. Changes in the details of this structure, such as the angle of the two arms of the "L" or the protrusion of individual bases, may distinguish the individual tRNAs.

All tRNAs can fit in the P and A sites of the ribosome, where at one end they are associated with mRNA via codon-anticodon pairing, while at the other end the polypeptide is being transferred. Similarly, all tRNAs (except the initiator) share the ability to be recognized by the translation factors (EF-Tu or eEF1) for binding to the ribosome. The initiator tRNA is recognized instead by IF-2 or eIF2. So the tRNA set must possess common features for interaction with elongation factors, but the initiator tRNA can be distinguished.

Amino acids enter the protein synthesis pathway through the aminoacyl-tRNA synthetases, which provide the interface for connection with nucleic acid. All synthetases function by the two-step mechanism depicted in **Figure 7.13**:

**Figure 7.13** An aminoacyl-tRNA synthetase charges tRNA with an amino acid.

- First, the amino acid reacts with ATP to form aminoacyl~adenylate, releasing pyrophosphate. Energy for the reaction is provided by cleaving the high energy bond of the ATP.
- Then the activated amino acid is transferred to the tRNA, releasing AMP.

The synthetases sort the tRNAs and amino acids into corresponding sets. Each synthetase recognizes a single amino acid and all the tRNAs that should be charged with it. Usually, each amino acid is represented by more than one tRNA. Several tRNAs may be needed to respond to synonym codons, and sometimes there are multiple species of tRNA reacting with the same codon. Multiple tRNAs representing the same amino acid are called **isoaccepting tRNAs**; because they are all recognized by the same synthetase, they are also described as its **cognate tRNAs**.

Many attempts to deduce similarities in sequence between cognate tRNAs, or to

induce chemical alterations that affect their charging, have shown that the basis for recognition is different for different tRNAs, and does not necessarily lie in some feature of primary or secondary structure alone. We know from the crystal structure that the acceptor stem and the anticodon stem make tight contacts with the synthetase, and mutations that alter recognition of a tRNA are found in these two regions. (The anticodon itself is not necessarily recognized as such; for example, the "suppressor" mutations discussed later in this chapter change a base in the anticodon, and therefore the codons to which a tRNA responds, without altering its charging with amino acids.)

A group of isoaccepting tRNAs must be charged only by the single aminoacyl-tRNA synthetase specific for their amino acid. So isoaccepting tRNAs must share some common feature(s) enabling the enzyme to distinguish them from the other tRNAs. The entire complement of tRNAs is divided into 20 isoaccepting groups; each group is able to identify itself to its particular synthetase.

tRNAs are identified by their synthetases by contacts that recognize a small number of bases, typically from 1-5. Three types of feature commonly are used:

- Usually (but not always), at least one base of the anticodon is recognized. Sometimes all the positions of the anticodon are important.
- Often one of the last three base pairs in the acceptor stem is recognized. An extreme case is represented by alanine tRNA, which is identified by a single unique base pair in the acceptor stem.
- The so-called discriminator base, which lies between the acceptor stem and the CCA terminus, is always invariant among isoacceptor tRNAs.

No one of these features constitutes a unique means of distinguishing 20 sets of tRNAs, or provides sufficient specificity, so it appears that recognition of tRNAs is idiosyncratic, each following its own rules.

Several synthetases can specifically charge a "minihelix" consisting only of the acceptor and T  $\psi$  C arms (equivalent to one arm of the L-shaped molecule) with the correct amino acid. For certain tRNAs, specificity depends exclusively upon the acceptor stem. However, it is clear that there are significant variations between tRNAs, and in some cases the anticodon region is important. Mutations in the anticodon can affect recognition by the class II Phe-tRNA synthetase. Multiple features may be involved; minihelices from the tRNA<sup>Val</sup> and tRNA<sup>Met</sup> (where we know that the anticodon is important *in vivo*) can react specifically with their synthetases.

So recognition depends on an interaction between a few points of contact in the tRNA, concentrated at the extremities, and a few amino acids constituting the active site in the protein. The relative importance of the roles played by the acceptor stem and anticodon is different for each tRNA-synthetase interaction (for review see 35).

## USING THE GENETIC CODE

### 2.7.10 Aminoacyl-tRNA synthetases fall into two groups

#### Key Concepts

- Aminoacyl-tRNA synthetases are divided into the class I and class II groups by sequence and structural similarities.

In spite of their common function, synthetases are a rather diverse group of proteins. The individual subunits vary from 40-110 kD, and the enzymes may be monomeric, dimeric, or tetrameric. Homologies between them are rare. Of course, the active site that recognizes tRNA comprises a rather small part of the molecule. It is interesting to compare the active sites of different synthetases.

Synthetases have been divided into two general groups, each containing 10 enzymes, on the basis of the structure of the domain that contains the active site. A general type of organization that applies to both groups is represented in **Figure 7.14**. The catalytic domain includes the binding sites for ATP and amino acid. It can be recognized as a large region that is interrupted by an insertion of the domain that binds the acceptor helix of the tRNA. This places the terminus of the tRNA in proximity to the catalytic site. A separate domain binds the anticodon region of tRNA. Those synthetases that are multimeric also possess an oligomerization domain (for review see 34).

**Figure 7.14** An aminoacyl-tRNA synthetase contains three or four regions with different functions. (Only multimeric synthetases possess an oligomerization domain.)

Class I synthetases have an N-terminal catalytic domain that is identified by the presence of two short, partly conserved sequences of amino acids, sometimes called "signature sequences." The catalytic domain takes the form of a motif called a nucleotide-binding fold (which is also found in other classes of enzymes that bind nucleotides). The nucleotide fold consists of alternating parallel  $\beta$ -strands and

-helices; the signature sequence forms part of the ATP-binding site. The insertion that contacts the acceptor helix of tRNA differs widely between different class I enzymes. The C-terminal domains of the class I synthetases, which include the tRNA anticodon-binding domain and any oligomerization domain, also are quite different from one another.

Class II enzymes share three rather general similarities of sequence in their catalytic domains. The active site contains a large antiparallel  $\beta$ -sheet surrounded by  $\alpha$ -helices. Again, the acceptor helix-binding domain that interrupts the catalytic domain has a structure that depends on the individual enzyme. The anticodon-binding domain tends to be N-terminal. The location of any oligomerization domain is widely variable.

The lack of any apparent relationship between the two groups of synthetases is a puzzle. Perhaps they evolved independently of one another. This makes it seem possible even that an early form of life could have existed with proteins that were made up of just the 10 amino acids coded by one type or the other.

A general model for synthetase-tRNA binding suggests that the protein binds the tRNA along the "side" of the L-shaped molecule. The same general principle applies for all synthetase-tRNA binding: the tRNA is bound principally at its two extremities, and most of the tRNA sequence is not involved in recognition by a synthetase. However, the detailed nature of the interaction is different between class I and class II enzymes, as can be seen from the models of **Figure 7.15**, which are based on crystal structures. The two types of enzyme approach the tRNA from opposite sides, with the result that the tRNA-protein models look almost like mirror images of one another.

**Figure 7.15** Crystal structures show that class I and class II aminoacyl-tRNA synthetases bind the opposite faces of their tRNA substrates. The tRNA is shown in red, and the protein in blue. Photographs kindly provided by Dino Moras.

A class I enzyme (Gln-tRNA synthetase) approaches the D-loop side of the tRNA. It recognizes the minor groove of the acceptor stem at one end of the binding site, and interacts with the anticodon loop at the other end. **Figure 7.16** is a diagrammatic representation of the crystal structure of the tRNA<sup>Gln</sup>-synthetase complex. A revealing feature of the structure is that contacts with the enzyme change the structure of the tRNA at two important points. These can be seen by comparing the

dotted and solid lines in the anticodon loop and acceptor stem:

**Figure 7.16** A class I tRNA synthetase contacts tRNA at the minor groove of the acceptor stem and at the anticodon.

- Bases U35 and U36 in the anticodon loop are pulled farther out of the tRNA into the protein.
- The end of the acceptor stem is seriously distorted, with the result that base pairing between U1 and A72 is disrupted. The single-stranded end of the stem pokes into a deep pocket in the synthetase protein, which also contains the binding site for ATP.

This structure explains why changes in U35, G73, or the U1-A72 base pair affect the recognition of the tRNA by its synthetase. At all of these positions, hydrogen bonding occurs between the protein and tRNA (447).

A class II enzyme (Asp-tRNA synthetase) approaches the tRNA from the other side, and recognizes the variable loop, and the major groove of the acceptor stem, as drawn in **Figure 7.17**. The acceptor stem remains in its regular helical conformation. ATP is probably bound near to the terminal adenine. At the other end of the binding site, there is a tight contact with the anticodon loop, which has a change in conformation that allows the anticodon to be in close contact with the protein (448).

**Figure 7.17** A class II aminoacyl-tRNA synthetase contacts tRNA at the major groove of the acceptor helix and at the anticodon loop.

---

## USING THE GENETIC CODE

### 2.7.11 Synthetases use proofreading to improve accuracy

---

#### Key Terms

**Proofreading** refers to any mechanism for correcting errors in protein or nucleic acid synthesis that involves scrutiny of individual units *after* they have been added to the chain.

**Kinetic proofreading** describes a proofreading mechanism that depends on incorrect events proceeding more slowly than correct events, so that incorrect events are reversed before a subunit is added to a polymeric chain.

**Chemical proofreading** describes a proofreading mechanism in which the correction event occurs after addition of an incorrect subunit to a polymeric chain, by reversing the addition reaction.

#### Key Concepts

- Specificity of recognition of both amino acid and tRNA is controlled by aminoacyl-tRNA synthetases by proofreading reactions that reverse the catalytic reaction if the wrong component has been incorporated.

---

Aminoacyl-tRNA synthetases have a difficult job. Each synthetase must distinguish 1 out of 20 amino acids, and must differentiate cognate tRNAs (typically 1-3) from the total set (perhaps 100 in all).

Many amino acids are closely related to one another, and all amino acids are related to the metabolic intermediates in their particular synthetic pathway. It is especially difficult to distinguish between two amino acids that differ only in the length of the carbon backbone (that is, by one  $\text{CH}_2$  group). Intrinsic discrimination based on relative energies of binding two such amino acids would be only  $\sim 1/5$ . The synthetase enzymes improve this ratio  $\sim 1000$  fold.

Intrinsic discrimination between tRNAs is better, because the tRNA offers a larger surface with which to make more contacts, but it is still true that all tRNAs conform to the same general structure, and there may be a quite limited set of features that distinguish the cognate tRNAs from the noncognate tRNAs.

We can imagine two general ways in which the enzyme might select its substrate:

- The cycle of admittance, scrutiny, rejection/acceptance could represent a single binding step that precedes all other stages of whatever reaction is involved. This is tantamount to saying that the affinity of the binding site is sufficient to control the entry of substrate. In the case of synthetases, this would mean that only the correct amino acids and cognate tRNAs could form a stable attachment at the site.

- Alternatively, the reaction proceeds through some of its stages, after which a decision is reached on whether the correct species is present. If it is not present, the reaction is reversed, or a bypass route is taken, and the wrong member is expelled. This sort of postbinding scrutiny is generally described as **proofreading**. In the example of synthetases, it would require that the charging reaction proceeds through certain stages even if the wrong tRNA or amino acid is present.

Synthetases use proofreading mechanisms to control the recognition of both types of substrates. They improve significantly on the intrinsic differences among amino acids or among tRNAs, but, consistent with the intrinsic differences in each group, make more mistakes in selecting amino acids (error rates are  $10^{-4}$  -  $10^{-5}$ ) than in selecting tRNAs (error rates are  $\sim 10^{-6}$ ) (see **Figure 6.8**).

Transfer RNA binds to synthetase by the two stage reaction depicted in **Figure 7.18**. Cognate tRNAs have a greater intrinsic affinity for the binding site, so they are bound more rapidly and dissociate more slowly. Following binding, the enzyme scrutinizes the tRNA that has been bound. If the correct tRNA is present, binding is stabilized by a conformational change in the enzyme. This allows aminoacylation to occur rapidly. If the wrong tRNA is present, the conformational change does not occur. As a result, the reaction proceeds much more slowly; this increases the chance that the tRNA will dissociate from the enzyme before it is charged. This type of control is called **kinetic proofreading** (450).

**Figure 7.18** Recognition of the correct tRNA by synthetase is controlled at two steps. First, the enzyme has a greater affinity for its cognate tRNA. Second, the aminoacylation of the incorrect tRNA is very slow.

Specificity for amino acids varies among the synthetases. Some are highly specific for initially binding a single amino acid, but others can also activate amino acids closely related to the proper substrate. Although the analog amino acid can sometimes be converted to the adenylate form, in none of these cases is an incorrectly activated amino acid actually used to form a stable aminoacyl-tRNA.

The presence of the cognate tRNA usually is needed to trigger proofreading, even if the reaction occurs at the stage before formation of aminoacyl-adenylate. (An exception is provided by Met-tRNA synthetase, which can reject noncognate aminoacyl-adenylate complexes even in the absence of tRNA.)

There are two stages at which proofreading of an incorrect aminoacyl-adenylate may

occur during formation of aminoacyl-tRNA. **Figure 7.19** shows that both use **chemical proofreading**, in which the catalytic reaction is reversed. The extent to which one pathway or the other predominates varies with the individual synthetase:

**Figure 7.19** When a synthetase binds the incorrect amino acid, proofreading requires binding of the cognate tRNA. It may take place either by a conformation change that causes hydrolysis of the incorrect aminoacyl-adenylate, or by transfer of the amino acid to tRNA, followed by hydrolysis.

- The noncognate aminoacyl-adenylate may be hydrolyzed when the cognate tRNA binds. This mechanism is used predominantly by several synthetases, including those for methionine, isoleucine, and valine. (Usually, the reaction cannot be seen *in vivo*, but it can be followed for Met-tRNA synthetase when the incorrectly activated amino acid is homocysteine, which lacks the methyl group of methionine). Proofreading releases the amino acid in an altered form, as homocysteine thiolactone. In fact, homocysteine thiolactone is produced in *E. coli* as a by-product of the charging reaction of Met-tRNA synthetase. This shows that continuous proofreading is part of the process of charging a tRNA with its amino acid (451).
- Some synthetases use chemical proofreading at a later stage. The wrong amino acid is actually transferred to tRNA, is then recognized as incorrect by its structure in the tRNA binding site, and so is hydrolyzed and released. The

process requires a continual cycle of linkage and hydrolysis until the correct amino acid is transferred to the tRNA.

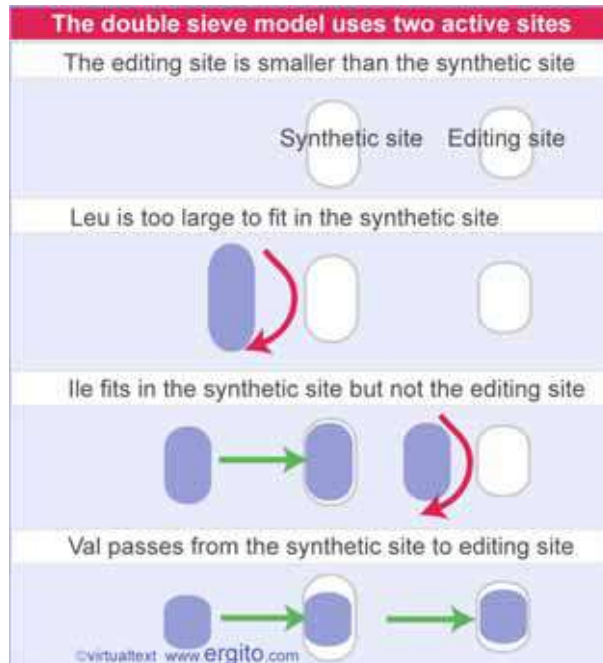

A classic example in which discrimination between amino acids depends on the presence of tRNA is provided by the Ile-tRNA synthetase of *E. coli*. The enzyme can charge valine with AMP, but hydrolyzes the valyl-adenylate when tRNA<sup>Ile</sup> is added. The overall error rate depends on the specificities of the individual steps, as summarized in **Figure 7.20**. The overall error rate of  $1.5 \times 10^{-5}$  is less than the measured rate at which valine is substituted for isoleucine (in rabbit globin), which is  $2-5 \times 10^{-4}$ . So mischarging probably provides only a small fraction of the errors that actually occur in protein synthesis.

Errors are controlled at each stage	
Step	Frequency of Error
Activation of valine to Val-AMP <sup>Ile</sup>	1/225
Release of Val-tRNA	1/270
Overall rate of error	$1/225 \times 1/270 = 1/60,000$

©virtualtext www.ergito.com

**Figure 7.20** The accuracy of charging tRNA<sup>Ile</sup> by its synthetase depends on error control at two stages.

Ile-tRNA synthetase uses size as a basis for discrimination among amino acids. **Figure 7.21** shows that it has two active sites: the synthetic (or activation) site and the editing (or hydrolytic) site. The crystal structure of the enzyme shows that the synthetic site is too small to allow leucine (a close analog of isoleucine) to enter. All amino acids large than isoleucine are excluded from activation because they cannot enter the synthetic site. An amino acid that can enter the synthetic site is placed on tRNA. Then the enzyme tries to transfer it to the editing site. Isoleucine is safe from editing because it is too large to enter the editing site. However, valine can enter this site, and as a result an incorrect Val-tRNA<sup>Ile</sup> is hydrolyzed. Essentially the enzyme provides a double molecular sieve, in which size of the amino acid is used to discriminate between closely related species (452; for review see 40).

**Figure 7.21** Ile-tRNA synthetase has two active sites. Amino acids larger than Ile cannot be activated because they do not fit in the synthetic site. Amino acids smaller than Ile are removed because they are able to enter the editing site.

One interesting feature of Ile-tRNA synthetase is that the synthetic and editing sites are a considerable distance apart,  $\sim 34\text{\AA}$ . A crystal structure of the enzyme complexed with an edited analog of isoleucine shows that the amino acid is transported from the synthetic site to the editing site (2164). **Figure 7.22** shows that this involves a change in the conformation of the tRNA. The amino acid acceptor stem of tRNA<sup>Ile</sup> can exist in alternative conformations. It adopts an unusual hairpin in order to be aminoacylated by an amino acid in the synthetic site. Then it returns to the more common helical structure in order to move the amino acid to the editing site. The translocation between sites is the rate-limiting step in proofreading (2165). Ile-tRNA synthetase is a class I synthetase, but the double sieve mechanism is used also by class II synthetases (2166).

**Figure 7.22** An amino acid is transported from the synthetic site to the editing site of Ile-tRNA synthetase by a change in the conformation of the amino acceptor stem of tRNA.

## USING THE GENETIC CODE

### 2.7.12 Suppressor tRNAs have mutated anticodons that read new codons

---

#### Key Terms

A **suppressor** is a second mutation that compensates for or alters the effects of a primary mutation.

A **nonsense suppressor** is a gene coding for a mutant tRNA able to respond to one or more of the termination codons and insert an amino acid at that site.

A **missense suppressor** codes for a tRNA that has been mutated so as to recognize a different codon. By inserting a different amino acid at a mutant codon, the tRNA suppresses the effect of the original mutation.

#### Key Concepts

- A suppressor tRNA typically has a mutation in the anticodon that changes the codons to which it responds.
- When the new anticodon corresponds to a termination codon, an amino acid is inserted and the polypeptide chain is extended beyond the termination codon. This results in nonsense suppression at a site of nonsense mutation or in readthrough at a natural termination codon.
- Missense suppression occurs when the tRNA recognizes a different codon from usual, so that one amino acid is substituted for another.

---

Isolation of mutant tRNAs has been one of the most potent tools for analyzing the ability of a tRNA to respond to its codon(s) in mRNA, and for determining the effects that different parts of the tRNA molecule have on codon-anticodon recognition.

Mutant tRNAs are isolated by virtue of their ability to overcome the effects of mutations in genes coding for proteins. In general genetic terminology, a mutation that is able to overcome the effects of another mutation is called a **suppressor**.

In tRNA suppressor systems, the primary mutation changes a codon in an mRNA so that the protein product is no longer functional. The secondary, suppressor mutation changes the anticodon of a tRNA, so that it recognizes the mutant codon instead of (or as well as) its original target codon. The amino acid that is now inserted restores protein function. The suppressors are described as **nonsense suppressors** or **missense suppressors**, depending on the nature of the original mutation.

In a wild-type cell, a nonsense mutation is recognized only by a release factor, terminating protein synthesis. The suppressor mutation creates an aminoacyl-tRNA that can recognize the termination codon; by inserting an amino acid, it allows protein synthesis to continue beyond the site of nonsense mutation. This new

capacity of the translation system allows a full-length protein to be synthesized, as illustrated in **Figure 7.23**. If the amino acid inserted by suppression is different from the amino acid that was originally present at this site in the wild-type protein, the activity of the protein may be altered.

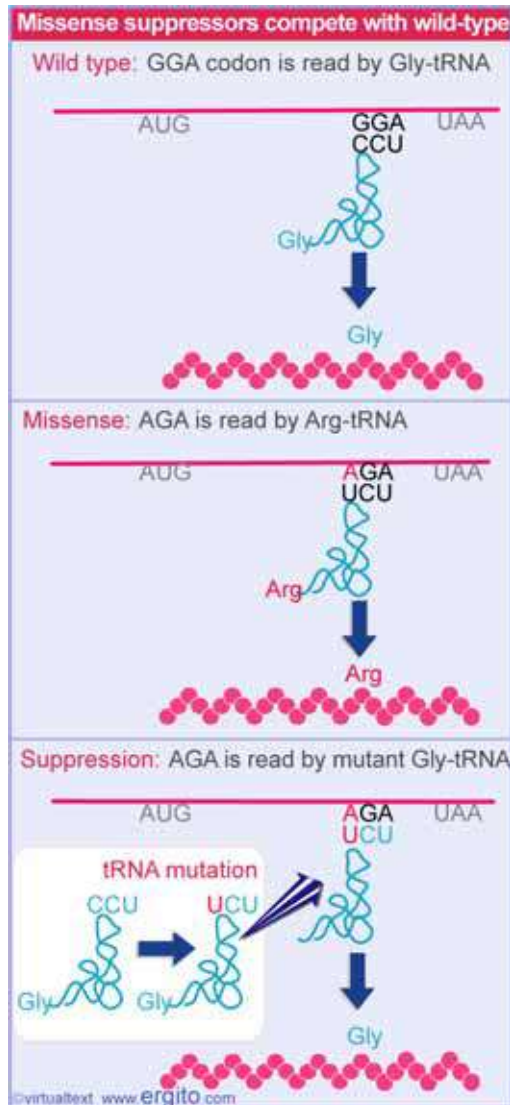

**Figure 7.23** Nonsense mutations can be suppressed by a tRNA with a mutant anticodon, which inserts an amino acid at the mutant codon, producing a full length protein in which the original Leu residue has been replaced by Tyr.

Missense mutations change a codon representing one amino acid into a codon representing another amino acid, one that cannot function in the protein in place of the original residue. (Formally, any substitution of amino acids constitutes a missense mutation, but in practice it is detected only if it changes the activity of the protein.) The mutation can be suppressed by the insertion either of the original amino acid or of some other amino acid that is acceptable to the protein.

**Figure 7.24** demonstrates that missense suppression can be accomplished in the

same way as nonsense suppression, by mutating the anticodon of a tRNA carrying an acceptable amino acid so that it responds to the mutant codon. So missense suppression involves a change in the meaning of the codon from one amino acid to another.

**Figure 7.24** Missense suppression occurs when the anticodon of tRNA is mutated so that it responds to the wrong codon. The suppression is only partial because both the wild-type tRNA and the suppressor tRNA can respond to AGA.

## USING THE GENETIC CODE

### 2.7.13 There are nonsense suppressors for each termination codon

#### Key Concepts

- Each type of nonsense codon is suppressed by tRNAs with mutant anticodons.
- Some rare suppressor tRNAs have mutations in other parts of the molecule.

Nonsense suppressors fall into three classes, one for each type of termination codon. **Figure 7.25** describes the properties of some of the best characterized suppressors.

Suppressors have anticodon mutations				
Locus	tRNA	Wild Type		Suppressor
		Codon	Anti	Anti/Codon
supD (su1)	Ser	UCG	CGA	CUA UAG
supE (su2)	Gln	CAG	CUG	CUA UAG
supF (su3)	Tyr	UA <sup>C</sup> U	GUA	CUA UAG
supC (su4)	Tyr	UA <sup>C</sup> U	GUA	UUA UA <sup>A</sup> G
supG (su5)	Lys	AA <sup>A</sup> G	UUU	UUA UA <sup>A</sup> G
supU (su7)	Trp	UGG	CCA	UCA UG <sup>A</sup> G

**Figure 7.25** Nonsense suppressor tRNAs are generated by mutations in the anticodon.

The easiest to characterize have been amber suppressors. In *E. coli*, at least 6 tRNAs have been mutated to recognize UAG codons. All of the amber suppressor tRNAs have the anticodon CUA<sup>←</sup>, in each case derived from wild type by a single base change. The site of mutation can be any one of the three bases of the anticodon, as seen from *supD*, *supE*, and *supF*. Each suppressor tRNA recognizes only the UAG codon, instead of its former codon(s). The amino acids inserted are serine, glutamine, or tyrosine, the same as those carried by the corresponding wild-type tRNAs.

Ochre suppressors also arise by mutations in the anticodon. The best known are *supC* and *supG*, which insert tyrosine or lysine in response to both ochre (UAA) and amber (UAG) codons. This conforms with the prediction of the wobble hypothesis that UAA cannot be recognized alone.

A UGA suppressor has an unexpected property. It is derived from tRNA<sup>Trp</sup>, but its only mutation is the substitution of A in place of G at position 24. This change replaces a G·U pair in the D stem with an A·U pair, increasing the stability of the helix. The sequence of the anticodon remains the same as the wild type, CCA<sup>←</sup>. So the mutation in the D stem must in some way alter the conformation of the anticodon loop, allowing CCA<sup>←</sup> to pair with UGA in an unusual wobble pairing of C with A.

The suppressor tRNA continues to recognize its usual codon, UGG.

A related response is seen with a eukaryotic tRNA. Bovine liver contains a tRNA<sup>Ser</sup> with the anticodon <sup>m</sup>CCA<sup>←</sup>. The wobble rules predict that this tRNA should respond to the tryptophan codon UGG; but in fact it responds to the termination codon UGA. So it is possible that UGA is suppressed naturally in this situation.

The general importance of these observations lies in the demonstration that codon-anticodon recognition of either wild-type or mutant tRNA cannot be predicted entirely from the relevant triplet sequences, but is influenced by other features of the molecule.

## USING THE GENETIC CODE

### 2.7.14 Suppressors may compete with wild-type reading of the code

---

#### Key Terms

The **context** of a codon in mRNA refers to the fact that neighboring sequences may change the efficiency with which a codon is recognized by its aminoacyl-tRNA or is used to terminate protein synthesis.

**Readthrough** at transcription or translation occurs when RNA polymerase or the ribosome, respectively, ignores a termination signal because of a mutation of the template or the behavior of an accessory factor.

#### Key Concepts

- Suppressor tRNAs compete with wild-type tRNAs that have the same anticodon to read the corresponding codon(s).
- Efficient suppression is deleterious because it results in readthrough past normal termination codons.
- The UGA codon is leaky and is misread by Trp-tRNA at 1-3% frequency.

---

There is an interesting difference between the usual recognition of a codon by its proper aminoacyl-tRNA and the situation in which mutation allows a suppressor tRNA to recognize a new codon. In the wild-type cell, only one meaning can be attributed to a given codon, which represents either a particular amino acid or a signal for termination. But in a cell carrying a suppressor mutation, the mutant codon has the alternatives of being recognized by the suppressor tRNA or of being read with its usual meaning.

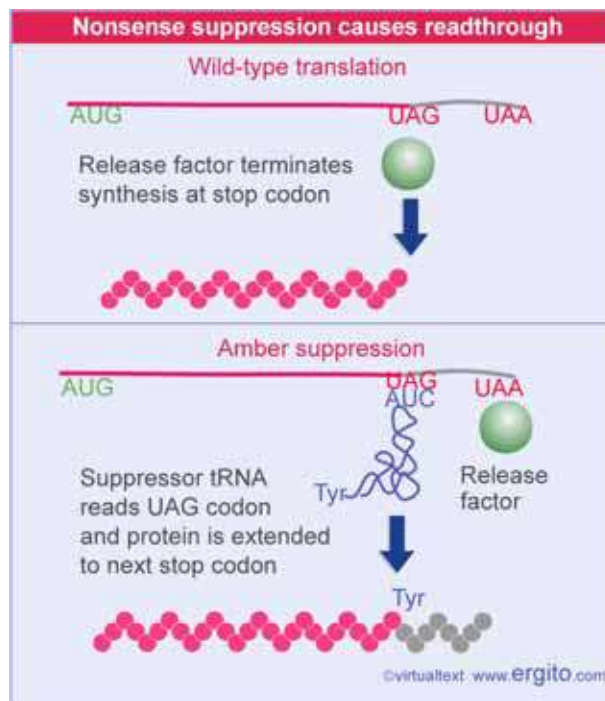

A nonsense suppressor tRNA must compete with the release factors that recognize the termination codon(s). A missense suppressor tRNA must compete with the tRNAs that respond properly to its new codon. The extent of competition influences the efficiency of suppression; so the effectiveness of a particular suppressor depends not only on the affinity between its anticodon and the target codon, but also on its concentration in the cell, and on the parameters governing the competing termination or insertion reactions.

The efficiency with which any particular codon is read is influenced by its location. So the extent of nonsense suppression by a given tRNA can vary quite widely, depending on the **context** of the codon. We do not understand the effect that neighboring bases in mRNA have on codon-anticodon recognition, but the context can change the frequency with which a codon is recognized by a particular tRNA by more than an order of magnitude. The base on the 3' side of a codon appears to have a particularly strong effect.

A nonsense suppressor is isolated by its ability to respond to a mutant nonsense

codon. But the same triplet sequence constitutes one of the normal termination signals of the cell! The mutant tRNA that suppresses the nonsense mutation must in principle be able to suppress natural termination at the end of any gene that uses this codon. **Figure 7.26** shows that this **readthrough** results in the synthesis of a longer protein, with additional C-terminal material. The extended protein will end at the next termination triplet sequence found in the phase of the reading frame. Any extensive suppression of termination is likely to be deleterious to the cell by producing extended proteins whose functions are thereby altered.

**Figure 7.26** Nonsense suppressors also read through natural termination codons, synthesizing proteins that are longer than wild-type.

Amber suppressors tend to be relatively efficient, usually in the range of 10-50%, depending on the system. This efficiency is possible because amber codons are used relatively infrequently to terminate protein synthesis in *E. coli*.

Ochre suppressors are difficult to isolate. They are always much less efficient, usually with activities below 10%. All ochre suppressors grow rather poorly, which indicates that suppression of both UAA and UAG is damaging to *E. coli*, probably because the ochre codon is used most frequently as a natural termination signal.

UGA is the least efficient of the termination codons in its natural function; it is misread by Trp-tRNA as frequently as 1-3% in wild-type situations. In spite of this deficiency, however, it is used more commonly than the amber triplet to terminate bacterial genes.

One gene's missense suppressor is likely to be another gene's mutator. A suppressor corrects a mutation by substituting one amino acid for another at the mutant site. But in other locations, the same substitution will replace the wild-type amino acid with a

new amino acid. The change may inhibit normal protein function.

This poses a dilemma for the cell: it must suppress what is a mutant codon at one location, while failing to change too extensively its normal meaning at other locations. The absence of any strong missense suppressors is therefore explained by the damaging effects that would be caused by a general and efficient substitution of amino acids.

A mutation that creates a suppressor tRNA can have two consequences. First, it allows the tRNA to recognize a new codon. Second, sometimes it prevents the tRNA from recognizing the codons to which it previously responded. It is significant that all the high-efficiency amber suppressors are derived by mutation of one copy of a redundant tRNA set. In these cases, the cell has several tRNAs able to respond to the codon originally recognized by the wild-type tRNA. So the mutation does not abolish recognition of the old codons, which continue to be served adequately by the tRNAs of the set. In the unusual situation in which there is only a single tRNA that responds to a particular codon, any mutation that prevents the response is lethal (for review see 31; 36; 37; 38).

Suppression is most often considered in the context of a mutation that changes the reading of a codon. However, there are some situations in which a stop codon is read as an amino acid at a low frequency in the wild-type situation. The first example to be discovered was the coat protein gene of the RNA phage Q  $\beta$ . The formation of infective Q  $\beta$  particles requires that the stop codon at the end of this gene is suppressed at a low frequency to generate a small proportion of coat proteins with a C-terminal extension. In effect, this stop codon is leaky. The reason is that Trp-tRNA recognizes the codon at a low frequency (3062; 3063).

Readthrough past stop codons occurs also in eukaryotes, where it is employed most often by RNA viruses. This may involve the suppression of UAG/UAA by Tyr-tRNA, Gln-tRNA, or Leu-tRNA, or the suppression of UGA by Trp-tRNA or Arg-tRNA. The extent of partial suppression is dictated by the context surrounding the codon (for review see 3061).

---

**USING THE GENETIC CODE****2.7.15 The ribosome influences the accuracy of translation**

---

**Key Concepts**

- The structure of the 16S rRNA at the P and A sites of the ribosome influences the accuracy of translation.
- 

The lack of detectable variation when the sequence of a protein is analyzed demonstrates that protein synthesis must be extremely accurate. Very few mistakes are apparent in the form of substitutions of one amino acid for another. There are two general stages in protein synthesis at which errors might be made (see **Figure 6.8** in *Molecular Biology 2.6.3 Special mechanisms control the accuracy of protein synthesis*):

- Charging a tRNA only with its correct amino acid clearly is critical. This is a function of the aminoacyl-tRNA synthetase. Probably the error rate varies with the particular enzyme, but generally mistakes occur in  $<1/10^5$  aminoacylations.
- The specificity of codon-anticodon recognition is crucial, but puzzling. Although binding constants vary with the individual codon-anticodon reaction, the specificity is always much too low to provide an error rate of  $<10^{-5}$ . When free in solution, tRNAs bind to their trinucleotide codon sequences only rather weakly. Related, but erroneous, triplets (with two correct bases out of three) are recognized  $10^{-1}$ – $10^{-2}$  times as efficiently as the correct triplets.

Codon-anticodon base pairing therefore seems to be a weak point in the accuracy of translation. The ribosome has an important role in controlling the specificity of this interaction, functioning directly or indirectly as a "proofreader," to distinguish correct and incorrect codon-anticodon pairs, and thus amplifying the rather modest intrinsic difference by  $\sim 1000\times$ . And in addition to the role of the ribosome itself, the factors that place initiator- and aminoacyl-tRNAs in the ribosome also may influence the pairing reaction.

So there must be some mechanism for stabilizing the correct aminoacyl-tRNA, allowing its amino acid to be accepted as a substrate for receipt of the polypeptide chain; contacts with an incorrect aminoacyl-tRNA must be rapidly broken, so that the complex leaves without reacting. Suppose that there is no specificity in the initial collision between the aminoacyl-tRNA·EF-Tu·GTP complex and the ribosome. If any complex, irrespective of its tRNA, can enter the A site, the number of incorrect entries must far exceed the number of correct entries.

There are two basic models for how the ribosome might discriminate between correctly and incorrectly paired aminoacyl-tRNAs. The actual situation incorporates elements of both models.

- The direct recognition model supposes that the structure of the ribosome is designed to recognize aminoacyl-tRNAs that are correctly paired. This would mean that the correct pairing results in some small change in the conformation of the aminoacyl-tRNA that the ribosome can recognize. Discrimination occurs before any further reaction occurs.
- The kinetic proofreading model proposes that there are two (or more) stages in the process, so that the aminoacyl-tRNA has multiple opportunities to disengage. An incorrectly paired aminoacyl-tRNA may pass through some stages of the reaction before it is rejected. Overall selectivity can in principle be the product of the selectivities at each stage.

**Figure 7.27** illustrates diagrammatically what happens to correctly and incorrectly paired aminoacyl-tRNAs. A correctly paired aminoacyl-tRNA is able to make stabilizing contacts with rRNA. An incorrectly paired aminoacyl-tRNA does not make these contacts, and therefore is able to diffuse out of the A site.

**Figure 7.27** Any aminoacyl-tRNA can be placed in the A site (by EF-Tu), but only one that pairs with the anticodon can make stabilizing contacts with rRNA. In the absence of these contacts, the aminoacyl-tRNA diffuses out of the A site.

The path to discovering these interactions started with investigations of the effects of the antibiotic streptomycin in the 1960s. Streptomycin inhibits protein synthesis by binding to 16S rRNA and inhibiting the ability of EF-G to catalyze translocation. It also increases the level of misreading of the pyrimidines U and C (usually one is mistaken for the other, occasionally for A). The site at which streptomycin acts is influenced by the S12 protein; the sequence of this protein is altered in resistant mutants. Ribosomes with an S12 protein derived from resistant bacteria show a reduction in the level of misreading compared with wild-type ribosomes. In effect, S12 controls the level of misreading. When it is mutated to decrease misreading, it suppresses the effect of streptomycin.

S12 stabilizes the structure of 16S rRNA in the region that is bound by streptomycin.

*The important point to note here is that the P/A site region influences the accuracy of translation: translation can be made more or less accurate by changing the structure of 16S rRNA.* The combination of the effects of the S12 protein and streptomycin on the rRNA structure explains the behavior of different mutants in S12, some of which even make the ribosome *dependent* on the presence of streptomycin for correct translation (1185).

We now know from the crystal structure of the ribosome that 16S rRNA is in a position to make contacts with aminoacyl-tRNA (for review see 2390). Two bases of 16S rRNA can contact the minor groove of the helix formed by pairing between the anticodon in tRNA with the first two bases of the codon in mRNA (2392). This directly stabilizes the structure when the correct codon-anticodon contacts are made at the first two codon positions, but it does not monitor contacts at the third position.

The stabilization of correctly paired aminoacyl-tRNA may have two effects. By holding the aminoacyl-tRNA in the A site, it prevents it from escaping before the next stage of protein synthesis. And the conformational change in the rRNA may help to trigger the next stage of the reaction, which is the hydrolysis of GTP by EF-Tu.

Part of the proofreading effect is determined by timing. An aminoacyl-tRNA in the A site may in effect be trapped if the next stage of protein synthesis occurs while it is there. So a delay between entry into the A site and peptidyl transfer may give more opportunity for a mismatched aminoacyl-tRNA to dissociate. Mismatched aminoacyl-tRNA dissociates more rapidly than correctly matched aminoacyl-tRNA, probably by a factor of  $\sim 5\times$ . Its chance of escaping is therefore increased when the peptide transfer step is slowed (for review see 437).

The specificity of decoding has been assumed to reside with the ribosome itself, but some recent results suggest that translation factors influence the process at both the P site and A site. An indication that EF-Tu is involved in maintaining the reading frame is provided by mutants of the factor that suppress frameshifting. This implies that EF-Tu does not merely bring aminoacyl-tRNA to the A site, but also is involved in positioning the incoming aminoacyl-tRNA relative to the peptidyl-tRNA in the P site.

A striking case where factors influence meaning is found at initiation. Mutation of the AUG initiation codon to UUG in the yeast gene *HIS4* prevents initiation. Extragenic suppressor mutations can be found that allow protein synthesis to be initiated at the mutant UUG codon. Two of these suppressors prove to be in genes coding for the  $\alpha$  and  $\beta$  subunits of eIF2, the factor that binds Met-tRNA<sub>i</sub> to the P site. The mutation in eIF  $\beta 2$  resides in a part of the protein that is almost certainly involved in binding nucleic acid. It seems likely that its target is either the initiation sequence of mRNA as such or the base-paired association between the mRNA codon and tRNA<sub>i</sub><sup>Met</sup> anticodon. This suggests that eIF2 participates in the discrimination of initiation codons as well as bringing the initiator tRNA to the P site.

The cost of protein synthesis in terms of high-energy bonds may be increased by proofreading processes. An important question in calculating the cost of protein synthesis is the stage at which the decision is taken on whether to accept a tRNA. If a decision occurs immediately to release an aminoacyl-tRNA·EF-Tu·GTP complex,

there is little extra cost for rejecting the large number of incorrect tRNAs that are likely (statistically) to enter the A site before the correct tRNA is recognized. But if GTP is hydrolyzed before the mismatched aminoacyl-tRNA dissociates, the cost will be greater. A mismatched aminoacyl-tRNA can be rejected either before or after the cleavage of GTP, although we do not know yet where on average it is rejected. There is some evidence that the use of GTP *in vivo* is greater than the three high-energy bonds that are used in adding every (correct) amino acid to the chain

## USING THE GENETIC CODE

### 2.7.16 Recoding changes codon meanings

---

#### Key Terms

**Recoding** events occur when the meaning of a codon or series of codons is changed from that predicted by the genetic code. It may involve altered interactions between aminoacyl-tRNA and mRNA that are influenced by the ribosome.

#### Key Concepts

- Changes in codon meaning can be caused by mutant tRNAs or by tRNAs with special properties.
- The reading frame can be changed by frameshifting or bypassing, both of which depend on properties of the mRNA.

---

The reading frame of a messenger usually is invariant. Translation starts at an AUG codon and continues in triplets to a termination codon. Reading takes no notice of sense: insertion or deletion of a base causes a frameshift mutation, in which the reading frame is changed beyond the site of mutation. Ribosomes and tRNAs continue ineluctably in triplets, synthesizing an entirely different series of amino acids.

There are some exceptions to the usual pattern of translation that enable a reading frame with an interruption of some sort – such as a nonsense codon or frameshift – to be translated into a full-length protein. **Recoding** events are responsible for making exceptions to the usual rules, and can involve several types of events.

Changing the meaning of a single codon allows one amino acid to be substituted in place of another, or for an amino acid to be inserted at a termination codon. **Figure 7.28** shows that these changes rely on the properties of an individual tRNA that responds to the codon:

**Figure 7.28** A mutation in an individual tRNA (usually in the anticodon) can suppress the usual meaning of that codon. In a special case, a specific tRNA is bound by an unusual elongation factor to recognize a termination codon adjacent to a hairpin loop.

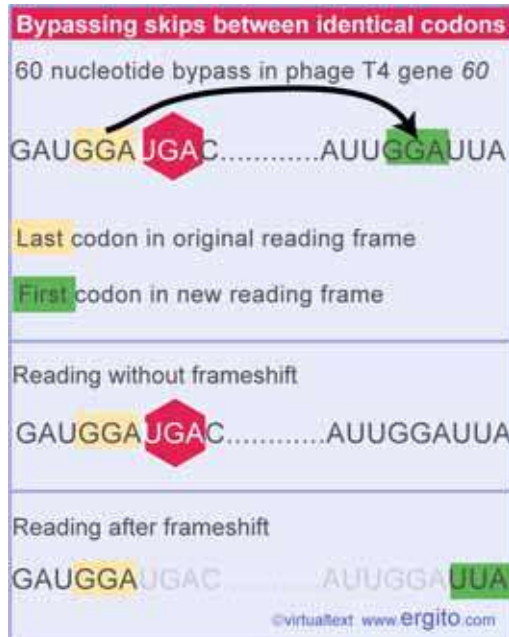

- Suppression involves recognition of a codon by a (mutant) tRNA that usually would respond to a different codon (see *Molecular Biology 2.7.12 Suppressor tRNAs have mutated anticodons that read new codons*).
- Redefinition of the meaning of a codon occurs when an aminoacyl-tRNA is modified (see *Molecular Biology 2.7.8 Novel amino acids can be inserted at certain stop codons*).

Changing the reading frame occurs in two types of situation:

- Frameshifting typically involves changing the reading frame when aminoacyl-tRNA slips by one base (+1 forward or -1 backward) (see *Molecular Biology 2.7.17 Frameshifting occurs at slippery sequences*). The result shown in **Figure 7.29** is that translation continues past a termination codon.
- Bypassing involves a movement of the ribosome to change the codon that is paired with the peptidyl-tRNA in the P site. The sequence between the two codons fails to be represented in protein. As shown in **Figure 7.30**, this allows translation to continue past any termination codons in the intervening region.

**Figure 7.29** A tRNA that slips one base in pairing with a codon causes a frameshift that can suppress termination. The efficiency is usually ~5%.

**Figure 7.30** Bypassing occurs when the ribosome moves along mRNA so that the peptidyl-tRNA in the P site is released from pairing with its codon and then repairs with another codon farther along.

#### Key Terms

**Programmed frameshifting** is required for expression of the protein sequences coded beyond a specific site at which a +1 or -1 frameshift occurs at some typical frequency.

#### Key Concepts

- The reading frame may be influenced by the sequence of mRNA and the ribosomal environment.
- Slippery sequences allow a tRNA to shift by 1 base after it has paired with its anticodon, thereby changing the reading frame.
- Translation of some genes depends upon the regular occurrence of programmed frameshifting.

---

Frameshifting is associated with specific tRNAs in two circumstances (for review see 3064):

- Some mutant tRNA suppressors recognize a "codon" for 4 bases instead of the usual 3 bases.
- Certain "slippery" sequences allow a tRNA to move a base up or down mRNA in the A site.

Frameshift mutants result from the insertion or deletion of a base. They can be suppressed by restoring the original reading frame. This can be achieved by compensating base deletions and insertions within a gene (see *Molecular Biology 1.1.21 The genetic code is triplet*). However, extragenic frameshift suppressors also can be found in the form of tRNAs with aberrant properties.

The simplest type of external frameshift suppressor corrects the reading frame when a mutation has been caused by inserting an additional base within a stretch of identical residues. For example, a G may be inserted in a run of several contiguous G bases. The frameshift suppressor is a tRNA<sup>Gly</sup> that has an extra base inserted in its anticodon loop, converting the anticodon from the usual triplet sequence CCC<sup>←</sup> to the quadruplet sequence CCCC<sup>←</sup>. The suppressor tRNA recognizes a 4-base "codon".

Some frameshift suppressors can recognize more than one 4-base "codon". For example, a bacterial tRNA<sup>Lys</sup> suppressor can respond to either AAAA or AAAU, instead of the usual codon AAA. Another suppressor can read any 4-base "codon" with ACC in the first three positions; the next base is irrelevant. In these cases, the alternative bases that are acceptable in the fourth position of the longer "codon" are

not related by the usual wobble rules. The suppressor tRNA probably recognizes a 3 base codon, but for some other reason – most likely steric hindrance – the adjacent base is blocked. This forces one base to be skipped before the next tRNA can find a codon.

Situations in which frameshifting is a normal event are presented by phages and viruses. Such events may affect the continuation or termination of protein synthesis, and result from the intrinsic properties of the mRNA.

In retroviruses, translation of the first gene is terminated by a nonsense codon in phase with the reading frame. The second gene lies in a different reading frame, and (in some viruses) is translated by a frameshift that changes into the second reading frame and therefore bypasses the termination codon (see **Figure 7.29**) (2324) (see *Molecular Biology 4.17.3 Retroviral genes codes for polyproteins*). The efficiency of the frameshift is low, typically ~5%. In fact, this is important in the biology of the virus; an increase in efficiency can be damaging. **Figure 7.31** illustrates the similar situation of the yeast Ty element, in which the termination codon of *tya* must be bypassed by a frameshift in order to read the subsequent *tyb* gene.

**Figure 7.31** A +1 frameshift is required for expression of the *tyb* gene of the yeast Ty element. The shift occurs at a 7 base sequence at which two Leu codon(s) are followed by a scarce Arg codon.

Such situations makes the important point that the rare (but predictable) occurrence of "misreading" events can be relied on as a necessary step in natural translation. This is called **programmed frameshifting** (for review see 43; 44). It occurs at particular sites at frequencies that are 100-1000× greater than the rate at which errors are made at nonprogrammed sites ( $\sim 3 \times 10^{-5}$  per codon).

There are two common features in this type of frameshifting:

- A "slippery" sequence allows an aminoacyl-tRNA to pair with its codon and then to move +1 (rare) or -1 base (more common) to pair with an overlapping triplet sequence that can also pair with its anticodon.
- The ribosome is delayed at the frameshifting site to allow time for the aminoacyl-tRNA to rearrange its pairing. The cause of the delay can be an adjacent codon that requires a scarce aminoacyl-tRNA, a termination codon that is recognized slowly by its release factor, or a structural impediment in mRNA (for example, a "pseudoknot," a particular conformation of RNA) that impedes the ribosome.

Slippery events can involve movement in either direction; a -1 frameshift is caused when the tRNA moves backwards, and a +1 frameshift is caused when it moves forwards. In either case, the result is to expose an out-of-phase triplet in the A site for the next aminoacyl-tRNA. The frameshifting event occurs before peptide bond synthesis. In the most common type of case, when it is triggered by a slippery sequence in conjunction with a downstream hairpin in mRNA, the surrounding sequences influence its efficiency.

The frameshifting in **Figure 7.31** shows the behavior of a typical slippery sequence. The 7 nucleotide sequence CUUAGGC is usually recognized by Leu-tRNA at CUU followed by Arg-tRNA at AGC. However, the Arg-tRNA is scarce, and when its scarcity results in a delay, the Leu-tRNA slips from the CUU codon to the overlapping UUA triplet. This causes a frameshift, because the next triplet in phase with the new pairing (GGC) is read by Gly-tRNA. Slippage usually occurs in the P site (when the Leu-tRNA actually has become peptidyl-tRNA, carrying the nascent chain).

Frameshifting at a stop codon causes readthrough of the protein. The base on the 3' side of the stop codon influences the relative frequencies of termination and frameshifting, and thus affects the efficiency of the termination signal. This helps to explain the significance of context on termination.

## USING THE GENETIC CODE

**2.7.18 Bypassing involves ribosome movement**

Certain sequences trigger a bypass event, when a ribosome stops translation, slides along mRNA with peptidyl-tRNA remaining in the P site, and then resumes translation (see **Figure 7.30**). This is a rather rare phenomenon, with only ~3 authenticated examples (for review see 2265). The most dramatic example of bypassing is in gene 60 of phage T4, where the ribosome moves 60 nucleotides along the mRNA (2325).

The key to the bypass system is that there are identical (or synonymous) codons at either end of the sequence that is skipped. They are sometimes referred to as the "take-off" and "landing" sites. Before bypass, the ribosome is positioned with a peptidyl-tRNA paired with the take-off codon in the P site, with an empty A site waiting for an aminoacyl-tRNA to enter. **Figure 7.32** shows that the ribosome slides along mRNA in this condition until the peptidyl-tRNA can become paired with the codon in the landing site. A remarkable feature of the system is its high efficiency, ~50%.

**Figure 7.32** In bypass mode, a ribosome with its P site occupied can stop translation. It slides along mRNA to a site where peptidyl-tRNA pairs with a new codon in the P site. Then protein synthesis is resumed.

The sequence of the mRNA triggers the bypass. The important features are the two GGA codons for take-off and landing, the spacing between them, a stem-loop structure that includes the take-off codon, and the stop codon adjacent to the take-off codon. The protein under synthesis is also involved.

The take-off stage requires the peptidyl-tRNA to unpair from its codon. This is followed by a movement of the mRNA that prevents it from re-pairing. Then the ribosome scans the mRNA until the peptidyl-tRNA can repair with the codon in the landing reaction. This is followed by the resumption of protein synthesis when aminoacyl-tRNA enters the A site in the usual way.

Like frameshifting, the bypass reaction depends on a pause by the ribosome. The probability that peptidyl-tRNA will dissociate from its codon in the P site is increased by delays in the entry of aminoacyl-tRNA into the A site. Starvation for an amino acid can trigger bypassing in bacterial genes because of the delay that occurs when there is no aminoacyl-tRNA available to enter the A site (2326). In phage T4 gene 60, one role of mRNA structure may be to reduce the efficiency of termination, thus creating the delay that is needed for the take-off reaction.

## USING THE GENETIC CODE

### 2.7.19 Summary

---

The sequence of mRNA read in triplets 5' → 3' is related by the genetic code to the amino acid sequence of protein read from N- to C-terminus. Of the 64 triplets, 61 code for amino acids and 3 provide termination signals. Synonym codons that represent the same amino acids are related, often by a change in the third base of the codon. This third-base degeneracy, coupled with a pattern in which related amino acids tend to be coded by related codons, minimizes the effects of mutations. The genetic code is universal, and must have been established very early in evolution. Changes in nuclear genomes are rare, but some changes have occurred during mitochondrial evolution.

Multiple tRNAs may respond to a particular codon. The set of tRNAs responding to the various codons for each amino acid is distinctive for each organism. Codon-anticodon recognition involves wobbling at the first position of the anticodon (third position of the codon), which allows some tRNAs to recognize multiple codons. All tRNAs have modified bases, introduced by enzymes that recognize target bases in the tRNA structure. Codon-anticodon pairing is influenced by modifications of the anticodon itself and also by the context of adjacent bases, especially on the 3' side of the anticodon. Taking advantage of codon-anticodon wobble allows vertebrate mitochondria to use only 22 tRNAs to recognize all codons, compared with the usual minimum of 31 tRNAs; this is assisted by the changes in the mitochondrial code.

Each amino acid is recognized by a particular aminoacyl-tRNA synthetase, which also recognizes all of the tRNAs coding for that amino acid. Aminoacyl-tRNA synthetases have a proofreading function that scrutinizes the aminoacyl-tRNA products and hydrolyzes incorrectly joined aminoacyl-tRNAs.

Aminoacyl-tRNA synthetases vary widely, but fall into two general groups according to the structure of the catalytic domain. Synthetases of each group bind the tRNA from the side, making contacts principally with the extremities of the acceptor stem and the anticodon stem-loop; the two types of synthetases bind tRNA from opposite sides. The relative importance attached to the acceptor stem and the anticodon region for specific recognition varies with the individual tRNA.

Mutations may allow a tRNA to read different codons; the most common form of such mutations occurs in the anticodon itself. Alteration of its specificity may allow a tRNA to suppress a mutation in a gene coding for protein. A tRNA that recognizes a termination codon provides a nonsense suppressor; one that changes the amino acid responding to a codon is a missense suppressor. Suppressors of UAG and UGA codons are more efficient than those of UAA codons, which is explained by the fact that UAA is the most commonly used natural termination codon. But the efficiency of all suppressors depends on the context of the individual target codon.

Frameshifts of the +1 type may be caused by aberrant tRNAs that read "codons" of 4 bases. Frameshifts of either +1 or -1 may be caused by slippery sequences in mRNA that allow a peptidyl-tRNA to slip from its codon to an overlapping sequence that

can also pair with its anticodon. This frameshifting also requires another sequence that causes the ribosome to delay. Frameshifts determined by the mRNA sequence may be required for expression of natural genes. Bypassing occurs when a ribosome stops translation and moves along mRNA with its peptidyl-tRNA in the P site until the peptidyl-tRNA pairs with an appropriate codon; then translation resumes.

## PROTEIN LOCALIZATION

### 2.8.1 Introduction

---

Proteins are synthesized in two types of location:

- The vast majority of proteins are synthesized by ribosomes in the cytosol.
- A small minority are synthesized by ribosomes within organelles (mitochondria or chloroplasts).

Proteins synthesized in the cytosol can be divided into two general classes with regard to localization: those that are not associated with membranes; and those that are associated with membranes (see *Molecular Biology Supplement 32.5 Membranes and membrane proteins*). **Figure 8.1** maps the cell in terms of the possible ultimate destinations for a newly synthesized protein and the systems that transport it:

**Figure 8.1** Overview: proteins that are localized post-translationally are released into the cytosol after synthesis on free ribosomes. Some have signals for targeting to organelles such as the nucleus or mitochondria. Proteins that are localized cotranslationally associate with the ER membrane during synthesis, so their ribosomes are "membrane-bound". The proteins pass into the endoplasmic reticulum, along to the Golgi, and then through the plasma membrane, unless they have signals that cause retention at one of the steps on the pathway. They may also be directed to other organelles, such as endosomes or lysosomes.

- Cytosolic (or "soluble") proteins are not localized in any particular organelle. They are synthesized in the cytosol, and remain there, where they function as individual catalytic centers, acting on metabolites that are in solution in the cytosol.
- Macromolecular structures may be located at particular sites in the cytoplasm; for example, centrioles are associated with the regions that become the poles of the mitotic spindle.
- Nuclear proteins must be transported from their site of synthesis in the cytosol through the nuclear envelope into the nucleus.

- Most of the proteins in cytoplasmic organelles are synthesized in the cytosol and transported specifically to (and through) the organelle membrane, for example, to the mitochondrion or peroxisome or (in plant cells) to the chloroplast. (Those proteins that are synthesized within the organelle remain within it.)
- The cytoplasm contains a series of membranous bodies, including endoplasmic reticulum (ER), Golgi apparatus, endosomes, and lysosomes. This is sometimes referred to as the "reticuloendothelial system." Proteins that reside within these compartments are inserted into ER membranes, and then are directed to their particular locations by the transport system of the Golgi apparatus. (For an introduction see *Molecular Biology Supplement 32.6 ER and Golgi*).
- Proteins that are secreted from the cell are transported to the plasma membrane and then must pass through it to the exterior. They start their synthesis in the same way as proteins associated with the reticuloendothelial system, but pass entirely through the system instead of halting at some particular point within it.

## PROTEIN LOCALIZATION

### 2.8.2 Passage across a membrane requires a special apparatus

---

#### Key Terms

Protein **translocation** describes the movement of a protein across a membrane. This occurs across the membranes of organelles in eukaryotes, or across the plasma membrane in bacteria. Each membrane across which proteins are translocated has a channel specialized for the purpose.

#### Key Concepts

- Proteins pass across membranes through specialized protein structures embedded in the membrane.
- Substrate proteins interact directly with the transport apparatus of the ER or mitochondria or chloroplasts, but require carrier proteins to interact with peroxisomes.
- A much larger and complex apparatus is required for transport into the nucleus.

---

The process of inserting into or passing through a membrane is called protein **translocation**. The same dilemma must be solved for every situation in which a protein passes through a membrane. The protein presents a hydrophilic surface, but the membrane is hydrophobic. Like oil and water, the two would prefer not to mix. The solution is to create a special structure in the membrane through which the protein can pass. There are three different types of arrangements for such structures.

The endoplasmic reticulum, mitochondria, and chloroplasts contain proteinaceous structures embedded in their membranes that allow proteins to pass through without contacting the surrounding hydrophobic lipids. **Figure 8.2** shows that a substrate protein binds directly to the structure, is transported by it to the other side, and then released.

**Figure 8.2** Proteins enter the ER or a mitochondrion by binding to a translocon that transports them across the membrane.

Peroxisomes also have such structures in their membranes, but the substrate proteins do not bind directly to them. **Figure 8.3** shows that instead they bind to carrier proteins in the cytosol, the carrier protein is transported through the channel into the peroxisome, and then the substrate protein is released.

**Figure 8.3** Proteins are transported into peroxisomes by a carrier protein that binds them in the cytosol, passes with them through the membrane channel, and releases them on the other side.

For transport into the nucleus, a much larger and more complex structure is employed. This is the nuclear pore. **Figure 8.4** shows that, although the pore provides the environment that allows a substrate to enter (or to leave) the nucleus, it does not actually provide the apparatus that binds to the substrate proteins and moves them through. Included in this apparatus are carrier proteins that bind to the substrates and transport them through the pore to the other side.

**Figure 8.4** Proteins enter the nucleus by passage through very large nuclear pores. The transport apparatus is distinct from the pore itself and includes components that carry the protein through the pore.

---

## PROTEIN LOCALIZATION

### 2.8.3 Protein translocation may be post-translational or co-translational

---

#### Key Terms

The **leader** of a protein is a short N-terminal sequence responsible for initiating passage into or through a membrane.

A protein to be imported into an organelle or secreted from bacteria is called a "**preprotein**" until its signal sequence has been removed.

#### Key Concepts

- Proteins that are imported into cytoplasmic organelles are synthesized on free ribosomes in the cytosol.
- Proteins that are imported into the ER-Golgi system are synthesized on ribosomes that are associated with the ER.
- Proteins associate with membranes by means of specific amino acid sequences called signal sequences.
- Signal sequences are most often leaders that are located at the N-terminus.
- N-terminal signal sequences are usually cleaved off the protein during the insertion process.

---

There are two ways for a protein to make its initial contact with a membrane:

- The nascent protein may associate with the translocation apparatus while it is still being synthesized on the ribosome. This called **co-translational translocation**.
- The protein may be released from a ribosome after translation has been completed. Then the completed protein diffuses to the appropriate membrane and associates with the translocation apparatus. This is called **post-translational translocation**.

The location of a ribosome depends on whether the protein under synthesis is associating with a membrane co-translationally:

- Co-translational translocation is used for proteins that enter the endoplasmic reticulum. The consequence of this association is that the ribosome is localized to the surface of the endoplasmic reticulum. Because the ribosomes are associated with the ER membranes during synthesis of these proteins, and are therefore found in membrane fractions of the cell, they are sometimes described as "membrane-bound".

- All other ribosomes are located in the cytosol; because they are not associated with any organelle, and fractionate separately from membranes, they are sometimes called "free ribosomes". The free ribosomes synthesize all proteins except those that are translocated co-translationally. The proteins are released into the cytosol when their synthesis is completed. Some of these proteins remain free in the cytosol in quasi-soluble form; others associate with macromolecular cytosolic structures, such as filaments, microtubules, centrioles, etc., or are transported to the nucleus, or associate with membrane-bound organelles by post-translational translocation.

To associate with a membrane (or any other type of structure), a protein requires an appropriate signal, typically a sequence motif that causes it to be recognized by a translocation system (or to be assembled into a macromolecular structure).

**Figure 8.5** summarizes some signals used by proteins released from cytosolic ribosomes. Import into the nucleus results from the presence of a variety of rather short sequences within proteins. These "nuclear localization signals" enable the proteins to pass through nuclear pores. One type of signal that determines transport to the peroxisome is a very short C-terminal sequence. Mitochondrial and chloroplast proteins are synthesized on "free" ribosomes; after their release into the cytosol they associate with the organelle membranes by means of N-terminal sequences of ~25 amino acids in length that are recognized by receptors on the organelle envelope.

**Figure 8.5** Proteins synthesized on free ribosomes in the cytosol are directed after their release to specific destinations by short signal motifs.

Proteins that reside within the reticuloendothelial system enter the endoplasmic reticulum while they are being synthesized. The principle of co-translational translocation is summarized in **Figure 8.6**. An important feature of this system is that the nascent protein is responsible for recognizing the translocation apparatus. This requires the signal for co-translational translocation to be part of the protein that is first synthesized, and, in fact, it is usually located at the N-terminus.

**Figure 8.6** Proteins can enter the ER-Golgi pathway only by associating with the endoplasmic reticulum while they are being synthesized.

A common feature is found in proteins that use N-terminal sequences to be transported co-translationally to the ER or post-translationally to mitochondria or chloroplasts. The N-terminal sequence comprises a **leader** that is not part of the mature protein. The protein carrying this leader is called a **preprotein**, and is a transient precursor to the mature protein. The leader is cleaved from the protein during protein translocation.

---

## PROTEIN LOCALIZATION

### 2.8.4 Chaperones may be required for protein folding

---

#### Key Terms

**Self-assembly** refers to the ability of a protein (or of a complex of proteins) to form its final structure without the intervention of any additional components (such as chaperones). The term can also refer to the spontaneous formation of any biological structure that occurs when molecules collide and bind to each other.

**Chaperones** are a class of proteins which bind to incompletely folded or assembled proteins in order to assist their folding or prevent them from aggregating.

#### Key Concepts

- Proteins that can acquire their conformation spontaneously are said to self-assemble.
- Proteins can often assemble into alternative structures.
- A chaperone directs a protein into one particular pathway by excluding alternative pathways.
- Chaperones prevent the formation of incorrect structures by interacting with unfolded proteins to prevent them from folding incorrectly

---

Some proteins are able to acquire their mature conformation spontaneously. A test for this ability is to denature the protein and determine whether it can then renature into the active form. This capacity is called **self-assembly**. A protein that can self-assemble can fold or refold into the active state from other conformations, including the condition in which it is initially synthesized. This implies that the internal interactions are intrinsically directed toward the right conformation. The classic case is that of ribonuclease; it was shown in the 1970s that, when the enzyme is denatured, it can renature *in vitro* into the correct conformation (1115). More recently the process of intrinsic folding has been described in detail for some small proteins.

When correct folding does not happen, and alternative sets of interactions can occur, a protein may become trapped in a stable conformation that is not the intended final form. Proteins in this category cannot self-assemble. Their acquisition of proper structure requires the assistance of a **chaperone**. (For a description of the discovery that proteins require assistance to fold *in vivo*, see *Great Experiments 5.2 The discovery of protein folding by chaperonins*. For an introduction to the other activities that are involved, see *Molecular Biology Supplement 32.4 Protein folding*.)

Protein folding takes place by interactions between reactive surfaces. Typically these surfaces consist of exposed hydrophobic side chains. Their interactions form a hydrophobic core. The intrinsic reactivity of these surfaces means that incorrect

interactions may occur unless the process is controlled. **Figure 8.7** illustrates what would happen. As a newly synthesized protein emerges from the ribosome, any hydrophobic patch in the sequence is likely to aggregate with another hydrophobic patch. Such associations are likely to occur at random and therefore will probably not represent the desired conformation of the protein. (For an account of the molecular interactions involved in folding see 2389).

**Figure 8.7** Hydrophobic regions of proteins are intrinsically interactive, and will aggregate with one another when a protein is synthesized (or denatured) unless prevented.

Chaperones are proteins that mediate correct assembly by causing a target protein to acquire one possible conformation instead of others (for review see 50; 2388). This is accomplished by binding to reactive surfaces in the target protein that are exposed during the assembly process, and preventing those surfaces from interacting with other regions of the protein to form an incorrect conformation. Chaperones function by preventing formation of incorrect structures rather than by promoting formation of correct structures. **Figure 8.8** shows an example in which a chaperone in effect sequesters a hydrophobic patch, allowing interactions to occur that would not have been possible in its presence, as can be seen by comparing the result with **Figure 8.7**.

**Figure 8.8** Chaperones bind to interactive regions of proteins as they are synthesized to prevent random aggregation. Regions of the protein are released to interact in an orderly manner to give the proper conformation.

An incorrect structure may be formed either by misfolding of a single protein or by interactions with another protein. The density of proteins in the cytosol is high, and "macromolecular crowding" can increase the efficiencies of many reactions compared to the rates observed *in vitro*. Crowding can cause folding proteins to aggregate, but chaperones can counteract this effect (2336). So one role of chaperones may be to protect a protein so that it can fold without being adversely affected by the crowded conditions in the cytosol.

We do not know what proportion of proteins can self-assemble as opposed to those that require assistance from a chaperone. (It is not axiomatic that a protein capable of self-assembly *in vitro* actually self-assembles *in vivo*, because there may be rate differences in the two conditions, and chaperones still could be involved *in vivo*. However, there is a distinction to be drawn between proteins that can in principle self-assemble and those that in principle must have a chaperone to assist acquisition of the correct structure.)

## PROTEIN LOCALIZATION

### 2.8.5 Chaperones are needed by newly synthesized and by denatured proteins

---

#### Key Concepts

- Chaperones act on newly synthesized proteins, proteins that are passing through membranes, or proteins that have been denatured.
- Hsp70 and some associated proteins form a major class of chaperones that act on many target proteins.
- Group I and group II chaperonins are large oligomeric assemblies that act on target proteins they sequester in internal cavities.
- Hsp90 is a specialized chaperone that acts on proteins of signal transduction pathways.

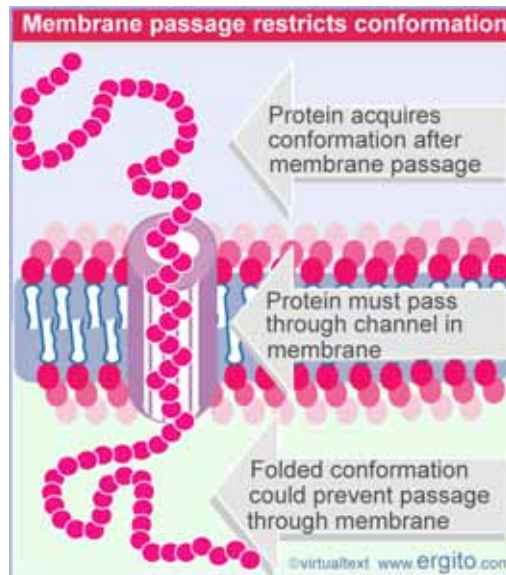

---

The ability of chaperones to recognize incorrect protein conformations allows them to play two related roles concerned with protein structure:

- When a protein is initially synthesized, that is to say, as it exits the ribosome to enter the cytosol, it appears in an unfolded form. Spontaneous folding then occurs as the emerging sequence interacts with regions of the protein that were synthesized previously. Chaperones influence the folding process by controlling the accessibility of the reactive surfaces. This process is involved in initial acquisition of the correct conformation.
- When a protein is denatured, new regions are exposed and become able to interact. These interactions are similar to those that occur when a protein (transiently) misfolds as it is initially synthesized. They are recognized by chaperones as comprising incorrect folds. This process is involved in recognizing a protein that has been denatured, and either assisting renaturation or leading to its removal by degradation.

Chaperones may also be required to assist the formation of oligomeric structures and for the transport of proteins through membranes. A persistent theme in membrane passage is that control (or delay) of protein folding is an important feature. **Figure 8.9** shows that it may be necessary to maintain a protein in an unfolded state before it enters the membrane because of the geometry of passage: the mature protein could simply be too large to fit into the available channel. Chaperones may prevent a protein from acquiring a conformation that would prevent passage through the membrane; in this capacity, their role is basically to maintain the protein in an unfolded, flexible state. Once the protein has passed through the membrane, it may require another chaperone to assist with folding to its mature conformation in much the same way that a cytosolic protein requires assistance from a chaperone as it emerges from the ribosome. The state of the protein as it emerges from a membrane is probably similar to that as it emerges from the ribosome – basically extended in a

more or less linear condition.

**Figure 8.9** A protein is constrained to a narrow passage as it crosses a membrane.

Two major types of chaperones have been well characterized (for review see 2284). They affect folding through two different types of mechanism:

- **Figure 8.10** shows that the *Hsp70* system consists of individual proteins that bind to, and act on, the substrates whose folding is to be controlled. It recognizes proteins as they are synthesized or emerge from membranes (and also when they are denatured by stress). Basically it controls the interactions between exposed reactive regions of the protein, enabling it to fold into the correct conformation *in situ*. The components of the system are Hsp70, Hsp40, and GrpE. The name of the system reflects the original identification of Hsp70 as a protein induced by heat shock. The Hsp70 and Hsp40 proteins bind individually to the substrate proteins. They use hydrolysis of ATP to provide the energy for changing the structure of the substrate protein, and work in conjunction with an exchange factor that regenerates ATP from ADP.
- **Figure 8.11** shows that a *chaperonin* system consists of a large oligomeric assembly (represented as a cylinder). This assembly forms a structure into which unfolded proteins are inserted. The protected environment directs their folding. There are two types of chaperonin system. GroEL/GroES is found in all classes of organism. TRiC is found in eukaryotic cytosol.

**Figure 8.10** Proteins emerge from the ribosome or from passage through a membrane in an unfolded state that attracts chaperones to bind and protect them from misfolding.

**Figure 8.11** A chaperonin forms a large oligomeric complex and folds a substrate protein within its interior.

The components of the systems are summarized in **Figure 8.12**. The Hsp70 system and the chaperonin systems both act on many different substrate proteins. Another system, the Hsp90 protein, functions in conjunction with Hsp70, but is directed against specific classes of proteins that are involved in signal transduction, especially the steroid hormone receptors and signaling kinases (for review see 2506). Its basic function is to maintain its targets in an appropriate conformation until they are stabilized by interacting with other components of the pathway (2507; 2508).

There are 2 major types of chaperone systems	
System	Structure/function
<b>Individual chaperones</b>	
Hsp70 system	
Hsp70 (DnaK)	ATPase
Hsp40 (DnaJ)	stimulates ATPase
GrpE (GrpE)	Nucleotide exchange factor
Hsp90	Functions on proteins involved in signal transduction
<b>Oligomeric structures (chaperonins)</b>	
Group I	
Hsp60 (GroEL)	Forms two heptameric rings;
Hsp10 (GroES)	Forms cap
Group II	
TRIC	Forms two octameric rings

©virtualtext www.ergito.com

**Figure 8.12** Chaperone families have eukaryotic and bacterial counterparts (named in parentheses).

(The reason many of these proteins are named "hsp", which stands for "heat shock protein" is that increase in temperature causes production of heat shock proteins whose function is to minimize the damage caused to proteins by heat denaturation. Many of the heat shock proteins are chaperones and were first discovered, and named, as part of the heat shock response.)

**PROTEIN LOCALIZATION****2.8.6 The Hsp70 family is ubiquitous**

---

**Key Concepts**

- Hsp70 is a chaperone that functions on target proteins in conjunction with DnaJ and GrpE.
  - Members of the Hsp70 family are found in the cytosol, in the ER, and in mitochondria and chloroplasts.
- 

The Hsp70 family is found in bacteria, eukaryotic cytosol, in the endoplasmic reticulum, and in chloroplasts and mitochondria (for review see 2284). A typical Hsp70 has two domains: the N-terminal domain is an ATPase; and the C-terminal domain binds the substrate polypeptide (2337; 2338). When bound to ATP, Hsp70 binds and releases substrates rapidly; when bound to ADP, the reactions are slow. Recycling between these states is regulated by two other proteins, Hsp40 (DnaJ) and GrpE.

**Figure 8.13** shows that Hsp40 (DnaJ) binds first to a nascent protein as it emerges from the ribosome. Hsp40 contains a region called the J domain (named for DnaJ), which interacts with Hsp70. Hsp70 (DnaK) binds to both Hsp40 and to the unfolded protein. In effect, two interacting chaperones bind to the protein. The J domain accounts for the specificity of the pairwise interaction, and drives a particular Hsp40 to select the appropriate partner from the Hsp70 family.

**Figure 8.13** Hsp40 binds the substrate and then Hsp70. ATP hydrolysis drives conformational change. GrpE displaces the ADP; this causes the chaperones to be released. Multiple cycles of association and dissociation may occur during the folding of a substrate protein.

The interaction of Hsp70 (DnaK) with Hsp40 (DnaJ) stimulates the ATPase activity of Hsp70. The ADP-bound form of the complex remains associated with the protein substrate until GrpE displaces the ADP. This causes loss of Hsp40 followed by dissociation of Hsp70. The Hsp70 binds another ATP and the cycle can be repeated. GrpE (or its equivalent) is found only in bacteria, mitochondria, and chloroplasts; in other locations, the dissociation reaction is coupled to ATP hydrolysis in a more complex way.

Protein folding is accomplished by multiple cycles of association and dissociation. As the protein chain lengthens, Hsp70 (DnaK) may dissociate from one binding site and then reassociate with another, thus releasing parts of the substrate protein to fold correctly in an ordered manner. Finally, the intact protein is released from the ribosome, folded into its mature conformation (for review see 54; 63; 66).

Different members of the Hsp70 class function on various types of target proteins. Cytosolic proteins (the eponymous Hsp70 and a related protein called Hsc70) act on nascent proteins on ribosomes. Variants in the ER (called BiP or Grp78 in higher eukaryotes, called Kar2 in *S. cerevisiae*), or in mitochondria or chloroplasts, function in a rather similar manner on proteins as they emerge into the interior of the organelle on passing through the membrane.

What feature does Hsp70 recognize in a target protein? It binds to a linear stretch of amino acids embedded in a hydrophobic context (2339; 2340). This is precisely the sort of motif that is buried in the hydrophobic core of a properly folded, mature protein. Its exposure therefore indicates that the protein is nascent or denatured. Motifs of this nature occur about every 40 amino acids. Binding to the motif prevents

it from misaggregating with another one.

This mode of action explains how the Hsp70 protein Bip can fulfill two functions: to assist in oligomerization and/or folding of newly translocated proteins in the ER; and to remove misfolded proteins. Suppose that BiP recognizes certain peptide sequences that are inaccessible within the conformation of a mature, properly folded protein. These sequences are exposed and attract BiP when the protein enters the ER lumen in an essentially one-dimensional form. And if a protein is misfolded or denatured, they may become exposed on its surface instead of being properly buried.

## PROTEIN LOCALIZATION

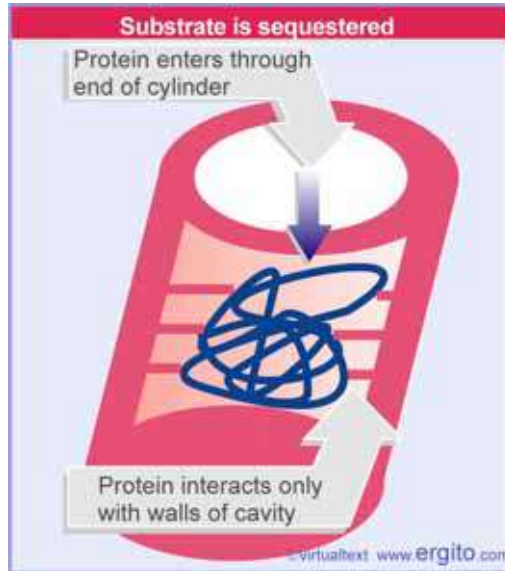

### 2.8.7 Hsp60/GroEL forms an oligomeric ring structure

---

#### Key Concepts

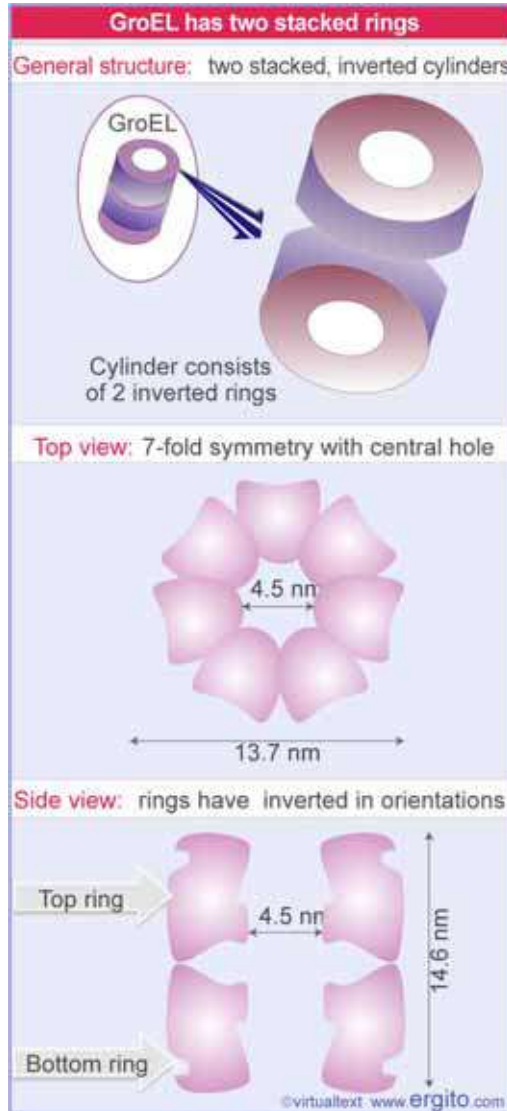

- Hsp60/GroEL forms an oligomeric structure consisting of 14 subunits arranged in two inverted heptameric rings.
  - A GroES heptamer forms a dome that caps one end of the double ring.
  - A substrate protein undergoes a cycle of folding in the cavity of one of the Hsp60/GroEL rings. It is released and rebound for further cycles until it reaches mature conformation.
  - Hydrolysis of ATP provides energy for the folding cycles.
- 

Large (oligomeric) structures with hollow cavities are often used for handling the folding or degradation of proteins (for review see 968). The typical structure is a ring of many subunits, forming a doughnut or cylinder. **Figure 8.14** shows that the target protein is in effect placed in a controlled environment – the cavity – where it is closely associated with the surrounding protein. This creates a high local concentration of binding sites and supports cooperative interactions. In the case of folding, the closed environment prevents the target protein from forming wrongful interactions with other proteins, which may be important in driving folding along the proper pathway. In the case of degradation, isolation presumably makes for a more controlled process than would be possible in open cytosol (see *Molecular Biology Supplement 8.32 The proteasome is a large machine that degrades ubiquitinated proteins*). The energy for these processes is provided by hydrolysis of ATP – typically the subunits of the ring are ATPases.

**Figure 8.14** A protein may be sequestered within a controlled environment for folding or degradation.

The Hsp60 class of chaperones forms a large apparatus that consists of two types of subunit. **Figure 8.15** illustrates the structure schematically. Hsp60 itself (known as GroEL in *E. coli*) forms a structure consisting of 14 subunits that are arranged in two heptameric rings stacked on top of each other in inverted orientation. This means that the top and bottom surfaces of the double ring are the same. The central hole is blocked at the equator of each ring by the COOH ends of the subunits, which protrude into the interior. So the ends of the double cylinder form symmetrical cavities extending about half way into each unit.

**Figure 8.15** GroEL forms an oligomer of two rings, each comprising a hollow cylinder made of 7 subunits.

This structure associates with a heptamer formed of subunits of Hsp10 (GroES in *E. coli*). A single GroES heptamer forms a dome that associates with one surface of the double ring, as shown in **Figure 8.16**. The dome sits over the central cavity, thus capping one opening of the cylinder. The dome is hollow and in effect extends the cavity into the closed surface. We can distinguish the two rings of GroEL as the proximal ring (bound to GroES) or the distal ring (not bound to GroES). The entire GroEL/GroES structure has a mass  $\sim 10^6$  daltons, comparable to a small ribosomal subunit. GroEL is sometimes called a chaperonin, and GroES is called a co-chaperonin, because GroEL plays the essential role in guiding folding, but GroES is required for its activity (459; 463; 465).

**Figure 8.16** Two rings of GroEL associate back to back to form a hollow cylinder. GroES forms a dome that covers the central cavity on one side. Protein substrates bind to the cavity in the proximal ring.

GroEL binds to many unfolded proteins, probably by recognizing a condensed "molten globule" state. Interaction with the substrate is based on hydrophobic interactions between surfaces of the substrate and residues of GroEL that are exposed in its central cavity. Substrates may be provided by proteins that have become denatured; or they may be transferred to GroEL by other chaperones – for example, Hsp70 may assist a nascent protein in folding, but then passes it on to GroEL for the process to be completed when it is released from the ribosome.

The key reactions in substrate binding and folding are illustrated in **Figure 8.17**. The reaction starts when substrate and ATP are bound to the same ring of GroEL. This defines the proximal ring. Then GroES caps this ring. Binding of GroES induces a conformational change in the proximal GroEL ring, increasing the volume of the central cavity. This also changes the environment for the substrate. The hydrophobic residues in GroEL that had previously bound substrate are involved in binding to GroES. The result is that the substrate now finds itself in a hydrophilic environment that forces a change in its conformation (460; 464).

**Figure 8.17** Protein folding occurs in the proximal GroEL ring and requires ATP. Release of substrate and GroES requires ATP hydrolysis in the distal ring. *This is a static version of an interactive figure; see <http://www.ergito.com/main.jsp?bcs=MBIO.2.8.7> to view properly.*

ATP plays an important role in GroEL function. Each subunit of GroEL has a molecule of ATP. The presence of ATP on the subunits of the proximal ring is required for folding to occur. Hydrolysis is required for the transition to the next stage. Hydrolysis of the ATP in the proximal ring changes the properties of the distal ring in such a way as to allow substrate and ATP to bind to it. This in turn triggers the dissociation of the substrate and GroES from the proximal ring. Now the situation at the start of the cycle has been restored. The ring that was the distal ring in the previous cycle is bound to substrate and ATP, and becomes the proximal ring for the next cycle. So the rings of GroEL alternate as proximal and distal (466; 967).

An important question in the action of this (and other macromolecular) chaperones is whether their action is processive. Does a substrate enter the central cavity, undergo

multiple cycles of folding within it, and become released in mature form? Or does it undergo a single folding cycle, after which it is released; typically it will still have improperly folded regions, and therefore will be bound again for another folding cycle. This process will continue until the protein has reached a mature conformation that does not offer a substrate to the chaperone.

These models have been tested by using a mutant GroEL that can bind unfolded proteins but cannot release them. When this "trap GroEL" is added to wild-type GroEL that is actively engaged with a substrate, it blocks the appearance of mature protein. This suggests that the substrate has been released before folding was completed. The simplest explanation is that substrate protein is released after each folding cycle. One cycle of folding, ATP hydrolysis, and release takes about 15 sec *in vitro* (461; 462).

## PROTEIN LOCALIZATION

### 2.8.8 Signal sequences initiate translocation

---

#### Key Terms

**Protein sorting (targeting)** is the direction of different types of proteins for transport into or between specific organelles.

A **signal sequence** is a short region of a protein that directs it to the endoplasmic reticulum for co-translational translocation.

#### Key Concepts

- Proteins associate with the ER system only co-translationally.
- The signal sequence of the substrate protein is responsible for membrane association.

---

Proteins that associate with membranes via N-terminal leaders use a hierarchy of signals to find their final destination. In the case of the reticuloendothelial system, the ultimate location of a protein depends on how it is directed as it transits the endoplasmic reticulum and Golgi apparatus. The leader sequence itself introduces the protein to the membrane; the intrinsic consequence of the interaction is for the protein to pass through the membrane into the compartment on the other side. For a protein to reside within the membrane, a further signal is required to stop passage through the membrane. Other types of signals are required for a protein to be sorted to a particular destination, that is, to remain within the membrane or lumen of some particular compartment. The general process of finding its ultimate destination by transport through successive membrane systems is called **protein sorting** or **targeting**, and is discussed in *Molecular Biology 6.27 Protein trafficking*.

The overall nature of the pathway is summarized in **Figure 8.18**. The "default pathway" takes a protein through the ER, into the Golgi, and on to the plasma membrane. Proteins that reside in the ER possess a C-terminal tetrapeptide (KDEL, which actually provides a signal for them to return to the ER from the Golgi). The signal that diverts a protein to the lysosome is a covalent modification: the addition of a particular sugar residue. Other signals are required for a protein to become a permanent constituent of the Golgi or the plasma membrane. We discuss direction to these locations in *Molecular Biology 6.27 Protein trafficking*.

**Figure 8.18** Proteins that enter the ER-Golgi pathway may flow through to the plasma membrane or may be diverted to other destinations by specific signals.

There is a common starting point for proteins that associate with, or pass through, the reticuloendothelial system of membranes. *These proteins can associate with the membrane only while they are being synthesized.* The ribosomes synthesizing these proteins become associated with the endoplasmic reticulum, enabling the nascent protein to be co-translationally transferred to the membrane. Regions in which ribosomes are associated with the ER are sometimes called the "rough ER," in contrast with the "smooth ER" regions that lack associated polysomes and which have a tubular rather than sheet-like appearance (for review see 1945). **Figure 8.19** shows ribosomes in the act of transferring nascent proteins to ER membranes.

**Figure 8.19** The endoplasmic reticulum consists of a highly folded sheet of membranes that extends from the nucleus. The small objects attached to the outer surface of the membranes are ribosomes. Photograph kindly provided by Lelio Orci.

The proteins synthesized at the rough endoplasmic reticulum pass from the ribosome directly to the membrane. Then they are transferred to the Golgi apparatus, and finally are directed to their ultimate destination, such as the lysosome or secretory

vesicle or plasma membrane. The process occurs within a membranous environment as the proteins are carried between organelles in small membrane-coated vesicles (see *Molecular Biology 6.27 Protein trafficking*.)

Co-translational insertion is directed by a **signal sequence**. Usually this is a cleavable leader sequence of 15-30 N-terminal amino acids. At or close to the N-terminus are several polar residues, and within the leader is a hydrophobic core consisting exclusively or very largely of hydrophobic amino acids (for review see 2356). There is no other conservation of sequence. **Figure 8.20** gives an example.

**Figure 8.20** The signal sequence of bovine growth hormone consists of the N-terminal 29 amino acids and has a central highly hydrophobic region, preceded or flanked by regions containing polar amino acids.

The signal sequence is both necessary and sufficient to sponsor transfer of any attached polypeptide into the target membrane. A signal sequence added to the N-terminus of a globin protein, for example, causes it to be secreted through cellular membranes instead of remaining in the cytosol (2790).

The signal sequence provides the connection that enables the ribosomes to attach to the membrane. There is no intrinsic difference between free ribosomes (synthesizing proteins in the cytosol) and ribosomes that are attached to the ER. A ribosome starts synthesis of a protein without knowing whether the protein will be synthesized in the cytosol or transferred to a membrane. It is the synthesis of a signal sequence that causes the ribosome to associate with a membrane (467; for review see 47).

## PROTEIN LOCALIZATION

### 2.8.9 The signal sequence interacts with the SRP

---

#### Key Terms

Protein **translocation** describes the movement of a protein across a membrane. This occurs across the membranes of organelles in eukaryotes, or across the plasma membrane in bacteria. Each membrane across which proteins are translocated has a channel specialized for the purpose.

The **signal recognition particle (SRP)** is a ribonucleoprotein complex that recognizes signal sequences during translation and guides the ribosome to the translocation channel. SRPs from different organisms may have different compositions, but all contain related proteins and RNAs.

**Signal peptidase** is an enzyme within the membrane of the ER that specifically removes the signal sequences from proteins as they are translocated. Analogous activities are present in bacteria, archaeobacteria, and in each organelle in a eukaryotic cell into which proteins are targeted and translocated by means of removable targeting sequences. Signal peptidase is one component of a larger protein complex.

#### Key Concepts

- The signal sequence binds to the SRP (signal recognition particle).
- Signal-SRP binding causes protein synthesis to pause.
- Protein synthesis resumes when the SRP binds to the SRP receptor in the membrane.
- The signal sequence is cleaved from the translocating protein by the signal peptidase located on the "inside" face of the membrane.

---

Protein **translocation** can be divided into two general stages: first ribosomes carrying nascent polypeptides associate with the membranes; and then the nascent chain is transferred to the channel and translocates through it.

The attachment of ribosomes to membranes requires the **signal recognition particle (SRP)**. The SRP has two important abilities:

- It can bind to the signal sequence of a nascent secretory protein.
- And it can bind to a protein (the SRP receptor) located in the membrane.

The SRP and SRP receptor function catalytically to transfer a ribosome carrying a nascent protein to the membrane. The first step is the recognition of the signal sequence by the SRP. Then the SRP binds to the SRP receptor and the ribosome binds to the membrane. The stages of translation of membrane proteins are

summarized in **Figure 8.21**.

**Figure 8.21** Ribosomes synthesizing secretory proteins are attached to the membrane via the signal sequence on the nascent polypeptide.

*This is a static version of an interactive figure; see <http://www.ergito.com/main.jsp?bcs=MBIO.2.8.9> to view properly.*

The role of the SRP receptor in protein translocation is transient. When the SRP binds to the signal sequence, it arrests translation (468). This usually happens when ~70 amino acids have been incorporated into the polypeptide chain (at this point the 25 residue leader has become exposed, with the next ~40 amino acids still buried in

the ribosome).

Then when the SRP binds to the SRP receptor, the SRP releases the signal sequence. The ribosome becomes bound by another component of the membrane. At this point, translation can resume. When the ribosome has been passed on to the membrane, the role of SRP and SRP receptor has been played. They now recycle, and are free to sponsor the association of another nascent polypeptide with the membrane (for review see 56).

This process may be needed to control the conformation of the protein. If the nascent protein were released into the cytoplasm, it could take up a conformation in which it might be unable to traverse the membrane. The ability of the SRP to inhibit translation while the ribosome is being handed over to the membrane is therefore important in preventing the protein from being released into the aqueous environment.

The signal peptide is cleaved from a translocating protein by a complex of 5 proteins called the **signal peptidase**. The complex is several times more abundant than the SRP and SRP receptor. Its amount is equivalent roughly to the amount of bound ribosomes, suggesting that it functions in a structural capacity. It is located on the luminal face of the ER membrane, which implies that the entire signal sequence must cross the membrane before the cleavage event occurs. Homologous signal peptidases can be recognized in eubacteria, archaea, and eukaryotes (3066).

## PROTEIN LOCALIZATION

### 2.8.10 The SRP interacts with the SRP receptor

---

#### Key Terms

The **Alu domain** comprises the parts of the 7S RNA of the SRP that are related to Alu RNA.

The **S domain** is the sequence of 7S RNA of the SRP that is not related to Alu RNA.

#### Key Concepts

- The SRP is a complex of 7S RNA with 6 proteins.
- The bacterial equivalent to the SRP is a complex of 4.5S RNA with two proteins.
- The SRP receptor is a dimer.
- GTP hydrolysis releases the SRP from the SRP receptor after their interaction.

---

The interaction between the SRP and the SRP receptor is the key event in eukaryotic translation in transferring a ribosome carrying a nascent protein to the membrane (for review see 2285). An analogous interacting system exists in bacteria, although its role is more restricted.

The SRP is an 11S ribonucleoprotein complex, containing 6 proteins (total mass 240 kD) and a small (305 base, 100 kD) 7S RNA. **Figure 8.24** shows that the 7S RNA provides the structural backbone of the particle; the individual proteins do not assemble in its absence (468; 469).

**Figure 8.24** 7S RNA of the SRP has two domains. Proteins bind as shown on the two dimensional diagram above to form the crystal structure shown below. Each function of the SRP is associated with a discrete part of the structure.

The 7S RNA of the SRP particle is divided into two parts. The 100 bases at the 5' end and 45 bases at the 3' end are closely related to the sequence of Alu RNA, a common mammalian small RNA. They therefore define the **Alu domain**. The remaining part of the RNA comprises the **S domain**.

Different parts of the SRP structure depicted in **Figure 8.24** have separate functions in protein targeting. SRP54 is the most important subunit. It is located at one end of the RNA structure, and is directly responsible for recognizing the substrate protein by binding to the signal sequence(2354). It also binds to the SRP receptor in conjunction with the SRP68-SRP72 dimer that is located at the central region of the RNA. The SRP9-SRP14 dimer is located at the other end of the molecule; it is responsible for elongation arrest (470).

The SRP is a flexible structure. In its unengaged form (not bound to signal sequence), it is quite extended, as can be seen from the crystal structure of **Figure 8.24**. **Figure 8.25** shows that binding to a signal sequence triggers a change of conformation, and the protein bends at a hinge to allow the SRP54 end to contact the ribosome at the protein exit site, while the SRP19 swings around to contact the ribosome at the elongation factor binding site (4767). This enables it to cause the elongation arrest that gives time for targeting to the translocation site on the membrane.

**Figure 8.25** SRP binds to a signal sequence as it emerges from the ribosome. The binding causes the SRP to change conformation by bending at a "hinge", allowing SRP54 to contact the ribosome at the protein exit site, while SRP19 makes a second set of contacts.

The SRP receptor is a dimer containing subunits SR  $\alpha$  (72 kD) and SR  $\beta$  (30 kD) (2355). The  $\beta$  subunit is an integral membrane protein. The amino-terminal end of the large  $\alpha$  subunit is anchored by the  $\beta$  subunit. The bulk of the  $\alpha$  protein protrudes into the cytosol. A large part of the sequence of the cytoplasmic region of the protein resembles a nucleic acid-binding protein, with many positive residues. This suggests the possibility that the SRP receptor recognizes the 7S RNA in the SRP.

There is a counterpart to SRP in bacteria, although it contains fewer components. *E. coli* contains a 4.5S RNA that associates with ribosomes and is homologous to the 7S RNA of the SRP. It associates with two proteins: Ffh is homologous to SRP54. FtsY is homologous to the  $\alpha$  subunit of the SRP receptor. In fact, FtsY replaces the functions of both the  $\alpha$  and  $\beta$  SRP subunits; its N-terminal domain substitutes for SRP  $\beta$  in membrane targeting, and the C-terminal domain interacts with the target protein. The role of this complex is more limited than that of SRP-SRP receptor. It is probably required to keep some (but not all) secreted proteins in a conformation that enables them to interact with the secretory apparatus. This could be the original connection between protein synthesis and secretion; in eukaryotes the SRP has acquired the additional roles of causing translational arrest and targeting to the

membrane.

Why should the SRP have an RNA component? The answer must lie in the evolution of the SRP: it must have originated very early in evolution, in an RNA-dominated world, presumably in conjunction with a ribosome whose functions were mostly carried out by RNA. The crystal structure of the complex between the protein-binding domain of 4.5S RNA and the RNA-binding domain of Ffh suggests that RNA continues to play a role in the function of SRP.

The 4.5S RNA has a region (domain IV) that is very similar to domain IV in 7S RNA (see **Figure 8.24**). Ffh consists of three domains (N, G, and M). The M domain (named for a high content of methionines) performs the key binding functions (954). It has a hydrophobic pocket that binds the signal sequence of a target protein. The hydrophobic side chains of the methionine residues create the pocket by projecting into a cleft in the protein structure. Next to the pocket is a helix-turn-helix motif that is typical of DNA-binding proteins (see *Molecular Biology 3.12.12 Repressor uses a helix-turn-helix motif to bind DNA*).

The crystal structure shows that the helix-loop-helix of the M domain binds to a duplex region of the 4.5S RNA in domain IV (953). The negatively charged backbone of the RNA is adjacent to the hydrophobic pocket. This raises the possibility that a signal sequence actually binds to both the protein and RNA components of the SRP. The positively charged sequences that start the signal sequence (see **Figure 8.20**) could interact with the RNA, while the hydrophobic region of the signal sequence could sit in the pocket.

GTP hydrolysis plays an important role in inserting the signal sequence into the membrane. Both the SRP and the SRP receptor have GTPase capability. The signal-binding subunit of the SRP, SRP54, is a GTPase. And both subunits of the SRP receptor are GTPases. All of the GTPase activities are necessary for a nascent protein to be transferred to the membrane. **Figure 8.23** shows that the SRP starts out with GDP when it binds to the signal sequence. The ribosome then stimulates replacement of the GDP with GTP. The signal sequence inhibits hydrolysis of the GTP. This ensures that the complex has GTP bound when it encounters the SRP receptor.

**Figure 8.23** The SRP carries GDP when it binds the signal sequence. The ribosome causes the GDP to be replaced with GTP.

For the nascent protein to be transferred from the SRP to the membrane, the SRP must be released from the SRP receptor. **Figure 8.22** shows that this requires hydrolysis of the GTPs of both the SRP and the SRP receptor. The reaction has been characterized in the bacterial system, where it has the unusual feature that Ffh

activates hydrolysis by FtsY, and FtsY reciprocally activates hydrolysis by Ffh (2335).

**Figure 8.22** The SRP and SRP receptor both hydrolyze GTP when the signal sequence is transferred to the membrane.

## PROTEIN LOCALIZATION

### 2.8.11 The translocon forms a pore

#### Key Terms

A **translocon** is a discrete structure in a membrane that forms a channel through which (hydrophilic) proteins may pass.

#### Key Concepts

- The Sec61 trimeric complex provides the channel for proteins to pass through a membrane.
- A translocating protein passes directly from the ribosome to the translocon without exposure to the cytosol.

There is a basic problem in passing a (largely) hydrophilic protein through a hydrophobic membrane. The energetics of the interaction between the charged protein and the hydrophobic lipids are highly unfavorable. However, a protein in the process of translocation across the ER membrane can be extracted by denaturants that are effective in an aqueous environment. The same denaturants do not extract proteins that are resident components of the membrane. This suggests the model for translocation illustrated in **Figure 8.26**, in which proteins that are part of the ER membrane form an aqueous channel through the bilayer. A translocating protein moves through this channel, interacting with the resident proteins rather than with the lipid bilayer. The channel is sealed on the luminal side to stop free transfer of ions between the ER and the cytosol.

**Figure 8.26** The translocon is a trimer of Sec61 that forms a channel through the membrane. It is sealed on the luminal (ER) side.

The channel through the membrane is called the **translocon**. Its components have been identified in two ways. Resident ER membrane proteins that are crosslinked to translocating proteins are potential subunits of the channel (2822). And *sec* mutants

in yeast (named because they fail to secrete proteins) include a class that cause precursors of secreted or membrane proteins to accumulate in the cytosol (2791; 2821). These approaches together identified the *Sec61 complex*, which consists of three transmembrane proteins: Sec61  $\alpha$ ,  $\beta$ ,  $\gamma$ . Sec61 is the major component of the translocon. In detergent (which provides a hydrophobic milieu that mimics the effect of a surrounding membrane), Sec61 forms cylindrical oligomers with a diameter of  $\sim 85\text{\AA}$  and a central pore of  $\sim 20\text{\AA}$ . Each oligomer consists of 4 heterotrimers (476).

Is the channel a preexisting structure (as implied in the figure) or might it be assembled in response to the association of a hydrophobic signal sequence with the lipid bilayer? Channels can be detected by their ability to allow the passage of ions (measured as a localized change in electrical conductance). Ion-conducting channels can be detected in the ER membrane, and their state depends on protein translocation (472; 474). This demonstrates that the channel is a permanent feature of the membrane.

A channel opens when a nascent polypeptide is transferred from a ribosome to the ER membrane. The translocating protein fills the channel completely, so ions cannot pass through during translocation. But if the protein is released by treatment with puromycin, then the channel becomes freely permeable. If the ribosomes are removed from the membrane, the channel closes, suggesting that the open state requires the presence of the ribosome. This suggests that the channel is controlled in response to the presence of a translocating protein.

Measurements of the abilities of fluorescence quenching agents of different sizes to enter the channel suggest that it is large, with an internal diameter of  $40\text{-}60\text{\AA}$ . This is much larger than the diameter of an extended  $\alpha$ -helical stretch of protein. It is also larger than the pore seen in direct views of the channel; this discrepancy remains to be explained (472).

The aqueous environment of an amino acid in a protein can be measured by incorporating variant amino acids that have photoreactive residues. The fluorescence of these residues indicates whether they are in an aqueous or hydrophobic environment. Experiments with such probes show that when the signal sequence is first synthesized in the ribosome, it is in an aqueous state, but is not accessible to ions in the cytosol. It remains in the aqueous state throughout its interaction with a membrane. This suggests that the translocating protein travels directly from an enclosed tunnel in the ribosome into an aqueous channel in the membrane.

In fact, access to the pore is controlled (or "gated") on *both* sides of the membrane. Before attachment of the ribosome, the pore is closed on the luminal side. **Figure 8.27** shows that when the ribosome attaches, it seals the pore on the cytosolic side. When the nascent protein reaches a length of  $\sim 70$  amino acids, that is, probably when it extends fully across the channel, the pore opens on the luminal side. So at all times, the pore is closed on one side or the other, maintaining the ionic integrities of the separate compartments (474; 475).

**Figure 8.27** A nascent protein is transferred directly from the ribosome to the translocon. The ribosomal seals the channel on the cytosolic side.

The translocon is versatile, and can be used by translocating proteins in several ways:

- It is the means by which nascent proteins are transferred from cytosolic ribosomes to the lumen of endoplasmic reticulum (see *Molecular Biology 2.8.12 Translocation requires insertion into the translocon and (sometimes) a ratchet in the ER*).
- It is also the route by which integral membrane proteins of the ER system are transferred to the membrane; this requires the channel to open or disaggregate in some unknown way so that the protein can move laterally into the lipid bilayer (see *Molecular Biology 2.8.16 How do proteins insert into membranes?*).
- Proteins can also be transferred from the ER back to the cytosol; this is known as reverse translocation (see *Molecular Biology 2.8.13 Reverse translocation sends proteins to the cytosol for degradation*).

## PROTEIN LOCALIZATION

### 2.8.12 Translocation requires insertion into the translocon and (sometimes) a ratchet in the ER

---

#### Key Concepts

- The ribosome, SRP, and SRP receptor are sufficient to insert a nascent protein into a translocon.
  - Proteins that are inserted post-translationally require additional components in the cytosol and Bip in the ER.
  - Bip is a ratchet that prevents a protein from slipping backward.
- 

The translocon and the SRP receptor are the basic components required for co-translational translocation. When the Sec61 complex is incorporated into artificial membranes together with the SRP receptor, it can support translocation of some nascent proteins. Other nascent proteins require the presence of an additional component, TRAM, which is a major protein that becomes crosslinked to a translocating nascent chain. TRAM stimulates the translocation of all proteins.

The components of the translocon and their functions are summarized in **Figure 8.28**. The simplicity of this system makes several important points. We visualize Sec61 as forming the channel and also as interacting with the ribosome. The initial targeting is made when the SRP recognizes the signal sequence as the newly synthesized protein begins to emerge from the ribosome. The SRP binds to the SRP receptor, and the signal sequence is transferred to the translocon. When the signal sequence enters the translocon, the ribosome attaches to Sec61, forming a seal so that the pore is not exposed to the cytosol. Cleavage of the signal peptide does not occur in this system, and therefore cannot be necessary for translocation *per se*. In this system, components on the luminal side of the membrane are not needed for translocation.

**Figure 8.28** Translocation requires the translocon, SRP, SRP receptor, Sec61, TRAM, and signal peptidase.

Of course, the efficiency of the *in vitro* system is relatively low. Additional components could be required *in vivo* to achieve efficient transfer or to prevent other cellular proteins from interfering with the process (473; for review see 48; 60).

A more complex apparatus is required in certain cases in which a protein is inserted into a membrane post-translationally. The same Sec61 complex forms the channel, but four other Sec proteins are also required, and in addition the chaperone BiP (a member of the Hsp70 class) and a supply of ATP are required on the luminal side of the membrane. **Figure 8.29** shows that BiP behaves as ratchet (936). In the absence of BiP, Brownian motion allows the protein to slip back into the cytosol. But BiP grabs the protein as it exits the pore into the endoplasmic reticulum. This stops the protein from moving backward. BiP does not pull the protein through; it just stops it from sliding back. (The reason why BiP is required for post-translational translocation but not for co-translational translocation may be that a newly synthesized protein is continuously extruded from the ribosome and therefore cannot slip backward.)

**Figure 8.29** BiP acts as a ratchet to prevent backward diffusion of a translocating protein. This is a static version of an interactive figure; see <http://www.ergito.com/main.jsp?bcs=MBIO.2.8.12> to view properly.

## PROTEIN LOCALIZATION

### 2.8.13 Reverse translocation sends proteins to the cytosol for degradation

---

#### Key Terms

**Retrograde translocation (Reverse translocation)** is the translocation of a protein from the lumen of the ER to the cytoplasm. It usually occurs to allow misfolded or damaged proteins to be degraded by the proteasome.

#### Key Concepts

- Sec61 translocons can be used for reverse translocation of proteins from the ER into the cytosol.

---

Several important activities occur within the endoplasmic reticulum. Proteins move through the ER en route to a variety of destinations (see *Molecular Biology 6.27 Protein trafficking*). They are glycosylated and folded into their final conformations. The ER provides a "quality control" system in which misfolded proteins are identified and degraded. However, the degradation itself does not occur in the ER, but may require the protein to be exported back to the cytosol.

The first indication that ER proteins are degraded in the cytosol and not in the ER itself was provided by evidence for the involvement of the proteasome, a large protein aggregate with several proteolytic activities (see *Molecular Biology Supplement 8.32 The proteasome is a large machine that degrades ubiquitinated proteins*). Inhibitors of the proteasome prevent the degradation of aberrant ER proteins. Proteins are marked for cleavage by the proteasome when they are modified by the addition of ubiquitin, a small polypeptide chain (see *Molecular Biology 2.8.31 Ubiquitination targets proteins for degradation*). The important point to note now is that ubiquitination and proteasomal degradation both occur in the cytosol (with a minor proportion in the nucleus).

Transport from the ER back into the cytosol occurs by a reversal of the usual process of import (for review see 2979). This is called **reverse translocation**. The Sec61 translocon is used. The conditions are different; for example, the translocon is not associated with a ribosome. Some mutations in Sec61 prevent reverse translocation, but do not prevent forward translocation (2179; 2180). This could be either because there is some difference in the process or (more likely) because these regions interact with other components that are necessary for reverse translocation.

**Figure 8.30** points out that we do not know how the channel is opened to allow insertion of the protein on the ER side. Special components are presumably involved. One model is that misfolded or misassembled proteins are recognized by chaperones, which transfer them to the translocon (for review see 2178). In one particular case, human cytomegalovirus (CMV) codes for cytosolic proteins that destroy newly synthesized MHC class I (cellular major histocompatibility complex) proteins. This requires a viral protein product (US2), which is a membrane protein that functions in

the ER. It interacts with the MHC proteins and probably conveys them into the translocon for reverse translocation.

**Figure 8.30** Reverse translocation uses the translocon to send an unfolded protein from the ER to the cytosol, where it is degraded. The mechanism of putting the translocon into reverse is not known.

The system involved in the degradation of aberrant ER proteins can be identified by mutations (in yeast) that lead to accumulation of aberrant proteins. Usually a protein that misfolds (produced by a mutated gene) is degraded instead of being transported through the ER. Yeast mutants that cannot degrade the substrate fall into two classes: some identify components of the proteolytic apparatus, such as the enzymes involved in ubiquitination; other identify components of the transport apparatus, including Sec61, BiP, and Sec63. There is also a protein in the ER membrane that functions on the cytosolic side to localize the ubiquitination enzymes at the translocon. In fact, retrograde transport into the cytosol cannot occur in the absence of this protein, which suggests that there is a mechanical link between retrograde transport and degradation (494).

## PROTEIN LOCALIZATION

### 2.8.14 Proteins reside in membranes by means of hydrophobic regions

---

#### Key Terms

The **transmembrane region (transmembrane domain)** is the part of a protein that spans the membrane bilayer. It is hydrophobic and in many cases contains approximately 20 amino acids that form an  $\alpha$ -helix. It is also called the transmembrane domain.

A **transmembrane protein (Integral membrane protein)** extends across a lipid bilayer. A hydrophobic region (typically consisting of a stretch of 20-25 hydrophobic and/or uncharged amino acids) or regions of the protein resides in the membrane. Hydrophilic regions are exposed on one or both sides of the membrane.

#### Key Concepts

- Group I proteins have the N-terminus on the far side of the membrane; group II proteins have the opposite orientation.
- Some proteins have multiple membrane-spanning domains.

---

All biological membranes contain proteins, which are held in the lipid bilayer by noncovalent interactions. The operational definition of an **integral membrane protein** is that it requires disruption of the lipid bilayer in order to be released from the membrane. A common feature in such proteins is the presence of at least one **transmembrane domain**, consisting of an  $\alpha$ -helical stretch of 21-26 hydrophobic amino acids. A sequence that fits the criteria for membrane insertion can be identified by a hydrophathy plot, which measures the cumulative hydrophobicity of a stretch of amino acids. A protein that has domains exposed on both sides of the membrane is called a **transmembrane protein**. The association of a protein with a membrane takes several forms (see *Molecular Biology Supplement 32.5 Membranes and membrane proteins*). The topography of a membrane protein depends on the number and arrangement of transmembrane regions.

When a protein has a single transmembrane region, its position determines how much of the protein is exposed on either side of the membrane. A protein may have extensive domains exposed on both sides of the membrane or may have a site of insertion close to one end, so that little or no material is exposed on one side. The length of the N-terminal or C-terminal tail that protrudes from the membrane near the site of insertion varies from insignificant to quite bulky.

**Figure 8.31** shows that proteins with a single transmembrane domain fall into two classes. Group I proteins in which the N-terminus faces the extracellular space are more common than group II proteins in which the orientation has been reversed so that the N-terminus faces the cytoplasm. Orientation is determined during the insertion of the protein into the endoplasmic reticulum.

**Figure 8.31** Group I and group II transmembrane proteins have opposite orientations with regard to the membrane.

**Figure 8.32** shows orientations for proteins that have multiple membrane-spanning domains. An odd number means that both termini of the protein are on opposite sides of the membrane, whereas an even number implies that the termini are on the same face. The extent of the domains exposed on one or both sides is determined by the locations of the transmembrane domains. Domains at either terminus may be exposed, and internal sequences between the domains "loop out" into the extracellular space or cytoplasm. One common type of structure is the 7-membrane passage or "serpentine" receptor; another is the 12-membrane passage component of an ion channel.

**Figure 8.32** The orientations of the termini of multiple membrane-spanning proteins depends on whether there is an odd or even number of transmembrane segments.

Does a transmembrane domain itself play any role in protein function besides allowing the protein to insert into the lipid bilayer? In the simple group I or II proteins, it has little or no additional function; often it can be replaced by any other transmembrane domain. However, transmembrane domains play an important role in the function of proteins that make multiple passes through the membrane or that have subunits that oligomerize within the membrane. The transmembrane domains in such cases often contain polar residues, which are not found in the single membrane-spanning domains of group I and group II proteins. Polar regions in the membrane-spanning domains do not interact with the lipid bilayer, but instead interact with one another. This enables them to form a polar pore or channel within the lipid bilayer. Interaction between such transmembrane domains can create a hydrophilic passage through the hydrophobic interior of the membrane. This can allow highly charged ions or molecules to pass through the membrane, and is important for the function of ion channels and transport of ligands. Another case in which conformation of the transmembrane domains is important is provided by certain receptors that bind lipophilic ligands. In such cases, the transmembrane domains (rather than the extracellular domains) bind the ligand within the plane of the membrane.

## PROTEIN LOCALIZATION

### 2.8.15 Anchor sequences determine protein orientation

---

#### Key Terms

An **anchor (stop-transfer)** (often referred to as a "transmembrane anchor") is a segment of a transmembrane protein which resides in the membrane.

#### Key Concepts

- An anchor sequence halts the passage of a protein through the translocon. Typically this is located at the C-terminal end and results in a group I orientation in which the N-terminus has passed through the membrane.
- A combined signal-anchor sequence can be used to insert a protein into the membrane and anchor the site of insertion. Typically this is internal and results in a group II orientation in which the N-terminus is cytosolic.

---

Proteins that are secreted from the cell pass through a membrane while remaining in the aqueous channel of the translocon. By contrast, proteins that reside in membranes start the process in the same way, but then transfer from the aqueous channel into the hydrophobic environment. The challenge in accounting for insertion of proteins into membranes is to explain what distinguishes transmembrane proteins from secreted proteins, and causes this transfer. The pathway by which proteins of either type I or type II are inserted into the membrane follows the same initial route as that of secretory proteins, relying on a signal sequence that functions co-translationally. But proteins that are to remain within the membrane possess a second, **stop-transfer** signal. This takes the form of a cluster of hydrophobic amino acids adjacent to some ionic residues. The cluster serves as an **anchor** that latches on to the membrane and stops the protein from passing right through.

A surprising property of anchor sequences is that they can function as signal sequences when engineered into a different location. When placed into a protein lacking other signals, such a sequence may sponsor membrane translocation. One possible explanation for these results is that the signal sequence and anchor sequence interact with some common component of the apparatus for translocation. Binding of the signal sequence initiates translocation, but the appearance of the anchor sequence displaces the signal sequence and halts transfer.

Membrane insertion starts by the insertion of a signal sequence in the form of a hairpin loop, in which the N-terminus remains on the cytoplasmic side. Two features determine the position and orientation of a protein in the membrane: whether the signal sequence is cleaved; and the location of the anchor sequence.

The insertion of type I proteins is illustrated in **Figure 8.33**. The signal sequence is N-terminal. The location of the anchor signal determines when transfer of the protein is halted. When the anchor sequence takes root in the membrane, domains on the

N-terminal side will be located in the lumen, while domains on the C-terminal side are located facing the cytosol.

**Figure 8.33** Proteins that reside in membranes enter by the same route as secreted proteins, but transfer is halted when an anchor sequence passes into the membrane. If the anchor is at the C-terminus, the bulk of the protein passes through the membrane and is exposed on the far surface.

A common location for a stop-transfer sequence of this type is at the C-terminus. As shown in the figure, transfer is halted only as the last sequences of the protein enter the membrane. This type of arrangement is responsible for the location in the membrane of many proteins, including cell surface proteins. Most of the protein sequence is exposed on the lumenal side of the membrane, with a small or negligible tail facing the cytosol.

Type II proteins do not have a cleavable leader sequence at the N-terminus. Instead the signal sequence is combined with an anchor sequence. We imagine that the general pathway for the integration of type I proteins into the membrane involves the

steps illustrated in **Figure 8.34**. The signal sequence enters the membrane, but the joint signal-anchor sequence does not pass through. Instead it stays in the membrane (perhaps interacting directly with the lipid bilayer), while the rest of the growing polypeptide continues to loop into the endoplasmic reticulum.

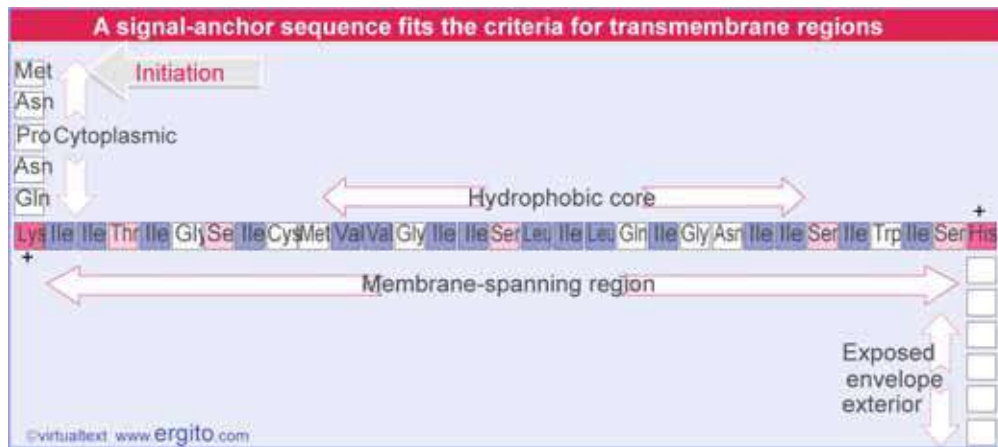

**Figure 8.34** A combined signal-anchor sequence causes a protein to reverse its orientation, so that the N-terminus remains on the inner face and the C-terminus is exposed on the outer face of the membrane.

The signal-anchor sequence is usually internal, and its location determines which parts of the protein remain in the cytosol and which are extracellular. Essentially all the N-terminal sequences that precede the signal-anchor are exposed to the cytosol.

Usually the cytosolic tail is short, ~6-30 amino acids. In effect the N-terminus remains constrained while the rest of the protein passes through the membrane. This reverses the orientation of the protein with regard to the membrane.

The combined signal-anchor sequences of type II proteins resemble cleavable signal sequences. **Figure 8.35** gives an example. Like cleavable leader sequences, the amino acid composition is more important than the actual sequence. The regions at the extremities of the signal-anchor carry positive charges; the central region is uncharged and resembles a hydrophobic core of a cleavable leader. Mutations to introduce charged amino acids in the core region prevent membrane insertion; mutations on either side prevent the anchor from working, so the protein is secreted or located in an incorrect compartment.

**Figure 8.35** The signal-anchor of influenza neuraminidase is located close to the N-terminus and has a hydrophobic core.

The distribution of charges around the anchor sequence has an important effect on the orientation of the protein. More positive charges are usually found on the cytoplasmic side (N-terminal side in type II proteins). If the positive charges are removed by mutation, the orientation of the protein can be reversed. The effect of charges on orientation is summarized by the "positive inside" rule, which says that the side of the anchor with the most positive charges will be located in the cytoplasm. The positive charges in effect provide a hook that latches on to the cytoplasmic side of the membrane, controlling the direction in which the hydrophobic region is inserted, and thus determining the orientation of the protein.

---

**PROTEIN LOCALIZATION****2.8.16 How do proteins insert into membranes?**

---

**Key Concepts**

- Transfer of transmembrane domains from the translocon into the lipid bilayer is triggered by the interaction of the transmembrane region with the translocon.
- 

We have a reasonable understanding of the processes by which secreted proteins pass through membranes and of how this relates to the insertion of the single-membrane spanning group I and group II proteins. We cannot yet explain the details of insertion of proteins with multiple membrane-spanning domains.

We understand how a secreted protein passes through a membrane without any conflict, but it is difficult to apply the same model to a protein that resides in the membrane. **Figure 8.36** illustrates the difference between the organization of a translocating protein, which is protected from the lipid bilayer by the aqueous channel, and a transmembrane protein, which has a hydrophobic segment directly in contact with the membrane. We do not know how a protein is transferred from its passage through the proteinaceous channel into the lipid bilayer itself. One possibility is that there is some mechanism for transferring hydrophobic transmembrane domains directly from the channel into the membrane, as suggested in **Figure 8.37**. This idea is supported by observations of an *in vitro* system which measured transfer into a lipid environment for proteins with different transmembrane domains. When the domain passed a threshold of hydrophobicity, the protein could pass from a channel consisting of Sec61 and TRAM into the lipid bilayer (1205). The simplest explanation is that the structure of the channel allows the translocating protein to contact the lipid bilayer, so that a sufficiently hydrophobic segment can simply partition directly into the lipid. An alternative is that hydrophobic domains cause the channel to disaggregate, exposing the hydrophobic amino acids to the lipid bilayer.

**Figure 8.36** How does a transmembrane protein make the transition from moving through a proteinaceous channel to interacting directly with the lipid bilayer?

**Figure 8.37** Newly synthesized membrane proteins are able to transfer laterally from the translocon into the lipid bilayer. The mechanism of transfer is not known.

It has always been a common assumption that, whatever the exact mechanism for transferring the transmembrane segment into the membrane, it is triggered by the presence of the transmembrane sequence in the pore. However, changes in the pore occur earlier in response to the synthesis of the transmembrane sequence in the ribosome (475). When a secreted protein passes through the pore, the channel

remains sealed on the cytosolic side but opens on the luminal side after synthesis of the first 70 residues. But as soon as a transmembrane sequence has been fully synthesized, that is, while it is still entirely within the ribosome, the pore closes on the luminal side. How this change relates to the transfer of the transmembrane sequence into the membrane is not clear.

The process of insertion into a membrane has been characterized for both type I proteins and type II proteins, in which there is a single transmembrane domain. How is a protein with multiple membrane-spanning regions inserted into a membrane? Much less is known about this process, but we assume that it relies on sequences that provide signal and/or anchor capabilities. One model is to suppose that there is an alternating series of signal and anchor sequences. Translocation is initiated at the first signal sequence and continues until stopped by the first anchor. Then it is reinitiated by a subsequent signal sequence, until stopped by the next anchor. It is possible that there are multiple pathways for integration into the membrane, because in some cases a transmembrane domain seems to move into the lipid bilayer as soon as it enters the translocon, but in other cases there can be a delay until other transmembrane regions have been synthesized (2736; 2737; 2772; 2779; for review see 49; 2739).

## PROTEIN LOCALIZATION

### 2.8.17 Post-translational membrane insertion depends on leader sequences

---

#### Key Concepts

- N-terminal leader sequences provide the information that allows proteins to associate with mitochondrial or chloroplast membranes
- 

Mitochondria and chloroplasts synthesize only some of their proteins. Mitochondria synthesize only ~10 organelle proteins; chloroplasts synthesize ~50 proteins. The majority of organelle proteins are synthesized in the cytosol by the same pool of free ribosomes that synthesize cytosolic proteins. They must then be imported into the organelle.

Many proteins that enter mitochondria or chloroplasts by a post-translational process have leader sequences that are responsible for primary recognition of the outer membrane of the organelle. As shown in the simplified diagram of **Figure 8.38**, the leader sequence initiates the interaction between the precursor and the organelle membrane. The protein passes through the membrane, and the leader is cleaved by a protease on the organelle side.

**Figure 8.38** Leader sequences allow proteins to recognize mitochondrial or chloroplast surfaces by a post-translational process.

The leaders of proteins imported into mitochondria and chloroplasts usually have both hydrophobic and basic amino acids. They consist of stretches of uncharged amino acids interrupted by basic amino acids, and they lack acidic amino acids. There is little other homology. An example is given in **Figure 8.39**. Recognition of the leader does not depend on its exact sequence, but rather on its ability to form an amphipathic helix, in which one face has hydrophobic amino acids, and the other face presents the basic amino acids.

**Figure 8.39** The leader sequence of yeast cytochrome *c* oxidase subunit IV consists of 25 neutral and basic amino acids. The first 12 amino acids are sufficient to transport any attached polypeptide into the mitochondrial matrix.

The leader sequence contains all the information needed to localize an organelle protein. The ability of a leader sequence can be tested by constructing an artificial protein in which a leader from an organelle protein is joined to a cytosolic protein. The experiment is performed by constructing a hybrid gene, which is then translated

into the hybrid protein.

Several leader sequences have been shown by such experiments to function independently to target any attached sequence to the mitochondrion or chloroplast. For example, if the leader sequence given in **Figure 8.39** is attached to the cytosolic protein DHFR (dihydrofolate reductase), the DHFR becomes localized in the mitochondrion.

The leader sequence and the transported protein represent domains that fold independently. Irrespective of the sequence to which it is attached, the leader must be able to fold into an appropriate structure to be recognized by receptors on the organelle envelope. The attached polypeptide sequence plays no part in recognition of the envelope (for review see 51; 59).

What restrictions are there on transporting a hydrophilic protein through the hydrophobic membrane? An insight into this question is given by the observation that methotrexate, a ligand for the enzyme DHFR, blocks transport into mitochondria of DHFR fused to a mitochondrial leader. The tight binding of methotrexate prevents the enzyme from unfolding when it is translocated through the membrane. So although the sequence of the transported protein is irrelevant for targeting purposes, in order to follow its leader through the membrane, it requires the flexibility to assume an unfolded conformation (455).

Hydrolysis of ATP is required both outside and inside for translocation across the membrane. It may be involved with pushing the protein from outside and pulling from inside. In the cases of mitochondrial import and bacterial export, there is also a requirement for an electrochemical potential across the inner membrane to transfer the amino terminal part of the leader.

## PROTEIN LOCALIZATION

### 2.8.18 A hierarchy of sequences determines location within organelles

---

#### Key Concepts

- The N-terminal part of a leader sequence targets a protein to the mitochondrial matrix or chloroplast lumen.
  - An adjacent sequence can control further targeting, to a membrane or the intermembrane spaces.
  - The sequences are cleaved successively from the protein
- 

The mitochondrion is surrounded by an envelope consisting of two membranes. Proteins imported into mitochondria may be located in the outer membrane, the intermembrane space, the inner membrane, or the matrix. A protein that is a component of one of the membranes may be oriented so that it faces one side or the other.

What is responsible for directing a mitochondrial protein to the appropriate compartment? The "default" pathway for a protein imported into a mitochondrion is to move through both membranes into the matrix. This property is conferred by the N-terminal part of the leader sequence. A protein that is localized within the intermembrane space or in the inner membrane itself requires an additional signal, which specifies its destination within the organelle. A multipart leader contains signals that function in a hierarchical manner, as summarized in **Figure 8.40**. The first part of the leader targets the protein to the organelle, and the second part is required if its destination is elsewhere than the matrix. The two parts of the leader are removed by successive cleavages.

**Figure 8.40** Mitochondria have receptors for protein transport in the outer and inner membranes. Recognition at the outer membrane may lead to transport through both receptors into the matrix, where the leader is cleaved. If it has a membrane-targeting signal, it may be re-exported.

Cytochrome *c1* is an example. It is bound to the inner membrane and faces the intermembrane space. Its leader sequence consists of 61 amino acids, and can be divided into regions with different functions. The sequence of the first 32 amino acids alone, or even the N-terminal half of this region, can transport DHFR all the way into the matrix. So the first part of the leader sequence (32 N-terminal amino acids) comprises a matrix-targeting signal. But the intact leader transports an attached sequence – such as murine DHFR – into the intermembrane space.

What prevents the protein from proceeding past the intermembrane space when it has an intact leader? The region following the matrix-targeting signal (comprising 19 amino acids of the leader) provides another signal that localizes the protein at the inner membrane or within the intermembrane space. For working purposes, we call this the membrane-targeting signal.

The two parts of a leader that contains both types of signal have different compositions. As indicated in **Figure 8.41**, the 35 N-terminal amino acids resemble other organelle leader sequences in the high content of uncharged amino acids,

punctuated by basic amino acids. The next 19 amino acids, however, comprise an uninterrupted stretch of uncharged amino acids, long enough to span a lipid bilayer. This membrane-targeting signal resembles the sequences that are involved in protein translocation into membranes of the endoplasmic reticulum (see *Molecular Biology 2.8.8 Signal sequences initiate translocation*).

**Figure 8.41** The leader of yeast cytochrome *c1* contains an N-terminal region that targets the protein to the mitochondrion, followed by a region that targets the (cleaved) protein to the inner membrane. The leader is removed by two cleavage events.

Cleavage of the matrix-targeting signal is the sole processing event required for proteins that reside in the matrix. This signal must also be cleaved from proteins that reside in the intermembrane space; but following this cleavage, the membrane-targeting signal (which is now the N-terminal sequence of the protein) directs the protein to its destination in the outer membrane, intermembrane space, or inner membrane. Then it in turn is cleaved.

The N-terminal matrix-targeting signal functions in the same manner for all mitochondrial proteins. Its recognition by a receptor on the outer membrane leads to transport through the two membranes. And the same protease is involved in cleaving the matrix-targeting signal, irrespective of the final destination of the protein. This protease is a water soluble,  $Mg^{2+}$ -dependent enzyme that is located in the matrix. So the N-terminal sequence must reach the matrix, even if the protein ultimately will reside in the intermembrane space.

Residence in the matrix occurs in the absence of any other signal. If there is a membrane-targeting signal, however, it is activated by cleavage of the matrix-targeting signal. Then the remaining part of the leader (which is now N-terminal) causes the protein to take up its final destination.

The nature of the membrane-targeting signal is controversial. One model holds that the entire protein enters the matrix, after which the membrane-targeting signal causes it to be re-exported into or through the inner membrane. An alternative model proposes that the membrane-targeting sequence simply prevents the rest of the protein from following the leader through the inner membrane into the matrix. Whichever model applies, another protease (located within the intermembrane space) completes the removal of leader sequences (453; 454).

Passage through chloroplast membranes is achieved in a similar manner. **Figure 8.42** illustrates the variety of locations for chloroplast proteins. They pass the outer and inner membranes of the envelope into the stroma, a process involving the same types of passage as into the mitochondrial matrix. But some proteins are transported yet further, across the stacks of the thylakoid membrane into the lumen. Proteins destined for the thylakoid membrane or lumen must cross the stroma en route.

**Figure 8.42** A protein approaches the chloroplast from the cytosol with a ~50 residue leader. The N-terminal half of the leader sponsors passage into the envelope or through it into the stroma. Cleavage occurs during envelope passage.

Chloroplast targeting signals resemble mitochondrial targeting signals. The leader consists of ~50 amino acids, and the N-terminal half is needed to recognize the chloroplast envelope. A cleavage between positions 20-25 occurs during or following passage across the envelope, and proteins destined for the thylakoid membrane or lumen have a new N-terminal leader that guides recognition of the thylakoid membrane. There are several (at least four) different systems in the chloroplast that catalyze import of proteins into the thylakoid membrane (for review see 64).

The general principle governing protein transport into mitochondria and chloroplasts therefore is that the N-terminal part of the leader targets a protein to the organelle matrix, and an additional sequence (within the leader) is needed to localize the protein at the outer membrane, intermembrane space, or inner membrane.

## PROTEIN LOCALIZATION

### 2.8.19 Inner and outer mitochondrial membranes have different translocons

---

#### Key Terms

The **TOM complex (TOM)** resides in the outer membrane of the mitochondrion and is responsible for importing proteins from the cytosol into the space between the membranes.

The **TIM complex (TIM)** resides in the inner membrane of mitochondria and is responsible for transporting proteins from the intermembrane space into the interior of the organelle.

#### Key Concepts

- Transport through the outer and inner mitochondrial membranes uses different receptor complexes.
- The TOM (outer membrane) complex is a large complex in which substrate proteins are directed to the Tom40 channel by one of two subcomplexes.
- Different TIM (inner membrane) complexes are used depending on whether the substrate protein is targeted to the inner membrane or to the lumen.
- Proteins pass directly from the TOM to the TIM complex.

---

There are different receptors for transport through each membrane in the chloroplast and mitochondrion. In the chloroplast they are called TOC and TIC, and in the mitochondrion they are called **TOM** and **TIM**, referring to the outer and inner membranes, respectively (for review see 2353).

The TOM complex consists of ~9 proteins, many of which are integral membrane proteins. A general model for the complex is shown in **Figure 8.43**. The TOM aggregate has a size of >500 kD, with a diameter of ~138 Å, and forms an ion-conducting channel. A complex contains 2-3 individual rings of diameter 75 Å, each with a pore of diameter 20 Å.

**Figure 8.43** TOM proteins form receptor complex(es) that are needed for translocation across the mitochondrial outer membrane.

Tom40 is deeply imbedded in the membrane and provides the channel for translocation. It contacts preproteins as they pass through the outer membrane. It binds to three smaller proteins, Tom5,6,7, which may be components of the channel or assembly factors. There are two subcomplexes that provide surface receptors. Tom20,22 form a subcomplex with exposed domains in the cytosol. Most proteins that are imported into mitochondria are recognized by the Tom20,22 subcomplex, which is the primary receptor and recognizes the N-terminal sequence of the translocating protein. Tom37,70,71 provides a receptor for a smaller number of proteins that have internal targeting sequences.

When a protein is translocated through the TOM complex, it passes from a state in which it is exposed to the cytosol into a state in which it is exposed to the intermembrane space. However, it is not usually released, but instead is transferred directly to the TIM complex. It is possible to trap intermediates in which the leader is cleaved by the matrix protease, while a major part of the precursor remains exposed on the cytosolic surface of the envelope. This suggests that a protein spans the two membranes during passage. The TOM and TIM complexes do not appear to interact directly (or at least do not form a detectable stable complex), and they may therefore be linked simply by a protein in transit. When a translocating protein reaches the intermembrane space, the exposed residues may immediately bind to a TIM complex, while the rest of the protein continues to translocate through the TOM complex (for review see 65).

There are two TIM complexes in the inner membrane.

The Tim17-23 complex translocates proteins to the lumen. Substrates are recognized by their possession of a positively charged N-terminal signal. Tim17-23 are transmembrane proteins that comprise the channel. **Figure 8.44** shows that they are associated with Tim44 on the matrix side of the membrane. Tim 44 in turn binds the chaperone Hsp70. This is also associated with another chaperone, Mge, the counterpart to bacterial GrpE. This association ensures that when the imported protein reaches the matrix, it is bound by the Hsp70 chaperone. The high affinity of Hsp70 for the unfolded conformation of the protein as it emerges from the inner membrane helps to "pull" the protein through the channel (for review see 3436).

**Figure 8.44** Tim proteins form the complex for translocation across the mitochondrial inner membrane.

A major chaperone activity in the mitochondrial matrix is provided by Hsp60 (which forms the same sort of structure as its counterpart GroEL). Association with Hsp60 is necessary for joining of the subunits of imported proteins that form oligomeric complexes. An imported protein may be "passed on" from Hsp70 to Hsp60 in the process of acquiring its proper conformation (458).

The Tim22-54 complex translocates proteins that reside in the inner membrane.

How does a translocating protein find its way from the TOM complex to the appropriate TIM complex? Two protein complexes in the intermembrane space escort a translocating protein from TIM to TOM. The Tim9-10 and Tim8-13 complexes act as escorts for different sets of substrate proteins (944). Tim9-10 may direct its substrates to either Tim22-54 or Tim23-17, while Tim8-13 directs substrates only to Tim22-54. Some substrates do not use either Tim9-10 or Tim8-13, so other pathways must also exist. The pathways are summarized in **Figure 8.45**.

**Figure 8.45** Tim9-10 takes proteins from TOM to either TIM complex, and Tim8-13 takes proteins to Tim22-54.

What is the role of the escorting complexes? They may be needed to help the protein exit from the TOM complex as well as for recognizing the TIM complex. **Figure 8.46** shows that a translocating protein may pass directly from the TOM channel to the Tim9,10 complex, and then into the Tim22-54 channel

**Figure 8.46** A translocating protein may be transferred directly from TOM to Tim22-54. This is a static version of an interactive figure; see <http://www.ergito.com/main.jsp?bcs=MBIO.2.8.19> to view properly.

A mitochondrial protein folds under different conditions before and after its passage through the membrane. Ionic conditions and the chaperones that are present are different in the cytosol and in the mitochondrial matrix. It is possible that a mitochondrial protein can attain its mature conformation *only* in the mitochondrion.

## PROTEIN LOCALIZATION

### 2.8.20 Peroxisomes employ another type of translocation system

---

#### Key Terms

The **peroxisome** is an organelle in the cytoplasm enclosed by a single membrane. It contains oxidizing enzymes.

**Peroxi**ns are the protein components of the peroxisome.

#### Key Concepts

- Proteins are imported into peroxisomes in their fully folded state.
- They have either a PTS1 sequence at the C-terminus or a PTS2 sequence at the N-terminus.
- The receptor Pex5p binds the PTS1 sequence, and the receptor Pex7p binds the PTS2 sequence.
- The receptors are cytosolic proteins that shuttle into the peroxisome carrying a substrate protein and then return to the cytosol.

---

**Peroxisomes** are small bodies (0.5-1.5  $\mu\text{m}$  diameter) enclosed by a single membrane. They contain enzymes concerned with oxygen utilization, which convert oxygen to hydrogen peroxide by removing hydrogen atoms from substrates. Catalase then uses the hydrogen peroxide to oxidize a variety of other substrates. Their activities are crucial for the cell. Since the fatal disease of Zellweger syndrome was found to be caused by lack of peroxisomes (2316), >15 human diseases have been linked to disorders in peroxisome function.

All of the components of the peroxisome are imported from the cytosol. Proteins that are required for peroxisome formation are called **peroxi**ns. 23 genes coding for peroxi

ns have been identified, and human peroxisomal diseases have been mapped to 12 complementation groups, most identified with specific genes. Peroxisomes appear to be absent from cells that have null mutations in some of these genes. In some of these cases, introduction of a wild-type gene leads to the reappearance of peroxisomes (2317; 2318). It has generally been assumed that, like other membrane-bounded organelles, peroxisomes can arise only by duplication of pre-existing peroxisomes. But these results raised the question of whether it might be possible to assemble them *de novo* from their components. In at least some cases, however, the absence of peroxi

ns leaves the cells with peroxisomal ghosts – empty membrane bodies. Even when they cannot be easily seen, it is hard to exclude the possibility that there is some remnant that serves to regenerate the peroxisomes (for review see 2305).

Transport of proteins to peroxisomes occurs post-translationally. Proteins that are imported into the matrix have either of two short sequences, called PTS1 and PTS2.

The PTS1 signal is a tri- or tetrapeptide at the C-terminus. It was originally characterized as the sequence SKL (Ser-Lys-Leu) (2319), but now a large variety of sequences have been shown to act as a PTS1 signal (2320). The addition of a suitable sequence to the C-terminus of cytosolic proteins is sufficient to ensure their import into the organelle. The PTS2 signal is a sequence of 9 amino acids, again with much diversity, and this can be located near the N-terminus or internally (for review see 1962). It is possible there may be a third type of sequence called PTS3.

Several peroxisomal proteins are necessary for the import of proteins from the cytosol. The peroxisomal receptors that bind the two types of signals are called Pex5p and Pex7p, respectively. The other proteins are part of membrane-associated complexes concerned with the translocation reaction.

Transport into the peroxisome has unusual features that mark important differences from the system used for transport into other organelles.

Proteins can be imported into the peroxisome in their mature, fully-folded state (1961). This contrasts with the requirement to unfold a protein for passage into the ER or mitochondrion, where it passes through a channel in the membrane into the organelle in something akin to an unfolded thread of amino acids. It is not clear how the structure of a preexisting channel could expand to permit this. One possibility is to resurrect an old idea and to suppose that the channel assembles around the substrate protein when it associates with the membrane.

The Pex5p and Pex7p receptors are not integral membrane proteins, but are largely cytosolic, with only a small proportion associated with peroxisomes (2321; 2322). They behave in the same way, cycling between the peroxisome and the cytosol. **Figure 8.47** shows that the receptor binds a substrate protein in the cytosol, takes it to the peroxisome, moves with it through the membrane into the interior, and then returns to the cytosol to undertake another cycle. This shuttling behavior resembles the carrier system for import into the nucleus (see *Molecular Biology 2.8.28 Transport receptors carry cargo proteins through the pore*).

**Figure 8.47** The Pex5p receptor binds a substrate protein in the cytosol, carries it across the membrane into the peroxisome, and then returns to the cytosol.

The import pathways converge at the peroxisomal membrane, where Pex5p and Pex7p both interact with the same membrane protein complex, consisting of Pex14p and Pex13p. The receptors dock with this complex, and then several other peroxins are involved with the process of transport into the lumen. The details of the transport process are not yet clear.

Proteins that are incorporated into the peroxisomal membrane have a sequence called the mPTS, but little is known about the process of integration. Pex3p may be a key protein, because in its absence other proteins are not found in peroxisomal membranes. Pex3p has its own mPTS, which raises the question of how it enters the membrane. Perhaps it interacts with Pex3p that is already in the membrane (for review see 2305). This bears on the question of whether peroxisomes can ever assemble *de novo*.

## PROTEIN LOCALIZATION

### 2.8.21 Bacteria use both co-translational and post-translational translocation

#### Key Terms

The **periplasm** (or periplasmic space) is the region between the inner and outer membranes in the bacterial envelope.

**Signal peptidase** is an enzyme within the membrane of the ER that specifically removes the signal sequences from proteins as they are translocated. Analogous activities are present in bacteria, archaeobacteria, and in each organelle in a eukaryotic cell into which proteins are targeted and translocated by means of removable targeting sequences. Signal peptidase is one component of a larger protein complex.

#### Key Concepts

- Bacterial proteins that are exported to or through membranes use both post-translational and co-translational mechanisms.

The bacterial envelope consists of two membrane layers. The space between them is called the **periplasm**. Proteins are exported from the cytoplasm to reside in the envelope or to be secreted from the cell. The mechanisms of secretion from bacteria are similar to those characterized for eukaryotic cells, and we can recognize some related components. **Figure 8.48** shows that proteins that are exported from the cytoplasm have one of four fates:

**Figure 8.48** Bacterial proteins may be exported either post-translationally or co-translationally, and may be located within either membrane or the periplasmic space, or may be secreted.

- to be inserted into the inner membrane
- to be translocated through the inner membrane to rest in the periplasm
- to be inserted into the outer membrane
- to be translocated through the outer membrane into the medium.

Different protein complexes in the inner membrane are responsible for transport of proteins depending on whether their fate is to pass through or stay within the inner membrane. This resembles the situation in mitochondria, where different complexes in each of the inner and outer membranes handle different subsets of protein substrates depending on their destinations (see *Molecular Biology 2.8.17 Post-translational membrane insertion depends on leader sequences*) A difference from import into organelles is that transfer in *E. coli* may be either co- or post-translational. Some proteins are secreted both co-translationally and post-translationally, and the relative kinetics of translation versus secretion through the membrane could determine the balance.

Exported bacterial proteins have N-terminal leader sequences, with a hydrophilic N-terminus and an adjacent hydrophobic core. The leader is cleaved by a **signal peptidase** that recognizes precursor forms of several exported proteins. The signal peptidase is an integral membrane protein, located in the inner membrane. Mutations in N-terminal leaders prevent secretion; they are suppressed by mutations in other genes, which are thus defined as components of the protein export apparatus. Several genes given the general description *sec* are implicated in coding for components of the secretory apparatus by the occurrence of mutations that block secretion of many or all exported proteins.

*This content is available online at <http://www.ergito.com/main.jsp?bcs=MBIO.2.8.21>*

**PROTEIN LOCALIZATION****2.8.22 The Sec system transport proteins into and through the inner membrane****Key Concepts**

- The bacterial SecYEG translocon in the inner membrane is related to the eukaryotic Sec61 translocon.
- Various chaperones are involved in directing secreted proteins to the translocon.

There are several systems for transport through the inner membrane. The best characterized is the Sec system, whose components are shown in **Figure 8.49**. The translocon that is embedded in the membrane consists of three subunits that are related to the components of mammalian/yeast Sec61 (for review see 45; 47). Each of the subunits is an integral transmembrane protein. (SecY has 10 transmembrane segments and SecE has 3 transmembrane segments.) The functional translocon is a trimer with one copy of each subunit (1066). The major pathway for directing proteins to the translocon consists of SecB and SecA. SecB is a chaperone that binds to the nascent protein to control its folding. It transfers the protein to SecA, which in turn transfers it to the translocon.

**Figure 8.49** The Sec system has the SecYEG translocon embedded in the membrane, the SecA associated protein that pushes proteins through the channel, the SecB chaperone that transfers nascent proteins to SecA, and the signal peptidase that cleaves the N-terminal signal from the translocated protein.

**Figure 8.50** shows that there are two predominant ways of directing proteins to the Sec channel:

**Figure 8.50** SecB/SecA transfer proteins to the translocon in order for them to pass through the membrane. 4.4S RNA transfers proteins that enter the membrane.

- the SecB chaperone;
- and the 4.5S RNA-based SRP (2357).

Several chaperones can increase the efficiency of bacterial protein export by preventing premature folding; they include "trigger factor" (characterized as a chaperone that assists export), GroEL (see earlier), and SecB (identified as the product of one of the *sec* mutants). Although SecB is the least abundant of these proteins, it has the major role in promoting export. It has two functions. First, it behaves as a chaperone and binds to a nascent protein to retard folding. It cannot reverse the change in structure of a folded protein, so it does not function as an unfolding factor. Its role is therefore to inhibit improper folding of the newly synthesized protein. Second, it has an affinity for the protein SecA. This allows it to target a precursor protein to the membrane (456; 457). The SecB-SecYEG pathway is used for translocation of proteins that are secreted into the periplasm and is summarized in **Figure 8.51**.

**Figure 8.51** SecB transfers a nascent protein to SecA, which inserts the protein into the channel. Translocation requires hydrolysis of ATP and a protonmotive force. SecA undergoes cycles of association and dissociation with the channel and provides the motive force to push the protein through.

SecA is a large peripheral membrane protein that has alternative ways to associate with the membrane. As a peripheral membrane protein, it associates with the membrane by virtue of its affinity for acidic lipids and for the SecY component of the translocon, which are part of a multisubunit complex that provides the translocase function. However, in the presence of other proteins (SecD and SecF), SecA can be found as a membrane-spanning protein. It probably provides the motor that pushes the substrate protein through the SecYEG translocon.

SecA recognizes both SecB and the precursor protein that it chaperones; probably features of the mature protein sequence as well as its leader are required for recognition. SecA has an ATPase activity that depends upon binding to lipids, SecY, and a precursor protein. The ATPase functions in a cyclical manner during translocation. After SecA binds a precursor protein, it binds ATP, and ~20 amino acids are translocated through the membrane. Hydrolysis of ATP is required to

release the precursor from SecA. Then the cycle may be repeated. Precursor protein is bound again to provide the spur to bind more ATP, translocate another segment of protein, and release the precursor. SecA may alternate between the peripheral and integral membrane forms during translocation; with each cycle, a 30 kD domain of SecA may insert into the membrane and then retract (471).

Another process can also undertake translocation. When a precursor is released by SecA, it can be driven through the membrane by a protonmotive force (that is, an electrical potential across the membrane). This process cannot initiate transfer through the membrane, but can continue the process initiated by a cycle of SecA ATPase action. So after or between cycles of the SecA-ATP driven reaction, the protonmotive force can drive translocation of the precursor.

The *E. coli* ribonucleoprotein complex of 4.5S RNA with Ffh and FtsY proteins is a counterpart to the eukaryotic SRP (see *Molecular Biology 2.8.10 The SRP interacts with the SRP receptor*). It probably plays the role of keeping the nascent protein in an appropriate conformation until it interacts with other components of the secretory apparatus. It is needed for the secretion of some, but not all, proteins. As we see in **Figure 8.50**, its substrates are integral membrane proteins (1065). The basis for differential selection of substrates is that the *E. coli* SRP recognizes an anchor sequence in the protein (anchor sequences by definition are present only in integral membrane proteins). Chloroplasts have counterparts to the Ffh and FtsY proteins, but do not require an RNA component.

**PROTEIN LOCALIZATION****2.8.23 Sec-independent translocation systems in *E. coli***

---

**Key Concepts**

- *E. coli* and organelles have related systems for protein translocation.
- One system allows certain proteins to insert into membranes without a translocation apparatus.
- YidC is homologous to a mitochondrial system for transferring proteins into the inner membrane.
- The *tat* system transfers proteins with a twin arginine motif into the periplasmic space.

---

The most striking alternative system for protein translocation in *E. coli* is revealed by the coat protein of phage M13. **Figure 8.52** shows that this does not appear to require any translocation apparatus! It can insert post-translationally into protein-free liposomes (2358). Targeting the protein to the membrane requires specific sequences (comprising basic residues) in the N- and C-terminal regions of the protein. They may interact with negatively charged heads of phospholipids. Then the protein enters the membrane by using hydrophobic groups in its N-terminal leader sequence and an internal anchor sequence. Hydrophobicity is the main driving force for translocation, but it can be assisted by a protonmotive force that is generated between the positively charged periplasmic side of the membrane and an acidic region in the protein. This drives the protein through the membrane, and leader peptidase can then cleave the N-terminal sequence. The generality of this mechanism in bacteria is unclear; it may apply only to the special case of bacteriophage coat proteins (for review see 2353). Some chloroplast proteins may insert into the thylakoid membrane by a similar pathway.

**Figure 8.52** M13 coat protein inserts into the inner membrane by making an initial electrostatic contact, followed by insertion of hydrophobic sequences. Translocation is driven by hydrophobic interactions and a protonmotive force until the anchor sequence enters the membrane.

Mutations in the gene *yidC* block insertion of proteins into the inner membrane (1065; 1088). YidC is homologous to the protein Oxa1p that is required when proteins are inserted into the inner mitochondrial membrane from the matrix. It can function either independently of SecYEG or in conjunction with it. The insertion of some of the YidC-dependent proteins requires SecYEG, suggesting that YidC acts in conjunction with the translocon to divert the substrate into membrane insertion as opposed to secretion (2360). Other proteins whose insertion depends on YidC do not require SecYEG: it seems likely that some other (unidentified) functions are required instead of the translocon.

The *Tat* system is named for its ability to transport proteins bearing a twin arginine

targeting motif. It is responsible for translocation of proteins that have tightly bound cofactors. This may mean that they have limitations on their ability to unfold for passage through the membrane. This would be contrary to the principle of most translocation systems, where the protein passes through the membrane in an unfolded state, and then must be folded into its mature conformation after passage (for review see 1064). This system is related to a system in the chloroplast thylakoid lumen called Hcf106 (for review see 1064). Both of these systems transport proteins into the periplasm.

## PROTEIN LOCALIZATION

### 2.8.24 Pores are used for nuclear import and export

#### Key Terms

The **nuclear envelope** is a layer of two concentric membranes (inner and outer nuclear membranes) that surrounds the nucleus and its underlying intermediate filament lattice, the nuclear lamina. The nuclear envelope is penetrated by nuclear pores. The outer membrane is continuous with the membrane of the rough endoplasmic reticulum.

A **nuclear pore complex (NPC)** is a very large, proteinaceous structure that extends through the nuclear envelope, providing a channel for bidirectional transport of molecules and macromolecules between the nucleus and the cytosol.

#### Key Concepts

- The same nuclear pores are used for importing proteins into the nucleus and for exporting proteins and RNA from the nucleus.

The nucleus is segregated from the cytoplasm by a layer of two membranes that constitute the **nuclear envelope**. The inner membrane contacts the nuclear lamina, providing in effect a surface layer for the nucleus. The outer membrane is continuous with the endoplasmic reticulum in the cytosol. The space between the two membranes is continuous with the lumen of the endoplasmic reticulum. The two membranes come into contact at openings called **nuclear pore complexes**. At the center of each complex is a pore that provides a water-soluble channel between nucleus and cytoplasm. This means that the nucleus and cytosol have the same ionic milieu. There are ~3000 pore complexes on the nuclear envelope of an animal cell.

Transport between nucleus and cytoplasm proceeds in both directions. Since all proteins are synthesized in the cytosol, any proteins required in the nucleus must be transported there. Since all RNA is synthesized in the nucleus, the entire cytoplasmic complement of RNA (mRNA, rRNA, tRNA, and other small RNAs) must be derived by export from the nucleus. The nuclear pores are used for both import and export of material. **Figure 8.53** summarizes the frequency with which the pores are used for some of the more prominent substrates.

Nuclear pores work in both directions		
Direction	Substrate	Passages /pore/min
Import	Histones	100
	Nonhistone proteins	100
	Ribosomal proteins	150
Export	Ribosomal subunits	~5
	mRNA	<1

©virtualtext www.ergito.com

**Figure 8.53** Nuclear pores are used for import and export.

We can form an impression of the magnitude of import by considering the histones, the major protein components of chromatin. In a dividing cell, enough histones must be imported into the nucleus during the period of DNA synthesis to associate with a diploid complement of chromosomes. Since histones form about half the protein mass of chromatin, we may conclude that overall about 200 chromosomal protein molecules must be imported through each pore per minute.

Uncertainties about the processing and stability of mRNA make it more difficult to calculate the number of mRNA molecules exported, but to account for the ~250,000 molecules of mRNA per cell probably requires ~1 event per pore per minute. The major RNA synthetic activity of the nucleus is of course the production of rRNA, which is exported in the form of assembled ribosomal subunits. Just to double the number of ribosomes during one cell cycle would require the export of ~5 ribosomal subunits (60S and 40S) through each pore per minute.

For ribosomal proteins to assemble with the rRNA, they must first be imported into the nucleus. So ribosomal proteins must shuttle into the nucleus as free proteins and out again as assembled ribosomal subunits. Given ~80 proteins per ribosome, their import must be comparable in magnitude to that of the chromosomal proteins.

## PROTEIN LOCALIZATION

### 2.8.25 Nuclear pores are large symmetrical structures

#### Key Concepts

- The nuclear pore is an annular structure with 8-fold symmetry.

How does a nuclear pore accommodate the transit of material of varied sizes and characteristics in either direction? Nuclear pore complexes have a uniform appearance when examined by microscopy. The pores can be released from the nuclear envelope by detergent, and **Figure 8.54** shows that they appear as annular structures, consisting of rosettes made of 8 spokes. **Figure 8.55** shows a model for the pore based on three-dimensional reconstruction of electron microscopic images. It consists of an upper ring and a lower ring, connected by a lattice of 8 structures.

**Figure 8.54** Nuclear pores appear as annular structures by electron microscopy. The circle around one pore has a diameter of 120 nm. Photograph kindly provided by Ronald Milligan.

**Figure 8.55** A model for the nuclear pore shows 8-fold symmetry. Two rings form the upper and lower surfaces (shown in yellow); they are connected by the spokes (shown in green on the inside and blue on the outside). Photograph kindly provided by Ronald Milligan.

The basis for the 8-fold symmetry is explained in terms of individual components in the schematic view from above shown in **Figure 8.56**. This includes the central structure of **Figure 8.55**, and extends it with an internal transporter and surrounding radial arms. The outside of the pore complex as such consists of a ring of diameter ~120 nm. The ring itself consists of 8 subunits. The 8 radial arms outside the ring may be responsible for anchoring the pore complex in the nuclear envelope; they penetrate the membrane. The 8 interior spokes project from the ring, closing the opening to a diameter of ~48 nm. Within this region is the transporter, which contains a pore that approximates a cylinder <10 nm in diameter (482).

**Figure 8.56** The outsides of the nuclear coaxial (cytoplasmic and nucleoplasmic) rings are connected to radial arms. The interior is connected to spokes that project towards the transporter that contains the central pore.

The pore provides a passage across the outer and inner membranes of the nuclear envelope. As illustrated in **Figure 8.57**, the side view has two-fold symmetry about a horizontal axis in the plane of the nuclear envelope. There are matching annuli at the outer and inner membranes, comprising the surfaces that project into the cytosol and into the nucleus, and each is connected to the spokes, which form a central ring. (Only 2 of the 8 spokes are seen in this side view.) The spokes are symmetrical about the horizontal axis. The central pore projects for the distance across the envelope. Sometimes material can be seen within the pore, but it has been difficult to equate such views with the transport of any particular material.

**Figure 8.57** The nuclear pore complex spans the nuclear envelope by means of a triple ring structure. The side view shows two-fold symmetry from either horizontal or perpendicular axes.

The size of the nuclear pore complex corresponds to a total mass  $\sim 50 \times 10^6$  daltons (compare this with the 80S ribosome at  $4 \times 10^6$  daltons). We can identify the smallest repeating component by using the 8-fold symmetry as seen in cross-section (see **Figure 8.56**) and the 2-fold symmetry seen from the side (see **Figure 8.57**). This divides the scaffold into 16 identical units. Each of these units consists of  $\sim 30$  different proteins, most often each present in 1-2 copies per unit (959). The central pore constitutes only a small part of the overall complex (for review see 52; 57).

Individual protein components of the nuclear pore can be localized by immunoelectron microscopy. Most proteins are found on both sides of the pore; very few are found on only one side (2705). This supports the view of the complex as a symmetrical structure built from identical assemblies. Some of the pore complex proteins are transmembrane proteins; they probably help to anchor the complex in the envelope.

**PROTEIN LOCALIZATION****2.8.26 The nuclear pore is a size-dependent sieve for smaller material****Key Concepts**

- The central channel is large enough to allow proteins of <50 kD to pass.
- Larger proteins must require the channel to open wider for passage.

The ability of compounds to diffuse freely through the pores is limited by their size. **Figure 8.58** summarizes the results of two sets of experiments in which material was injected into the cytoplasm, and its entry into the nucleus was followed over 24 hours (3068). Using dextrans (large saccharides) of different sizes shows that the smallest size equilibrates very rapidly, with just over half of the material localized in the nucleus within minutes. As the size of the dextran increases, entry into the nucleus becomes limited. By a diameter of 7 nm, virtually no dextran can pass through the nuclear pore. Analogous results are obtained with proteins (see panel on right of figure), where there is a progressive reduction in the proportion in the nucleus as the size increases.

**Figure 8.58** Small molecules and macromolecules can enter the nucleus freely, but diffusion is limited by size.

It is convenient to consider the material in three size classes:

- Molecules of <5000 daltons that are injected into the cytoplasm appear virtually instantaneously in the nucleus: we may conclude that the nuclear envelope is freely permeable to ions, nucleotides, and other small molecules.
- Proteins of 5-50 kD diffuse at a rate that is inversely related to their size, presumably determined by random contacts with, and passage through, the pore. It takes a few hours for the levels of an injected protein to equilibrate between

cytoplasm and nucleus. We may conclude that small proteins can enter the nucleus by passive diffusion (but they may also be actively transported). The nuclear envelope in effect provides a mesh or molecular sieve that permits passage of material <50 kD. A globular protein of 50 kD in mass would have a diameter of ~5 nm if it were spherical.

- Proteins >50 kD in size do not enter the nucleus by passive diffusion; a mechanism of active transport must be required for their passage (480; for review see 46).

Proteins are transported through the central pore. Electron-dense objects can sometimes be seen in the pore, and are usually assumed to represent material being transported (although this has not been proven). It is likely that the size limits on diffusion into the nucleus are determined by the diameter of the central channel. However, surrounding this channel are eight smaller openings, and it remains possible that smaller material can pass through them.

The ability of small proteins to diffuse through the pore means that, in the absence of any intervention, they will equilibrate between cytosol and nucleus. However, the distribution will be influenced by other interactions; for example, a small protein that is a component of chromatin could be bound to chromatin after it has diffused into the nucleus, and therefore will be largely localized in the nucleus. Larger proteins must use an active transport mechanism that overcomes the apparent size restriction of the pores. Also, active transport must be used for any protein that requires transport against a concentration gradient (for example, a protein that is localized freely in the nucleoplasm).

Transport through the pore has been characterized by using colloidal gold particles coated with a nuclear protein. When these particles are injected into the cytoplasm, they cluster at the nuclear pores, and then accumulate in the nucleus (477). This suggests that the pore structure can widen to accommodate objects of the size of the coated gold particles (~20 nm). Similar experiments have shown that gold particles coated with polynucleotides can be exported from the nucleus via pores. Following a simultaneous injection of RNA-gold particles of one size together with protein-gold particles of another size, pores can be seen to have both sizes of particles, which suggests that the same pores can be used for export and import (2604).

The rigidity of the gold particle excludes the possibility that transport through the pore requires the protein to change into a conformation with a diameter physically smaller than the pore. We conclude that the nuclear pore has a "gating" mechanism that allows the interior to expand as material passes through. Pores engaged in transporting material appear to be opened to a diameter of ~20 nm, possibly by a mechanism akin to the iris of a camera lens. It is possible that two irises, one connected with the cytoplasmic ring and one connected with the nucleoplasmic ring, open in turn as material proceeds through the pore. Very large substrates, such as exported ribonucleoprotein particles, may have to change their conformation to conform with the limit of 20 nm.

We believe that all pores are identical. The nuclear pore complex provides a structural framework that supports the proteins actually responsible for binding and transporting material into (or out of) the nucleus. However, it does not include all of

the active components that are involved in binding and translocation from one side to the other. Accessory factors that associate with the pore are responsible for the actual transport process.

**PROTEIN LOCALIZATION****2.8.27 Proteins require signals to be transported through the pore****Key Terms**

A **nuclear localization signal (NLS)** is a domain of a protein, usually a short amino acid sequence, that interacts with an importin, allowing the protein to be transported into the nucleus.

A **nuclear export signal (NES)** is a domain of a protein, usually a short amino acid sequence, which interacts with an exportin, resulting in the transport of the protein from the nucleus to the cytoplasm.

**Key Concepts**

- The NLS and NES consist of short sequences that are necessary and sufficient for proteins to be transported through the pores into or out of the nucleus.

To be transported through the nuclear pore, a protein must have a special signal in its sequence. The most common motif responsible for import into the nucleus is called the *nuclear localization signal (NLS)*. Its presence in a cytosolic protein is necessary and sufficient to sponsor import into the nucleus (2601). Mutation of the signal can prevent the protein from entering the nucleus (1014).

The summary of nuclear localization signals in **Figure 8.59** shows that there is no apparent conservation of sequence of NLS signals; perhaps the shape of the region or its basicity are the important features. Many NLS sequences take the form of a short, rather basic stretch of amino acids (2639). Often there is a proline residue to break  $\alpha$ -helix formation upstream of the basic residues. Hydrophobic residues are rare. Some NLS signals are bipartite and require two separate short clusters (481). Competition studies suggest that NLS sequences are interchangeable, suggesting that they are all recognized by the same import system.

**Figure 8.59** Nuclear localization signals have basic residues.

Many exported proteins have a common type of signal that is necessary and sufficient for the protein to move from the nucleus to the cytosol. It is called an **NES** (nuclear export signal), and typically consists of an ~10 amino acid sequence. The only common feature in the NES sequences in different proteins is a pattern of conserved leucines (1016; 1017).

A protein may have both an NLS and an NES, the former used for its import into the nucleus, and the latter for its export. They may function constitutively, or their use can be regulated, for example, by association with other proteins that obscure or expose the relevant sequences (486).

## PROTEIN LOCALIZATION

### 2.8.28 Transport receptors carry cargo proteins through the pore

---

#### Key Terms

**Importins** are transport receptors that bind cargo molecules in the cytoplasm and translocate into the nucleus, where they release the cargo.

**Exportins** are transport receptors that bind their cargo and associate with RanGTP in the nucleus. The trimeric complex translocates across the nuclear envelope into the cytoplasm, where hydrolysis of GTP bound to Ran results in release of cargo.

The initial association of a translating ribosome with the translocation channel in the membrane of the ER is called **docking**.

**Translocation** describes the stage of nuclear import or export when a protein or RNA substrate moves through the nuclear pore.

**Nucleoporin** was originally defined to describe the components of the nuclear pore complex that bind to the inhibitory lectins, but now is used to mean any component of the basic nuclear pore complex.

#### Key Concepts

- Transport receptors have the dual properties of recognizing NLS or NES sequences and binding to the nuclear pore.
- Exportins transport substrates from nucleus to cytoplasm; importins transport substrates from cytoplasm to nucleus.
- Exportins and importins interact with nucleoporins in the pore.

---

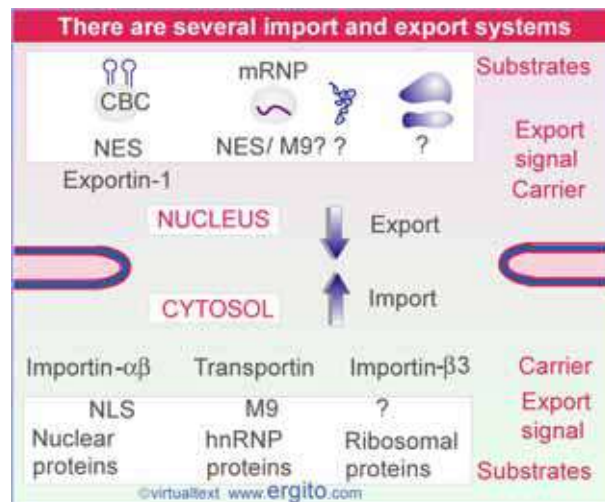

The basic principle of import and export is illustrated in **Figure 8.60**. A carrier protein (or transport receptor) takes the substrate through the pore. The transport receptor must then be returned across the membrane to function in another cycle. The transport receptors are classified according to the direction in which they transport the cargo. **Importins** bind the cargo in the cytoplasm and release it in the nucleus. **Exportins** bind the cargo in the nucleus and release it in the cytoplasm.

**Figure 8.60** A carrier protein binds to a substrate, moves with it through the nuclear pore, is released on the other side, and must be returned for reuse.

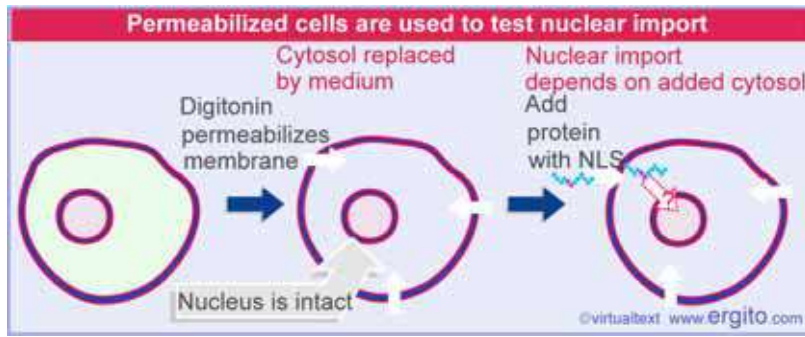

*This is a static version of an interactive figure; see <http://www.ergito.com/main.jsp?bcs=MBIO.2.8.28> to view properly.*

There are multiple pathways for import and export. Transport for all of the substrates for any particular pathway can be inhibited by saturating that pathway with one of its substrates. **Figure 8.61** summarizes the independent pathways. At least two different types of pathways exist for import of proteins; and each class of RNA is exported by a different system. Each transport receptor recognizes a particular type of sequence in its substrate, thus defining the specificity of the system (for review see 1004).

**Figure 8.61** There are multiple pathways for nuclear export and import.

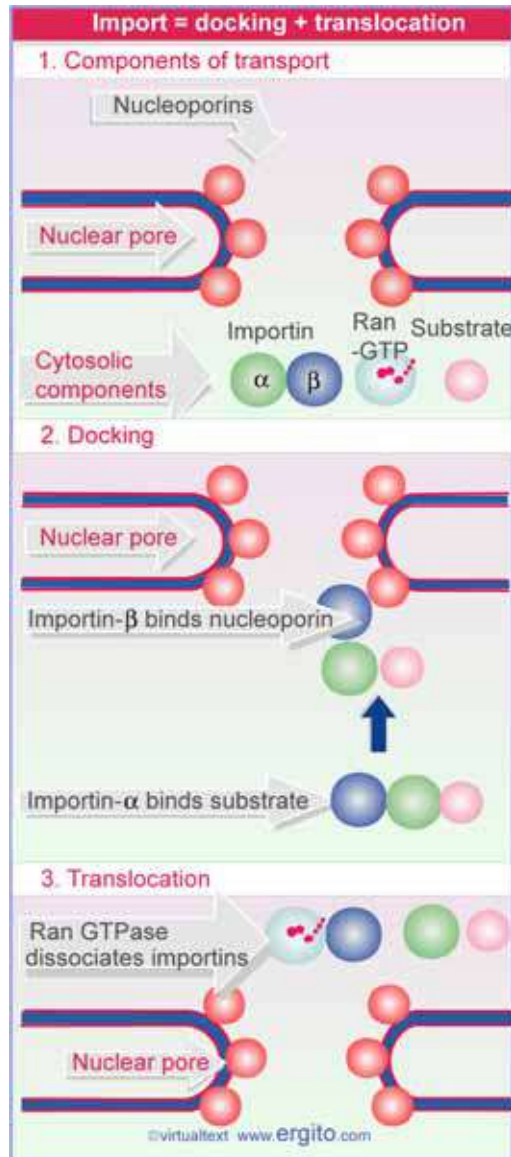

The first handle on the process of import was provided by systems for transport that depend upon the presence of an NLS in the substrate protein. An *in vitro* assay for nuclear pore import has been developed by using permeabilized cells. When cells are treated with digitonin, the plasma membrane becomes permeable, but the nuclear envelope remains intact. Labeled proteins can be imported into the nucleus in a process that is dependent upon the provision of cytosolic components (1015). **Figure 8.62** shows how this system has been used to characterize the transport process.

**Figure 8.62** The assay for nuclear pore function uses permeabilized cells.

Transport can be divided into two stages: **docking**, which consists of binding to the pore; and **translocation**, which consists of movement through it. In the absence of ATP, proteins containing a nuclear import signal can bind at the pore, but they remain at the cytoplasmic face. A cytosolic fraction is needed for binding. When ATP is provided, proteins can be translocated through the pore. A different cytosolic fraction is needed to support translocation. The need for cytosolic fractions at both stages reinforces the view of the pore as a structure that provides the framework for transport, but that does not provide all of the necessary facilities for handling the substrates (478; 479; 483).

**Figure 8.63** summarizes the functions of the components involved in nuclear import. The transport receptor is the key intermediate in the docking reaction. It can bind to both the nuclear pore and the cargo protein. Some transport receptors are single proteins, such as transportin or importin-  $\beta$ , which undertake both binding reactions (484). Others are dimers in which one subunit binds to the pore, and the other is an adaptor that binds to the cargo protein. In the best characterized case, importin-  $\alpha$   $\beta$  has a  $\beta$  subunit that binds to the nuclear pore. The  $\alpha$  subunit binds proteins that have an NLS sequence. The single protein receptors transportin and importin-  $\beta$  are related to the  $\beta$  subunit of importin-  $\alpha$   $\beta$ .

**Figure 8.63** Nuclear import takes place in two stages. Both docking and translocation depend on cytosolic components. Translocation requires nucleoporins.

Translocation through the pore is inhibited by wheat germ agglutinin, a lectin (glycoprotein). The component proteins of the pore that bind to lectins were originally called **nucleoporins**. Note that nucleoporin has since come to be used to mean any component of the nuclear pore complex. The lectin-binding components are localized at or near the region of the central pore, and appear to be located on both sides of the nuclear envelope. When they are removed, pore complexes remain normal in appearance, but can no longer function to transport large material. Material smaller than the pore size continues to be able to move through by diffusion. When the lectin-binding proteins are added back, they restore full activity to the deficient pores. This suggests that they are needed for active transport of material larger than the resting diameter. Some of these proteins have some simple peptide repeating

motifs (GKFG, FG, FXFG), and it is probably these motifs that bind the importin-  $\beta$  carrier proteins (485). They are called FG-nucleoporins.

**PROTEIN LOCALIZATION****2.8.29 Ran controls the direction of transport**

---

**Key Concepts**

- The nucleus contains Ran-GTP, which stabilizes export complexes, while the cytosol contains Ran-GDP, which stabilizes import complexes.
  - Movement through the nuclear pore does not involve a motor.
- 

How does material move through the pore? One of the striking features of the composition of the nuclear pore complex is the lack of any protein with motor activity (959). This suggests that movement must depend on the affinity of the carrier proteins for the pore itself. But now we have to explain how transport can work for both import and export. The answer lies in the properties of the monomeric G-protein, Ran.

The cytosolic fraction that supports translocation has two active components. One is Ran; the other may be involved in targeting Ran to the nuclear pore. Ran is a typical monomeric G-protein that can exist in either the GTP-bound or GDP-bound state (see *Molecular Biology Supplement 32.10 G proteins*). Its GTPase activity generates Ran-GDP. Then an exchange factor is needed to replace GDP with GTP to regenerate Ran-GTP.

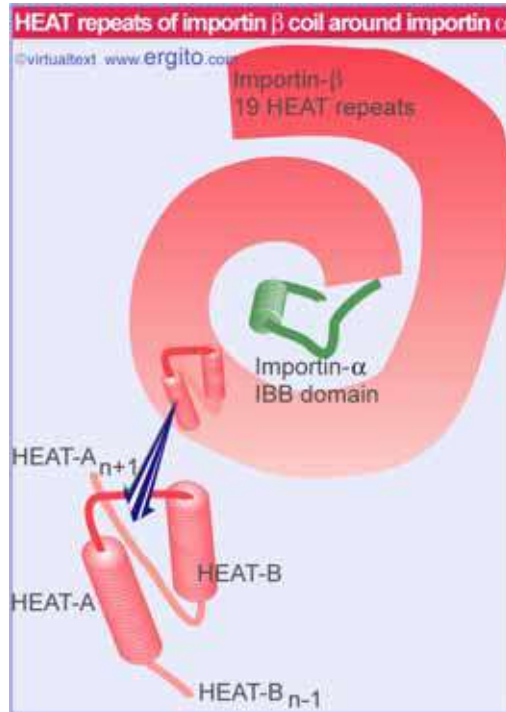

The directionality of nuclear import is controlled by the state of Ran (for review see 1004; 2293). **Figure 8.64** shows that conditions in the nucleus and cytosol differ so that typically there is Ran-GTP in the nucleus, but there is Ran-GDP in the cytosol. The reason for this difference is an asymmetric distribution of two proteins that act on Ran. The nucleus contains Ran-GEF, which stimulates replacement of GDP by GTP, thus converting Ran-GDP to Ran-GTP. (In fact, this protein, also known as Rcc1, is localized to chromatin.) The cytoplasm contains Ran-GAP, which causes the GTP to be hydrolyzed to GDP. The Ran-GAP is localized on the surface of the cytoplasmic side of the nuclear pore complex, together with a Ran-binding protein (RanBP1) that stimulates its activity.

**Figure 8.64** The state of the guanine nucleotide bound to Ran controls directionality of nuclear import and export.

Export complexes are stable in the presence of Ran-GTP, whereas import complexes are stable in the presence of Ran-GDP. So export complexes are driven to form in the nucleus and dissociate in the cytosol, whereas the reverse is true of import complexes. The reaction has been best characterized for the complex of importin- $\alpha$   $\beta$  with an NLS-containing protein. The triple complex is stable in the presence of Ran-GDP, and thus can form in the cytosol. However, Ran-GTP causes importin- $\alpha$  to dissociate from importin- $\beta$ . This leads to release of the substrate protein in the nucleus (1018; 1019). The effect of Ran-GTP in causing the importin dimer to release its substrate is also important at mitosis, when importins release proteins that trigger the attachment of microtubules to the spindle (see *Molecular Biology* 6.29.23 *A monomeric G protein controls spindle assembly*).

The crystal structures of complexes containing importin- $\beta$  show how it binds to importin- $\alpha$  and to Ran. Importin- $\beta$  consists of a series of repeating units coiled into a superhelix. The individual repeating unit (called HEAT) itself consists of two  $\alpha$ -helices (HEAT-A and HEAT-B). Importin- $\alpha$  has a similar structure, but in addition has a domain (IBB for importin-binding domain) that binds importin- $\beta$ . **Figure 8.65** shows that importin- $\beta$  winds around the IBB of importin- $\alpha$ , making a tightly integrated dimer (1020).

**Figure 8.65** Importin-  $\beta$  consists of 19 HEAT repeats organized in a right-handed superhelix. Each HEAT unit consists of two  $\alpha$ -helices (A and B) lying at an angle to one another. Importin-  $\beta$  is folded tightly around the IBB domain of importin-  $\alpha$ .

**Figure 8.66** shows that Ran-GTP binds tightly to two of the HEAT repeats in importin-  $\beta$ . Its binding site partially overlaps the binding site of importin-  $\alpha$  (1021). This explains why binding of Ran-GTP displaces importin-  $\alpha$  (and the NLS of the cargo protein) from importin-  $\beta$ . There is a large structural change in Ran when GTP is hydrolyzed to GDP (involving the unfolding of a helical region), which explains why the displacement reaction is specific for Ran-GTP.

**Figure 8.66** Importin-  $\beta$  binds Ran-GTP through close contacts to the N-terminal HEAT repeats and to repeats 7-8. The structure is significantly different from the importin-  $\beta$  importin-  $\alpha$  structure.

As pointed out in **Figure 8.60**, in order to function more than once, an importin must return to the cytosol after taking its substrate into the nucleus. In effect, when an importin is released in the nucleus, it must become a substrate for an exportin! Such a reaction has been characterized for importin-  $\alpha$ , which is bound in the presence of Ran-GTP by a protein called CAS (489). CAS behaves in a similar manner to importin-  $\beta$ , except that it moves in the opposite direction. Like exportins, it dissociates from its substrate (importin-  $\alpha$ ) when Ran-GTP is hydrolyzed in the cytosol.

The NES binds to exportin-1, which is related in sequence to importin-  $\beta$ . Exportin-1 is needed for the export of U snRNAs, some proteins, and possibly (some) mRNAs. It binds the NES motif; it binds nucleoporins; and it binds Ran-GTP. The complex forms in the presence of Ran-GTP; hydrolysis of the GTP to generate Ran-GDP is accompanied by dissociation of the complex. So Ran controls directionality of export in the reverse sense from its control of import: because Ran-GTP is high in the nucleus, the complex forms there; because it becomes Ran-GDP in the cytosol, the complex dissociates there.

It was thought for a long time that energy for transport would be provided by the hydrolysis of GTP by Ran. However, this is not exactly true. Transport through the pore does not itself require energy (2330). But the hydrolysis of GTP is required for a second cycle of transport, because it is necessary to generate Ran-GDP.

How does the importin-substrate complex cross the nuclear pore? It has a considerable distance to travel, ~200 nm. The pore itself has a symmetrical structure, and very few of its component proteins are concentrated on one side or the other (959). There are no obvious markers that might be used to indicate directionality. However, it is controversial whether the directionality of transport is intrinsic to the pore. At one time it was thought that it could be reversed by reversing the relative concentrations of Ran-GDP and Ran-GTP on either side, but more recent experiments suggest that it cannot (2330; 2332). This leaves us with two types of model: there is some unknown intrinsic directionality resulting from an uneven

distribution of proteins within the pore; or transport is stochastic, with receptor-substrate complexes bumping through the pore until they emerge on the other side, where conditions ensure dissociation.

Importins and exportins move through the pore by a process of facilitated diffusion, but the details are still unclear. The crucial property that enables the importins and exportins to translocate through the pore is their ability to interact with the FG-nucleoporins by binding to the hydrophobic (Phe-Gly) repeats. The various transport receptors compete with one another to bind to the FG-nucleoporins, which argues that there is a common mechanism of translocation. FG-nucleoporins are distributed throughout the central pore, with a concentration at the midpoint. One model suggests that the hydrophobic repeats interact in this region to form a large mesh (2679). The ability of transport receptors to interact with the repeats allows them to "dissolve" in the mesh and thus to pass through it. The different rates at which different substrates are translocated by the pore is determined by how easily they can be incorporated into the mesh. Some crucial questions remain unanswered, especially what determines directionality within the pore itself, since the process seems to be too rapid to be the result of a random walk that is ended by dissociation of the complex on the appropriate side of the pore.

## PROTEIN LOCALIZATION

### 2.8.30 RNA is exported by several systems

#### Key Concepts

- There are (at least) three export systems for RNA.
- Each consists of an exportin that binds particular types of RNA.

Export systems have similar components to import systems. **Figure 8.67** illustrates some examples of export systems. The major substrates for export from the nucleus are ribonucleoproteins – ribosomes, mRNPs, snRNPs, and tRNA-protein complexes. In the first three cases, one of the protein components of the complex may be responsible for export (for example, for snRNAs it is the cap-binding complex (CBC). tRNA is bound directly by a specific export protein (487; 488).

**Figure 8.67** The common feature in proteins that are exported from the nucleus to the cytosol is the presence of an NES.

Export of mRNA has similar requirements to import. Mutations in a yeast FG-nucleoporin block export of RNA from the nucleus without affecting import of proteins. This suggests the possibility that the apparatus is similar for both import and export, but could have components that confer directionality or specificity for particular substrates. There is evidence for diversity in the export apparatus; using an assay for export of microinjected RNAs from the nucleus of the *Xenopus* oocyte, tRNAs, other small RNAs, and mRNAs each saturate transport only of their own class. This suggests that there are at least three groups of exported RNAs.

Some proteins "shuttle" between the cytoplasm and nucleus; they remain only briefly in either compartment before cycling back to the other. This behavior is characteristic of certain proteins that are bound to poly(A)<sup>+</sup> RNA in both the nucleus and the cytoplasm. The motif responsible for transport in one such protein (M9) has a single amino acid stretch that functions as both an import and export signal, and is therefore responsible for movement in both directions (for review see 58).

One particular issue with the export of mRNA is how to distinguish the final, processed mRNA from precursors that are not fully processed (for example, which retain some introns). Part of the answer may lie in the relative timing of events. Processing is connected with transcription in such a way that it is likely to be completed by the time the RNA is released from DNA. However, there are also some specific links that may connect export to the preceding events. One of the mRNA-binding proteins that is exported from the nucleus bound to mRNA attaches to the RNA via an interaction with the transcription apparatus when transcription is initiated (2246). This suggests that the proteins involved in exporting mRNA may become complexed with it at a very early stage of its production. And then mRNAs that are spliced may require splicing to occur in order for other components of the export apparatus to bind to the mRNA (see *Molecular Biology 5.24.10 Splicing is connected to export of mRNA*). The proteins bound to the mRNA then interact with a protein called Mex67 (in yeast) or Tap (in animal cells), which is unrelated to the exportin or importin families, but can interact directly with nucleoporins (for review see 2422).

## PROTEIN LOCALIZATION

### 2.8.31 Ubiquitination targets proteins for degradation

---

#### Key Terms

**Ubiquitin** has a highly conserved sequence of 76 amino acids. It is linked via its COOH group to the  $\epsilon$  NH<sub>2</sub> group of a lysine residue in a target protein.

#### Key Concepts

- Ubiquitin is added to proteins that are targeted for degradation by an apparatus consisting of three components.
- 

A major pathway for protein degradation involves two stages: first the protein is targeted; and then it is proteolysed by a large complex that we describe in the next section. A small polypeptide called **ubiquitin** is connected by a covalent link to the substrate protein that is to be degraded (490; for review see 55; see *Great Experiments 5.3 Ubiquitin conjugation as a proteolytic signal: The first experiments*). **Figure 8.68** shows that there are three components of the ubiquitination system (for review see 1818).

**Figure 8.68** The ubiquitin cycle involves three activities. E1 is linked to ubiquitin. E3 binds to the substrate protein. E2 transfers ubiquitin from E1 to the substrate. Further cycles generate polyubiquitin.

- The ubiquitin-activating enzyme, E1, utilizes the cleavage of ATP to link itself via a high energy thiolester bond from a Cys residue to the C-terminal Gly residue of ubiquitin (for review see 53).
- The ubiquitin is then transferred to the ubiquitin-conjugating enzyme, E2.
- The ubiquitin ligase, E3, transfers the ubiquitin from E2 to form an isopeptide bond to the  $\epsilon$  NH<sub>2</sub> group of a Lys in the substrate protein (for review see 2283).

Ubiquitin is released from a degraded substrate by an isopeptidase.

Responsibility for choosing substrate proteins to be ubiquitinated lies with both E2 and E3. In many cases, E3 selects the substrate protein by binding to it before transfer of ubiquitin is initiated. A cell may contain several E3 proteins that use different criteria for selecting substrates. There are also multiple varieties of E2, and they also may play a role in targeting substrate proteins, sometimes independently of E3 (for review see 1813).

The addition of a single ubiquitin residue to a substrate protein is not sufficient to

cause its degradation. **Figure 8.69** shows that further ubiquitin residues are added to form a polyubiquitin chain, in which each additional ubiquitin is added to the Lys at position 46 of the preceding ubiquitin. The formation of polyubiquitin is a signal for the proteasome to degrade the protein (491).

**Figure 8.69** Polyubiquitin is generated by successive cycles of adding ubiquitin.

Targeting for degradation by the proteasome in the cytosol is the major function of ubiquitination. However, it also targets plasma membrane proteins for degradation in lysosomes, and possibly may have other regulatory effects.

In addition to ubiquitin, there are ubiquitin-like proteins that modify target proteins in a similar way. The best characterized of these is SUMO (also known as Sentrin). A difference between the ubiquitin system and the SUMO system is that only a single SUMO residue is added to a target protein, compared with polyubiquitination. The consequences of sumoylation are not entirely clear; it may be concerned with protein localization or with protection against ubiquitination. SUMO has fewer targets than ubiquitin, but they often include important cellular proteins (for review see 3451).

Ubiquitination (or sumoylation) can be reversed by proteases that cleave the conjugate from the target protein, so there is the potential for significant complexity in regulation.

## PROTEIN LOCALIZATION

### 2.8.32 The proteasome is a large machine that degrades ubiquitinated proteins

---

#### Key Terms

The **proteasome** is a large complex with an interior cavity that degrades cytosolic proteins previously marked by covalent addition of ubiquitin.

#### Key Concepts

- Protein degradation in the cytosol is catalyzed by the proteasome.
- The 20S proteasome consists of four stacked rings each containing 7 subunits.
- The 26S proteasome is formed in eukaryotes when caps associate with one or both ends of the 20S proteasome.
- Caps pass ubiquitinated proteins to the core for proteolysis.
- The proteasome contains several different protease activities.

---

What determines the stability of proteins? A cell contains many proteases, with varying specificities. We may divide them into three general groups:

- Some proteases are involved in specific processing events to generate mature proteins that are smaller than the precursors. Such proteases are involved in a variety of activities, including cleaving the signal sequence from a secreted protein, and cleaving cytosolic enzymes into their mature forms. The caspase group of proteases are involved a pathway that leads to cell death (see *Molecular Biology 6.29.27 A common pathway for apoptosis functions via caspases*).
- Lysosomes are membrane-bounded organelles that degrade proteins imported into the cell; we discuss this process in the context of protein transport through membranes in *Molecular Biology 6.27.15 Receptors recycle via endocytosis*.
- The **proteasome** is a large complex that degrades cytosolic proteins. It is involved in both general degradation (the complete conversion of a protein into small fragments) and in certain specific processing events. The major substrates for complete degradation are proteins that have been misfolded – this is basically a quality control system – and certain proteins whose degradation is a regulatory event, for example, to allow progress through the cell cycle.

The proteasome was originally discovered as a large complex that degrades proteins conjugated to ubiquitin. It exists in two forms. A 20S complex of ~700 kD has protease activity. Additional proteins convert the complex to a 26S form of ~2000 kD; they are regulatory subunits that confer specificity – for example, for binding to ubiquitin conjugates. ATP cleavage is required for the conversion from 20S to 26S,

and is also required later in the reaction for cleaving peptide bonds, releasing the products, etc (for review see 996).

The 20S complex takes the form of a hollow cylinder, and the additional components of the 26S complex are attached to the ends of the cylinder, making a dumbbell. Basically, the active sites are contained in the interior of a barrel, and access is obtained through relatively narrow channels, typically allowing only access only to unfolded proteins. This protects normal, mature proteins from adventitious degradation (492; for review see 67).

This general type of structure is common to ATP-dependent proteases. For example, the ClpAP protease in *E. coli*, which is not related by sequence to the proteasome, has a structure in which the ClpP protease forms two rings of 7 subunits each, with the proteolytic activities contained in a central cavity (2226). ClpA is hexameric and stacks on to the ClpP complex (which implies an interesting symmetry mismatch in the ClpAP complex). ClpA provides the ATPase activity. It unfolds the substrates and translocates them in denatured form through a narrow passage into the ClpP cavity, where they are degraded (2209; 2210). Degradation is processive; once a substrate has been admitted to the central cavity, the reaction proceeds to its end.

The simplest proteasome is found in the archaea. **Figure 8.70** shows the top view of the crystal structure of the 20S assembly. It consists of two types of subunits, organized in the form  $\alpha_7-\beta_7-\beta_7-\alpha_7$ , where each septamer forms a ring. **Figure 8.71** shows the side view of the backbone. The  $\alpha$  subunits form the two outer rings (on top and on the bottom), and the  $\beta$  subunits form the two inner rings. The  $\beta$  subunits have the protease activities, and the active sites are located at the N-terminal ends that project into the interior. The opening of  $\sim 20\text{\AA}$  restricts the entrance for substrates. A yet simpler structure is found in *E. coli*, where a protein related to the  $\beta$  subunit, HslV, forms a structure of two six-member rings with a proteolytic core (493).

**Figure 8.70** The top view of the archaeal 20S proteasome shows a hollow cylinder consisting of heptameric rings of  $\alpha$  subunits (red) and  $\beta$  subunits (blue). Photograph kindly provided by Robert Huber.

**Figure 8.71** The side view of the archaeal 20S proteasome shows the rings of  $\alpha$  subunits (red) and  $\beta$  subunits (blue). Photograph kindly provided by Robert Huber.

The eukaryotic 20S proteasome is more complex, consisting of 7 different  $\alpha$  subunits and 7 different  $\beta$  subunits. **Figure 8.72** shows that it has the same general structure of  $\alpha$ - $\beta$ - $\beta$ - $\alpha$  rings. The rings in each half of the structure are organized in the opposite rotational sense. A significant structural difference with the archaeal proteasome is that the central hole is occluded, so that there is no obvious entrance from the ends of the cylinder. This probably means that the structure is rearranged at some point to allow entrance from the ends (495).

**Figure 8.72** The eukaryotic 20S proteasome consists of two dimeric rings organized in counter-rotation.

The eukaryotic 26S proteasome is formed when the 19S caps associate with the 20S core, binding to one or both ends, to form an elongated structure of ~45 nm in length. The 19S caps are found only in eukaryotic (not archaeal or bacterial) proteasomes. The caps recognize ubiquitinated proteins, and pass them to the 20S core for proteolysis. The 19S caps contain ~18 subunits, several of which are ATPases; presumably the hydrolysis of ATP provides energy for handling the substrate proteins (for review see 61).

The hydrolytic mechanism of the proteasome is different from that of other proteases. The active site of a catalytic  $\beta$ -subunit is an N-terminal threonine; the hydroxyl group of the threonine attacks the peptide bond of the substrate. The proteasome contains several protease activities, with different specificities, for example, for cleaving after basic, acidic, or hydrophobic amino acids, allowing it to attack a variety of types of targets. Proteolytic activities with different substrate specificities may be provided by different  $\beta$  subunits. More than one  $\beta$  subunit may be needed for a particular enzymatic activity. The peptide products typically are octa- and nona-peptides. Proteasomes function processively, that is, a substrate is degraded to completion within the cavity, without any intermediates being released. Basically the central chamber traps proteins until they have been degraded to fragments below a certain size.

Inhibitors of the proteasome block the degradation of most cellular proteins, showing that it is responsible for bulk degradation. In fact, a significant proportion of newly synthesized proteins are immediately degraded by the proteasome (which casts a light on the efficiency of the production of proteins) (1024; 1025). It is also responsible for cleaving antigens in cells of the immune system to generate the small peptides that are presented on the surface of the cell to provoke the immune response (see *Molecular Biology 5.25.18 T cell receptors are related to immunoglobulins*). The peptide fragments are then transported by TAP (the transporter associated with antigen processing) from the cytosol into the ER, where they are bound by MHC

molecules. Other reactions in which target proteins are completely degraded include the removal of cell cycle regulators; in particular, cyclins are degraded during mitosis (see *Molecular Biology 6.29.18 Protein degradation is important in mitosis*), and replication control proteins are degraded during the phase of DNA synthesis. In addition to these reactions, the proteasome may undertake specific processing events, for example, cleaving a precursor to a transcription factor to generate the active protein. The means by which these activities are regulated remain to be discovered.

## PROTEIN LOCALIZATION

### 2.8.33 Summary

---

A protein that is inserted into, or passes through, a membrane has a signal sequence that is recognized by a receptor that is part of the membrane or that can associate with it. The protein passes through an aqueous channel that is created by transmembrane protein(s) that reside in the membrane. In almost all cases, the protein passes through the channel in an unfolded form, and association with chaperones when it emerges is necessary in order to acquire the correct conformation. The major exception is the peroxisome, where an imported protein in its mature conformation binds to a cytosolic protein that carries it through the channel in the membrane.

Synthesis of proteins in the cytosol starts on "free" ribosomes. Proteins that are secreted from the cell or that are inserted into membranes of the reticuloendothelial system start with an N-terminal signal sequence that causes the ribosome to become attached to the membrane of the endoplasmic reticulum. The protein is translocated through the membrane by co-translational transfer. The process starts when the signal sequence is recognized by the SRP (a ribonucleoprotein particle), which interrupts translation. The SRP binds to the SRP receptor in the ER membrane, and transfers the signal sequence to the Sec61/TRAM receptor in the membrane. Synthesis resumes, and the protein is translocated through the membrane while it is being synthesized, although there is no energetic connection between the processes. The channel through the membrane provides a hydrophilic environment, and is largely made of the protein Sec61.

A secreted protein passes completely through the membrane into the ER lumen. Proteins that are integrated into membranes can be divided into two general types based on their orientation. For type I integral membrane proteins, the N-terminal signal sequence is cleaved, and transfer through the membrane is halted later by an anchor sequence. The protein becomes oriented in the membrane with its N-terminus on the far side and its C-terminus in the cytosol. Type II proteins do not have a cleavable N-terminal signal, but instead have a combined signal-anchor sequence, which enters the membrane and becomes embedded in it, causing the C-terminus to be located on the far side, while the N-terminus remains in the cytosol. The orientation of the signal-anchor is determined by the "positive inside" rule that the side of the anchor with more positive charges will be located in the cytoplasm. Proteins that have single transmembrane spanning regions move laterally from the channel into the lipid bilayer. Proteins may have multiple membrane-spanning regions, with loops between them protruding on either side of the membrane. The mechanism of insertion of multiple segments is unknown.

In the absence of any particular signal, a protein is released into the cytosol when its synthesis is completed. Proteins are imported post-translationally into mitochondria or chloroplasts. They possess N-terminal leader sequences that target them to the outer membrane of the organelle envelope; then they are transported through the outer and inner membranes into the matrix. Translocation requires ATP and a potential across the inner membrane. The N-terminal leader is cleaved by a protease within the organelle. Proteins that reside within the membranes or intermembrane

space possess a signal (which becomes N-terminal when the first part of the leader is removed) that either causes export from the matrix to the appropriate location or which halts transfer before all of the protein has entered the matrix. Control of folding, by Hsp70 and Hsp60 in the mitochondrial matrix, is an important feature of the process.

Mitochondria and chloroplasts have separate receptor complexes that create channels through each of the outer and inner membranes. All imported proteins pass directly from the TOM complex in the outer membrane to a TIM complex in the inner membrane. Proteins that reside in the inter-membrane space or in the outer membrane are re-exported from the TIM complex after entering the matrix. The TOM complex uses different receptors for imported proteins depending on whether they have N-terminal or internal signal sequences, and directs both types into the Tom40 channel. There are two TIM receptors in the inner membrane, one used for proteins whose ultimate destination is the inner matrix, the other used for proteins that are re-exported to the inter-membrane space or outer membrane.

Bacteria have components for membrane translocation that are related to those of the co-translational eukaryotic system, but translocation often occurs by a post-translational mechanism. SecY/E provide the translocase, and SecA associates with the channel and is involved in inserting and propelling the substrate protein. SecB is a chaperone that brings the protein to the channel. Some integral membrane proteins are inserted into the channel by an interaction with an apparatus resembling the SRP, consisting of 4.5S RNA and the Fth and FtsY proteins. The protein YidC is homologous to a mitochondrial protein and is required for insertion of some membrane proteins.

Nuclear pore complexes are massive structures embedded in the nuclear membrane, and are responsible for all transport of protein into the nucleus and RNA out of the nucleus. They have 8-fold symmetry seen in cross section and 2-fold symmetry viewed from the side. Each nuclear pore complex contains a central pore, which forms a channel of diameter <10 nm. The central channel can be opened to a diameter of ~20 nm to allow passage of larger material, some of which may need to undergo conformational changes to fit. The proteins of the complex are called nucleoporins; a subset called FG-nucleoporins have hydrophobic repeated sequences of Phe-Gly, are found in the central pore, and may be important in the translocation process.

Proteins that are actively transported into the nucleus require specific NLS sequences, which are short, but do not seem to share common features except for their basicity. Proteins that are exported from the nucleus have specific NES sequences, which share a pattern of leucine residues. Transport is a two stage process, involving docking followed by translocation. The docking reaction is undertaken by a transport receptor. Importins carry proteins into the nucleus, and exportins carry proteins out of the nucleus. The best characterized transport receptor is importin-  $\alpha$   $\beta$ , which has subunits that bind to the substrate protein and to a nucleoporin protein in the pore, respectively. Other transport receptors consist of single proteins that have both functions. The direction of translocation is controlled by Ran. The presence of Ran-GDP in the cytosol destabilizes export complexes. The presence of Ran-GTP in the nucleus destabilizes import complexes. This ensures release of substrate on the appropriate side of the nuclear envelope. ATP is required for translocation only in order to support the regeneration of Ran-GTP from

Ran-GDP; energy is not required for the translocation process itself. The mechanism of translocation is not understood in detail, but is likely to involve interactions of the transport receptors with the FG-nucleoporins.

The major system responsible for bulk degradation of proteins, but also for certain specific processing events, is the proteasome, a large complex that contains several protease activities. It acts upon substrate proteins that have been conjugated to ubiquitin through an isopeptide bond, and upon which a polyubiquitin chain has formed.

## TRANSCRIPTION

### 3.9.1 Introduction

---

#### Key Terms

The **coding strand (Sense strand)** of DNA has the same sequence as the mRNA and is related by the genetic code to the protein sequence that it represents.

The **antisense strand (Template strand)** of DNA is complementary to the sense strand, and is the one that acts as the template for synthesis of mRNA.

**RNA polymerases** are enzymes that synthesize RNA using a DNA template (formally described as DNA-dependent RNA polymerases).

A **promoter** is a region of DNA where RNA polymerase binds to initiate transcription.

**Startpoint (startsite) (Startsite)** refers to the position on DNA corresponding to the first base incorporated into RNA.

A **terminator** is a sequence of DNA that causes RNA polymerase to terminate transcription.

A **transcription unit** is the distance between sites of initiation and termination by RNA polymerase; may include more than one gene.

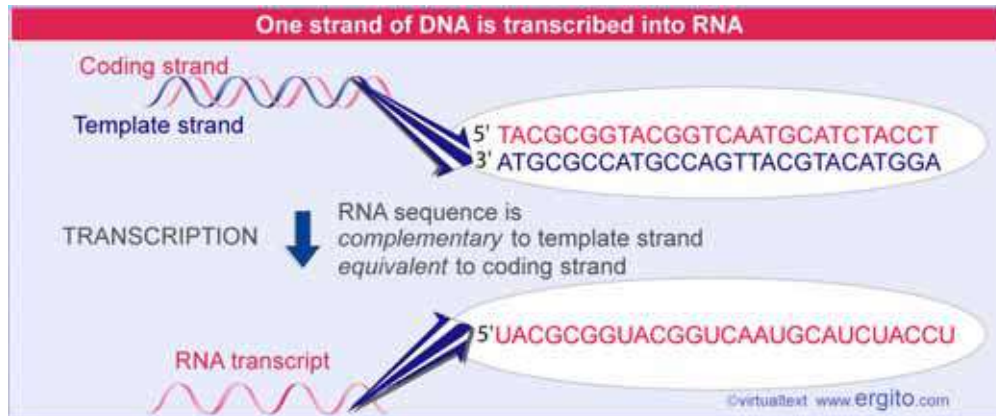

**Upstream** identifies sequences proceeding in the opposite direction from expression; for example, the bacterial promoter is upstream of the transcription unit, the initiation codon is upstream of the coding region.

**Downstream** identifies sequences proceeding farther in the direction of expression; for example, the coding region is downstream of the initiation codon.

A **primary transcript** is the original unmodified RNA product corresponding to a transcription unit.

---

Transcription involves synthesis of an RNA chain representing one strand of a DNA duplex. By "representing" we mean that the RNA is *identical in sequence* with one strand of the DNA, which is called the **coding strand**. It is *complementary* to the other strand, which provides the **template strand** for its synthesis. **Figure 9.1** recapitulates the relationship between double-stranded DNA and its single-stranded RNA transcript.

**Figure 9.1** The function of RNA polymerase is to copy one strand of duplex DNA into RNA.

RNA synthesis is catalyzed by the enzyme **RNA polymerase**. Transcription starts when RNA polymerase binds to a special region, the **promoter**, at the start of the gene. The promoter surrounds the first base pair that is transcribed into RNA, the **startpoint**. From this point, RNA polymerase moves along the template, synthesizing RNA, until it reaches a **terminator** sequence. This action defines a **transcription unit** that extends from the promoter to the terminator. The critical feature of the transcription unit, depicted in **Figure 9.2**, is that it constitutes a stretch of DNA *expressed via the production of a single RNA molecule*. A transcription unit may include more than one gene.

**Figure 9.2** A transcription unit is a sequence of DNA transcribed into a single RNA, starting at the promoter and ending at the terminator.

Sequences prior to the startpoint are described as **upstream** of it; those after the startpoint (within the transcribed sequence) are **downstream** of it. Sequences are conventionally written so that transcription proceeds from left (upstream) to right (downstream). This corresponds to writing the mRNA in the usual 5' → 3' direction.

Often the DNA sequence is written to show only the coding strand, which has the

same sequence as the RNA. Base positions are numbered in both directions away from the startpoint, which is assigned the value +1; numbers are increased going downstream. The base before the startpoint is numbered -1, and the negative numbers increase going upstream. (There is no base assigned the number 0.)

The immediate product of transcription is called the **primary transcript**. It would consist of an RNA extending from the promoter to the terminator, possessing the original 5' and 3' ends. However, the primary transcript is almost always unstable. In prokaryotes, it is rapidly degraded (mRNA) or cleaved to give mature products (rRNA and tRNA). In eukaryotes, it is modified at the ends (mRNA) and/or cleaved to give mature products (all RNA).

Transcription is the first stage in gene expression, and the principal step at which it is controlled. Regulatory proteins determine whether a particular gene is available to be transcribed by RNA polymerase. The initial (and often the only) step in regulation is the decision on whether or not to transcribe a gene. Most regulatory events occur at the initiation of transcription, although subsequent stages in transcription (or other stages of gene expression) are sometimes regulated.

Within this context, there are two basic questions in gene expression:

- How does RNA polymerase find promoters on DNA? This is a particular example of a more general question: how do proteins distinguish their specific binding sites in DNA from other sequences?
- How do regulatory proteins interact with RNA polymerase (and with one another) to activate or to repress specific steps in the initiation, elongation, or termination of transcription?

In this chapter, we analyze the interactions of bacterial RNA polymerase with DNA, from its initial contact with a gene, through the act of transcription, culminating in its release when the transcript has been completed. *Molecular Biology 3.10 The operon* discusses the various means by which regulatory proteins can assist or prevent bacterial RNA polymerase from recognizing a particular gene for transcription. *Molecular Biology 3.11 Regulatory circuits* discusses other means of regulation, including the use of small RNAs, and considers how these interactions can be connected into larger regulatory networks. In *Molecular Biology 3.12 Phage strategies* we consider how individual regulatory interactions can be connected into more complex networks. In *Molecular Biology 5.21 Promoters and enhancers* and *Molecular Biology 5.22 Activating transcription*, we consider the analogous reactions between eukaryotic RNA polymerases and their templates.

## TRANSCRIPTION

### 3.9.2 Transcription occurs by base pairing in a "bubble" of unpaired DNA

---

#### Key Concepts

- RNA polymerase separates the two strands of DNA in a transient "bubble" and uses one strand as a template to direct synthesis of a complementary sequence of RNA.
  - The length of the bubble is ~12-14 bp, and the length of RNA-DNA hybrid within it is ~8-9 bp.
- 

Transcription takes place by the usual process of complementary base pairing. **Figure 9.3** illustrates the general principle of transcription. RNA synthesis takes place within a "transcription bubble," in which DNA is transiently separated into its single strands, and the template strand is used to direct synthesis of the RNA strand.

**Figure 9.3** DNA strands separate to form a transcription bubble. RNA is synthesized by complementary base pairing with one of the DNA strands.

The RNA chain is synthesized from the 5' end toward the 3' end. The 3' -OH group of the last nucleotide added to the chain reacts with an incoming nucleoside 5' triphosphate. The incoming nucleotide loses its terminal two phosphate groups ( $\gamma$  and  $\beta$ ); its  $\alpha$  group is used in the phosphodiester bond linking it to the chain. The overall reaction rate is ~40 nucleotides/second at 37°C (for the bacterial RNA polymerase); this is about the same as the rate of translation (15 amino acids/sec), but much slower than the rate of DNA replication (800 bp/sec).

RNA polymerase creates the transcription bubble when it binds to a promoter. **Figure 9.4** shows that as RNA polymerase moves along the DNA, the bubble moves with it, and the RNA chain grows longer. The process of base pairing and base addition within the bubble is catalyzed and scrutinized by the enzyme.

**Figure 9.4** Transcription takes place in a bubble, in which RNA is synthesized by base pairing with one strand of DNA in the transiently unwound region. As the bubble progresses, the DNA duplex reforms behind it, displacing the RNA in the form of a single polynucleotide chain.

The structure of the bubble within RNA polymerase is shown in the expanded view of **Figure 9.5**. As RNA polymerase moves along the DNA template, it unwinds the duplex at the front of the bubble (the unwinding point), and rewinds the DNA at the back (the rewinding point). The length of the transcription bubble is ~12-14 bp, but the length of the RNA-DNA hybrid region within it is shorter (1903; for review see 68).

**Figure 9.5** During transcription, the bubble is maintained within bacterial RNA polymerase, which unwinds and rewinds DNA, maintains the conditions of the partner and template DNA strands, and synthesizes RNA.

There is a major change in the topology of DNA extending over  $\sim 1$  turn, but it is not clear how much of this region is actually base paired with RNA at any given moment. Certainly the RNA-DNA hybrid is short and transient. As the enzyme moves on, the DNA duplex reforms, and the RNA is displaced as a free polynucleotide chain. About the last 25 ribonucleotides added to a growing chain are complexed with DNA and/or enzyme at any moment.

## TRANSCRIPTION

### 3.9.3 The transcription reaction has three stages

---

#### Key Terms

**Initiation** describes the stages of transcription up to synthesis of the first bond in RNA. This includes binding of RNA polymerase to the promoter and melting a short region of DNA into single strands.

**Elongation** is the stage in a macromolecular synthesis reaction (replication, transcription, or translation) when the nucleotide or polypeptide chain is being extended by the addition of individual subunits.

**Termination** is a separate reaction that ends a macromolecular synthesis reaction (replication, transcription, or translation), by stopping the addition of subunits, and (typically) causing disassembly of the synthetic apparatus.

#### Key Concepts

- RNA polymerase initiates transcription after binding to a promoter site on DNA.
  - During elongation the transcription bubble moves along DNA and the RNA chain is extended in the 5'–3' direction.
  - Transcription stops, the DNA duplex reforms and RNA polymerase dissociates at a terminator site.
- 

The transcription reaction can be divided into the stages illustrated in **Figure 9.6**, in which a bubble is created, RNA synthesis begins, the bubble moves along the DNA, and finally is terminated:

**Figure 9.6** Transcription has four stages, which involve different types of interaction between RNA polymerase and DNA. The enzyme binds to the promoter and melts DNA, remains stationary during initiation, moves along the template during elongation, and dissociates at termination.

- *Template recognition* begins with the binding of RNA polymerase to the double-stranded DNA at a promoter to form a "closed complex". Then the strands of DNA are separated to form the "open complex" that makes the template strand available for base pairing with ribonucleotides. The transcription bubble is created by a local unwinding that begins at the site bound by RNA polymerase.
- **Initiation** describes the synthesis of the first nucleotide bonds in RNA. The enzyme remains at the promoter while it synthesizes the first ~9 nucleotide bonds. The initiation phase is protracted by the occurrence of abortive events, in which the enzyme makes short transcripts, releases them, and then starts synthesis of RNA again. The initiation phase ends when the enzyme succeeds in extending the chain and clears the promoter. *The sequence of DNA needed for*

*RNA polymerase to bind to the template and accomplish the initiation reaction defines the promoter. Abortive initiation probably involves synthesizing an RNA chain that fills the active site. If the RNA is released, the initiation is aborted and must start again. Initiation is accomplished if and when the enzyme manages to move along the template to move the next region of the DNA into the active site.*

- During **elongation** the enzyme moves along the DNA and extends the growing RNA chain. As the enzyme moves, it unwinds the DNA helix to expose a new segment of the template in single-stranded condition. Nucleotides are covalently added to the 3' end of the growing RNA chain, forming an RNA-DNA hybrid in the unwound region. Behind the unwound region, the DNA template strand pairs with its original partner to reform the double helix. The RNA emerges as a free single strand. *Elongation involves the movement of the transcription bubble by a disruption of DNA structure, in which the template strand of the transiently unwound region is paired with the nascent RNA at the growing point.*
- **Termination** involves recognition of the point at which no further bases should be added to the chain. To terminate transcription, the formation of phosphodiester bonds must cease, and the transcription complex must come apart. When the last base is added to the RNA chain, the transcription bubble collapses as the RNA-DNA hybrid is disrupted, the DNA reforms in duplex state, and the enzyme and RNA are both released. *The sequence of DNA required for these reactions defines the terminator.*

The traditional view of elongation has been that it is a monotonic process, in which the enzyme moves forward 1 bp along DNA for every nucleotide added to the RNA chain. Changes in this pattern occur in certain circumstances, in particular when RNA polymerase pauses. One type of pattern is for the "front end" of the enzyme to remain stationary while the "back end" continues to move, thus compressing the footprint on DNA. After movement of several base pairs, the "front end" is released, restoring a footprint of full length. This gave rise to the "inchworm" model of transcription, in which the enzyme proceeds discontinuously, alternatively compressing and releasing the footprint on DNA. However, it may be the case that these events describe an aberrant situation rather than normal transcription (502; 504).

**TRANSCRIPTION****3.9.4 Phage T7 RNA polymerase is a useful model system**

---

**Key Concepts**

- T3 and T7 phage RNA polymerases are single polypeptides with minimal activities in recognizing a small number of phage promoters.
  - Crystal structures of T7 RNA polymerase with DNA identify the DNA-binding region and the active site.
- 

The existence of very small RNA polymerases, comprising single polypeptide chains coded by certain phages, gives some idea of the "minimum" apparatus necessary for transcription. These RNA polymerases recognize just a few promoters on the phage DNA; and they have no ability to change the set of promoters to which they respond. They provide simple model systems for characterizing the binding of RNA polymerase to DNA and the initiation reaction.

The RNA polymerases coded by the related phages T3 and T7 are single polypeptide chains of <100 kD each. They synthesize RNA at rates of ~200 nucleotides/second at 37°C, more rapidly than bacterial RNA polymerase.

The T7 RNA polymerase is homologous to DNA polymerases, and has a similar structure, in which DNA lies in a "palm" surrounded by "fingers" and a "thumb" (see **Figure 14.7**). We now have a direct view of the active site from a crystal structure of a phage T7 RNA polymerase engaged in transcription (925).

The T7 RNA polymerase recognizes its target sequence in DNA by binding to bases in the major groove at a position upstream from the startpoint, as shown in **Figure 9.7**. The enzyme uses a *specificity loop* that is formed by a  $\beta$  ribbon (1565). This feature is unique to the RNA polymerase (it is not found in DNA polymerases). The common point with all RNA polymerases is that the enzyme recognizes specific bases in DNA that are upstream of the sequence that is transcribed.

**Figure 9.7** T7 RNA polymerase has a specificity loop that binds positions -7 to -11 of the promoter while positions -1 to -4 enter the active site.

When transcription initiates, the conformation of the enzyme remains essentially the same while several nucleotides are added, and the transcribed template strand is "scrunched" in the active site. The active site can hold a transcript of 6-9 nucleotides. The transition from initiation to elongation is defined as the point when the enzyme begins to move along DNA. This occurs when the nascent transcript extends beyond the active site and interacts with the specificity loop (1566). The RNA emerges to the surface of the enzyme when 12-14 nucleotides have been synthesized. These features are similar to those displayed by bacterial RNA polymerase.

## TRANSCRIPTION

### 3.9.5 A model for enzyme movement is suggested by the crystal structure

---

#### Key Concepts

- DNA moves through a groove in yeast RNA polymerase that makes a sharp turn at the active site.
  - A protein bridge changes conformation to control the entry of nucleotides to the active site.
- 

We now have much information about the structure and function of RNA polymerase as the result of the crystal structures of the bacterial and yeast enzymes. Bacterial RNA polymerase has overall dimensions of  $\sim 90 \times 95 \times 160 \text{ \AA}$ . Eukaryotic RNA polymerase is larger but less elongated. Structural analysis shows that they share a common type of structure, in which there is a "channel" or groove on the surface  $\sim 25 \text{ \AA}$  wide that could be the path for DNA. This is illustrated in **Figure 9.8** for the example of bacterial RNA polymerase. The length of the groove could hold 16 bp in the bacterial enzyme, and  $\sim 25$  bp in the eukaryotic enzyme, but this represents only part of the total length of DNA bound during transcription. The enzyme surface is largely negatively charged, but the groove is lined with positive charges, enabling it to interact with the negatively charged phosphate groups of DNA.

**Figure 9.8** The  $\beta$  (cyan) and  $\beta'$  subunit (pink) of RNA polymerase have a channel for the DNA template. Synthesis of an RNA transcript (copper) has just begun; the DNA template (red) and coding (yellow) strands are separated in a transcription bubble. Photograph kindly provided by Seth Darst.

The yeast enzyme is a large structure with 12 subunits (see *Molecular Biology 5.21.2 Eukaryotic RNA polymerases consist of many subunits*). Ten subunits of the yeast RNA polymerase II have been located on the crystal structure, as shown in **Figure 9.9**. The catalytic site is formed by a cleft between the two large subunits (#1 and #2), which grasp DNA downstream in "jaws" as it enters the RNA polymerase. Subunits 4 and 7 are missing from this structure; they form a subcomplex that dissociates from the complete enzyme. The structure is generally similar to that of bacterial RNA polymerase (1714; 1913; 1914; for review see 4528). This can be seen more clearly in the crystal structure of **Figure 9.10**. RNA polymerase surrounds the DNA, as seen in the view of **Figure 9.11**. A catalytic  $Mg^{2+}$  ion is found at the active site. The DNA is clamped in position at the active site by subunits 1, 2, and 6. **Figure 9.12** shows that DNA is forced to take a turn at the entrance to the site, because of an adjacent wall of protein. The length of the RNA hybrid is limited by another protein obstruction, called the rudder. Nucleotides probably enter the active site from below, via pores through the structure.

**Figure 9.9** Ten subunits of RNA polymerase are placed in position from the crystal structure. The colors of the subunits are the same as in the crystal structures of the following figures.

**Figure 9.10** The side view of the crystal structure of RNA polymerase II from yeast shows that DNA is held downstream by a pair of jaws and is clamped in position in the active site, which contains an  $Mg^{++}$  ion. Photograph kindly provided by Roger Kornberg (see 1714).

**Figure 9.11** The end view of the crystal structure of RNA polymerase II from yeast shows that DNA is surrounded by  $\sim 270^\circ$  of protein. Photograph kindly provided by Roger Kornberg (see 1714).

**Figure 9.12** DNA is forced to make a turn at the active site by a wall of protein. Nucleotides may enter the active site through a pore in the protein (see 1913).

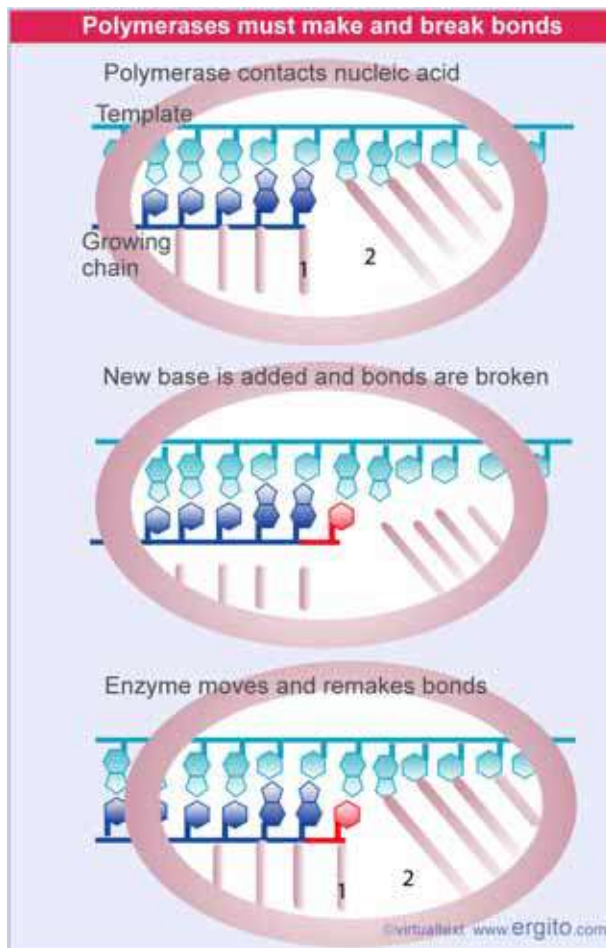

The expanded view of the active site in **Figure 9.13** shows that the transcription bubble includes 9 bp of DNA-RNA hybrid. Where the DNA takes its turn, the bases downstream are flipped out of the DNA helix. As the enzyme moves along DNA, the base in the template strand at the start of the turn will be flipped to face the nucleotide entry site. The 3' end of the RNA is forced to leave the DNA when it hits the protein rudder (see **Figure 9.12**).

**Figure 9.13** An expanded view of the active site shows the sharp turn in the path of DNA.

Once DNA has been melted, the individual strands have a flexible structure in the transcription bubble. This enables DNA to take its turn in the active site. But before transcription starts, the DNA double helix is a relatively rigid straight structure. How does this structure enter the polymerase without being blocked by the wall? The answer is that a large conformational shift must occur in the enzyme. Adjacent to the wall is a clamp. In the free form of RNA polymerase, this clamp swings away from the wall to allow DNA to follow a straight path through the enzyme. After DNA has been melted to create the transcription bubble, the clamp must swing back into position against the wall.

One of the dilemmas of any nucleic acid polymerase is that the enzyme must make tight contacts with the nucleic acid substrate and product, but must break these contacts and remake them with each cycle of nucleotide addition. Consider the situation illustrated in **Figure 9.14**. A polymerase makes a series of specific contacts with the bases at particular positions. For example, contact "1" is made with the base at the end of the growing chain, and contact "2" is made with the base in the template strand that is complementary to the next base to be added. But the bases that occupy these locations in the nucleic acid chains change every time a nucleotide is added!

**Figure 9.14** Movement of a nucleic acid polymerase requires breaking and remaking bonds to the nucleotides that occupy fixed positions relative to the enzyme structure. The nucleotides in these positions change each time the enzyme moves a base along the template.

The top and bottom panels of the figure show the same situation: a base is about to be added to the growing chain. The difference is that the growing chain has been extended by one base in the bottom panel. The geometry of both complexes is exactly the same, but contacts "1" and "2" in the bottom panel are made to bases in the nucleic acid chains that are located one position farther along the chain. The middle panel shows that this must mean that, after the base is added, and before the enzyme moves relative to the nucleic acid, the contacts made to specific positions must be broken so that they can be remade to bases that occupy those positions after the movement.

The RNA polymerase structure suggests an insight into how the enzyme retains contact with its substrate while breaking and remaking bonds (1914). A structure in the protein called the bridge is adjacent to the active site (see **Figure 9.12**). This feature is found in both the bacterial and yeast enzymes, but it has different shapes in the different crystal structures. In one it is bent, and in the other it is straight. **Figure 9.15** suggests that the change in conformation of the bridge structure is closely related to translocation of the enzyme along the nucleic acid.

**Figure 9.15** The RNA polymerase elongation cycle starts with a straight bridge adjacent to the nucleotide entry site. After nucleotide addition, the enzyme moves one base pair and bridge bends as it retains contact with the newly added nucleotide. When the bridge is released, the cycle can start again (see 1914).

At the start of the cycle of translocation, the bridge has a straight conformation adjacent to the nucleotide entry site. This allows the next nucleotide to bind at the nucleotide entry site. The bridge is in contact with the newly added nucleotide. Then the protein moves one base pair along the substrate. The bridge changes its conformation, bending to keep contact with the newly added nucleotide. In this conformation, the bridge obscures the nucleotide entry site. To end the cycle, the bridge returns to its straight conformation, allowing access again to the nucleotide entry site. The bridge acts as a ratchet that releases the DNA and RNA strands for translocation while holding on to the end of the growing chain.

**TRANSCRIPTION****3.9.6 Bacterial RNA polymerase consists of multiple subunits**

---

**Key Terms**

The **holoenzyme (complete enzyme)** is the complex of five subunits including core enzyme ( $\alpha$   $\alpha_2$   $\beta$   $\beta'$  and  $\sigma$ ) factor that is competent to initiate bacterial transcription.

**Key Concepts**

- Bacterial RNA core polymerases are ~500 kD multisubunit complexes with the general structure  $\alpha$   $\alpha_2$   $\beta$   $\beta'$ .
- DNA is bound in a channel and is contacted by both the  $\beta$  and  $\beta'$  subunits.

---

The best characterized RNA polymerases are those of eubacteria, for which *E. coli* is a typical case. *A single type of RNA polymerase appears to be responsible for almost all synthesis of mRNA, and all rRNA and tRNA, in a eubacterium.* About 7000 RNA polymerase molecules are present in an *E. coli* cell. Many of them are engaged in transcription; probably 2000-5000 enzymes are synthesizing RNA at any one time, the number depending on the growth conditions.

The **complete enzyme** or **holoenzyme** in *E. coli* has a molecular weight of ~465 kD. Its subunit composition is summarized in **Figure 9.16**.

**Figure 9.16** Eubacterial RNA polymerases have four types of subunit;  $\alpha$ ,  $\beta$ , and  $\beta'$  have rather constant sizes in different bacterial species, but  $\sigma$  varies more widely.

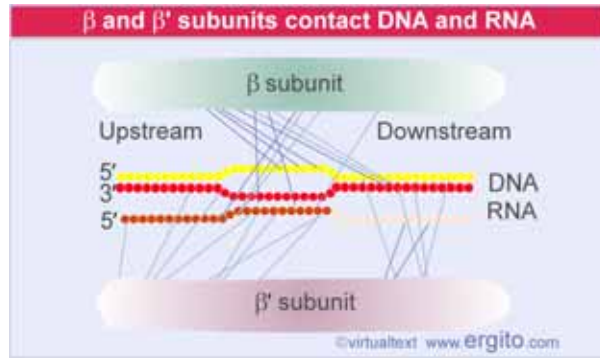

The  $\beta$  and  $\beta'$  subunits together make up the catalytic center. Their sequences are related to those of the largest subunits of eukaryotic RNA polymerases (see *Molecular Biology 5.21.2 Eukaryotic RNA polymerases consist of many subunits*), suggesting that there are common features to the actions of all RNA polymerases. The  $\beta$  subunit can be crosslinked to the template DNA, the product RNA, and the substrate ribonucleotides; mutations in *rpoB* affect all stages of transcription. Mutations in *rpoC* show that  $\beta'$  also is involved at all stages.

The  $\alpha$  subunit is required for assembly of the core enzyme. When phage T4 infects *E. coli*, the  $\alpha$  subunit is modified by ADP-ribosylation of an arginine. The modification is associated with a reduced affinity for the promoters formerly recognized by the holoenzyme, suggesting that the  $\alpha$  subunit plays a role in promoter recognition. The  $\alpha$  subunit also plays a role in the interaction of RNA polymerase with some regulatory factors.

The  $\sigma$  subunit is concerned specifically with promoter recognition, and we have more information about its functions than on any other subunit (see *Molecular Biology 3.9.7 RNA polymerase consists of the core enzyme and sigma factor*).

The crystal structure of the bacterial enzyme (**Figure 9.8**) shows that the channel for DNA lies at the interface of the  $\beta$  and  $\beta'$  subunits (1880). (The  $\alpha$  subunits are not visible in this view.) The DNA is unwound at the active site, where an RNA chain is being synthesized. Crosslinking experiments identify the points at which the RNA polymerase subunits contact DNA (1903). These are summarized in **Figure 9.17**. The  $\beta$  and  $\beta'$  subunits contact DNA at many points downstream of the active site. They make several contacts with the coding strand in the region of the transcription

bubble, thus stabilizing the separated single strands. The RNA is contacted largely in the region of the transcription bubble.

**Figure 9.17** Both the template and coding strands of DNA are contacted by the  $\beta$  and  $\beta'$  subunits largely in the region of the transcription bubble and downstream. The RNA is contacted mostly in the transcription bubble. (Usually there is no downstream RNA, and contacts with RNA downstream occur only in the special case when the enzyme backtracks.) (Based on data of 1903.)

The drug rifampicin (a member of the rifamycin antibiotic family) blocks transcription by bacterial RNA polymerase. It is a major drug used against tuberculosis. The crystal structure of RNA polymerase bound to rifampicin explains its action: it binds in a pocket of the  $\beta$  subunit,  $>12\text{\AA}$  away from the active site, but in a position where it blocks the path of the elongating RNA (1904). By preventing the RNA chain from extending beyond 2-3 nucleotides, this blocks transcription.

Originally defined simply by its ability to incorporate nucleotides into RNA under the direction of a DNA template, the enzyme RNA polymerase now is seen as part of a more complex apparatus involved in transcription. *The ability to catalyze RNA synthesis defines the minimum component that can be described as RNA polymerase.* It supervises the base pairing of the substrate ribonucleotides with DNA and catalyzes the formation of phosphodiester bonds between them.

All of the subunits of the basic polymerase that participate in elongation are necessary for initiation and termination. But transcription units differ in their dependence on additional polypeptides at the initiation and termination stages. Some of these additional polypeptides are needed at all genes, but others may be needed specifically for initiation or termination at particular genes. The analogy with the division of labors between the ribosome and the protein synthesis factors is obvious.

*E. coli* RNA polymerase can transcribe any one of many ( $>1000$ ) transcription units. The enzyme therefore requires the ability to interact with a variety of host and phage functions that modify its intrinsic transcriptional activities. The complexity of the enzyme therefore at least in part reflects its need to interact with regulatory factors, rather than any demand inherent in its catalytic activity (for review see 76).

**TRANSCRIPTION****3.9.7 RNA polymerase consists of the core enzyme and sigma factor**

---

**Key Terms**

The **core enzyme** is the complex of RNA polymerase subunits that undertakes elongation. It does not include additional subunits or factors that may be needed for initiation or termination.

**Sigma factor** is the subunit of bacterial RNA polymerase needed for initiation; it is the major influence on selection of promoters.

A **loose binding site** is any random sequence of DNA that is bound by the core RNA polymerase when it is not engaged in transcription.

**Key Concepts**

- Bacterial RNA polymerase can be divided into the  $\alpha_2 \beta \beta'$  core enzyme that catalyzes transcription and the sigma subunit that is required only for initiation.
- Sigma factor changes the DNA-binding properties of RNA polymerase so that its affinity for general DNA is reduced and its affinity for promoters is increased.
- Binding constants of RNA polymerase for different promoters vary over 6 orders of magnitude, corresponding to the frequency with which transcription is initiated at each promoter.

---

The holoenzyme ( $\alpha_2 \beta \beta' \sigma$ ) can be separated into two components, the **core enzyme** ( $\alpha_2 \beta \beta'$ ) and the **sigma factor** (the  $\sigma$  polypeptide). *Only the holoenzyme can initiate transcription. Sigma factor ensures that bacterial RNA polymerase binds in a stable manner to DNA only at promoters.* The sigma "factor" is usually released when the RNA chain reaches 8-9 bases, leaving the core enzyme to undertake elongation. *Core enzyme has the ability to synthesize RNA on a DNA template, but cannot initiate transcription at the proper sites* (496).

The core enzyme has a general affinity for DNA, in which electrostatic attraction between the basic protein and the acidic nucleic acid plays a major role. Any (random) sequence of DNA that is bound by core polymerase in this general binding reaction is described as a **loose binding site**. No change occurs in the DNA, which remains duplex. The complex at such a site is stable, with a half-life for dissociation of the enzyme from DNA ~60 minutes. *Core enzyme does not distinguish between promoters and other sequences of DNA.*

**Figure 9.18** shows that sigma factor introduces a major change in the affinity of RNA polymerase for DNA. *The holoenzyme has a drastically reduced ability to recognize loose binding sites* – that is, to bind to any general sequence of DNA. The association constant for the reaction is reduced by a factor of  $\sim 10^4$ , and the half-life of the complex is  $< 1$  second. So sigma factor destabilizes the general binding ability very considerably.

**Figure 9.18** Core enzyme binds indiscriminately to any DNA. Sigma factor reduces the affinity for sequence-independent binding, and confers specificity for promoters.

But sigma factor also *confers the ability to recognize specific binding sites*. The holoenzyme binds to promoters very tightly, with an association constant increased from that of core enzyme by (on average) 1000 times and with a half-life of several hours.

The specificity of holoenzyme for promoters compared to other sequences is  $\sim 10^7$ , but this is only an average, because there is wide variation in the rate at which the holoenzyme binds to different promoter sequences. This is an important parameter in determining the efficiency of an individual promoter in initiating transcription. The binding constants range from  $\sim 10^{12}$  to  $\sim 10^6$ . Other factors also affect the frequency of initiation, which varies from  $\sim 1/\text{sec}$  (rRNA genes) to  $\sim 1/30 \text{ min}$  (the *lacI* promoter).

## TRANSCRIPTION

### 3.9.8 The association with sigma factor changes at initiation

---

#### Key Terms

An **open complex** describes the stage of initiation of transcription when RNA polymerase causes the two strands of DNA to separate to form the "transcription bubble".

**Tight binding** of RNA polymerase to DNA describes the formation of an open complex (when the strands of DNA have separated).

The **ternary complex** in initiation of transcription consists of RNA polymerase and DNA and a dinucleotide that represents the first two bases in the RNA product.

**Abortive initiation** describes a process in which RNA polymerase starts transcription but terminates before it has left the promoter. It then reinitiates. Several cycles may occur before the elongation stage begins.

#### Key Concepts

- When RNA polymerase binds to a promoter, it separates the DNA strands to form a transcription bubble and incorporates up to 9 nucleotides into RNA.
  - There may be a cycle of abortive initiations before the enzyme moves to the next phase.
  - Sigma factor may be released from RNA polymerase when the nascent RNA chain reaches 8-9 bases in length.
- 

We can now describe the stages of transcription in terms of the interactions between different forms of RNA polymerase and the DNA template. The initiation reaction can be described by the parameters that are summarized in **Figure 9.19**:

**Figure 9.19** RNA polymerase passes through several steps prior to elongation. A closed binary complex is converted to an open form and then into a ternary complex.

- The holoenzyme-promoter reaction starts by forming a closed binary complex. "Closed" means that the DNA remains duplex. Because the formation of the closed binary complex is reversible, it is usually described by an equilibrium constant ( $K_B$ ). There is a wide range in values of the equilibrium constant for forming the closed complex.
- The closed complex is converted into an **open complex** by "melting" of a short region of DNA within the sequence bound by the enzyme. The series of events leading to formation of an open complex is called **tight binding**. For strong promoters, conversion into an open binary complex is irreversible, so this reaction is described by a rate constant ( $k_2$ ). This reaction is fast. Sigma factor is involved in the melting reaction (see *Molecular Biology 3.9.16 Substitution of sigma factors may control initiation*).
- The next step is to incorporate the first two nucleotides; then a phosphodiester bond forms between them. This generates a **ternary complex** that contains RNA as well as DNA and enzyme. Formation of the ternary complex is described by the rate constant  $k_1$ ; this is even faster than the rate constant  $k_2$ . Further

nucleotides can be added without any enzyme movement to generate an RNA chain of up to 9 bases. After each base is added, there is a certain probability that the enzyme will release the chain. This comprises an **abortive initiation**, after which the enzyme begins again with the first base. A cycle of abortive initiations usually occurs to generate a series of very short oligonucleotides.

- When initiation succeeds, sigma is no longer necessary, and the enzyme makes the transition to the elongation ternary complex of core polymerase·DNA·nascent RNA. The critical parameter here is *how long it takes for the polymerase to leave the promoter so another polymerase can initiate*. This parameter is the promoter clearance time; its minimum value of 1-2 sec establishes the maximum frequency of initiation as <1 event per second. The enzyme then moves along the template, and the RNA chain extends beyond 10 bases.

When RNA polymerase binds to DNA, the elongated dimension of the protein extends along the DNA, but some interesting changes in shape occur during transcription. Transitions in shape and size identify three forms of the complex, as illustrated in **Figure 9.20** (501):

**Figure 9.20** RNA polymerase initially contacts the region from -55 to +20. When sigma dissociates, the core enzyme contracts to -30; when the enzyme moves a few base pairs, it becomes more compactly organized into the general elongation complex.

- When RNA polymerase holoenzyme initially binds to DNA, it covers some 75-80 bp, extending from -55 to +20. (The long dimension of RNA polymerase (160 Å) could cover ~50 bp of DNA in extended form, which implies that binding of a longer stretch of DNA must involve some bending of the nucleic acid.)
- The shape of the RNA polymerase changes at the transition from initiation to elongation. This is associated with the loss of contacts in the -55 to -35 region, leaving only ~60 bp of DNA covered by the enzyme. This corresponds with the concept that the more upstream part of the promoter is involved in initial recognition by RNA polymerase, but is not required for the later stages of initiation (*Molecular Biology 3.9.13 Promoter efficiencies can be increased or decreased by mutation*).

- When the RNA chain extends to 15-20 bases, the enzyme makes a further transition, to form the complex that undertakes elongation; now it covers 30-40 bp (depending on the stage in the elongation cycle).

It has been a tenet of transcription since soon after the discovery of sigma factor that it is released after initiation. However, this may not be strictly true. Direct measurements of elongating RNA polymerase complexes show that ~70% of them retain sigma factor (2003; 2004). Since a third of elongating polymerases lack sigma, the original conclusion is certainly correct that it is not necessary for elongation. In those cases where it remains associated with core enzyme, the nature of the association has almost certainly changed (see *Molecular Biology 3.9.11 Sigma factor controls binding to DNA*).

**TRANSCRIPTION****3.9.9 A stalled RNA polymerase can restart**

---

**Key Concepts**

- An arrested RNA polymerase can restart transcription by cleaving the RNA transcript to generate a new 3' end.
- 

RNA polymerase must be able to handle situations when transcription is blocked. This can happen, for example, when DNA is damaged. A model system for such situations is provided by arresting elongation *in vitro* by omitting one of the necessary precursor nucleotides. When the missing nucleotide is restored, the enzyme can overcome the block by cleaving the 3' end of the RNA, to create a new 3' terminus for chain elongation. The cleavage involves accessory factors in addition to the enzyme itself. In the case of *E. coli* RNA polymerase, the proteins GreA and GreB release the RNA polymerase from elongation arrest. In eukaryotic cells, RNA polymerase II requires an accessory factor (TF<sub>II</sub>S), which enables the polymerase to cleave a few ribonucleotides from the 3' terminus of the RNA product.

The catalytic site of RNA polymerase undertakes the actual cleavage in each case. The roles of GreB and TF<sub>II</sub>S are to convert the enzyme's catalytic site into a ribonucleolytic site. Although there is no sequence homology between the factors, crystal structures of their complexes with the respective RNA polymerases suggest that they function in a similar way (4187; 4188). Each of the factors inserts a narrow protein domain (in one case a zinc ribbon, in the other a coiled coil) deep into RNA polymerase, where it terminates within the catalytic site. The inserted domain positions two acidic amino acids close to the primary catalytic magnesium ion of the active site; this allows the introduction of a second magnesium ion, which converts the catalytic site to a ribonucleolytic site.

The reason for this reaction may be that stalling causes the template to be mispositioned, so that the 3' terminus is no longer located in the active site. Cleavage and backtracking is necessary to place the terminus in the right location for addition of further bases.

We see therefore that RNA polymerase has the facility to unwind and rewind DNA, to hold the separated strands of DNA and the RNA product, to catalyze the addition of ribonucleotides to the growing RNA chain, and to adjust to difficulties in progressing by cleaving the RNA product and restarting RNA synthesis (with the assistance of some accessory factors).

## TRANSCRIPTION

### 3.9.10 How does RNA polymerase find promoter sequences?

#### Key Concepts

- The rate at which RNA polymerase binds to promoters is too fast to be accounted for by random diffusion.
- RNA polymerase probably binds to random sites on DNA and exchanges them with other sequences very rapidly until a promoter is found.

How is RNA polymerase distributed in the cell? A (somewhat speculative) picture of the enzyme's situation is depicted in **Figure 9.21**:

**Figure 9.21** Core enzyme and holoenzyme are distributed on DNA, and very little RNA polymerase is free.

- Excess core enzyme exists largely as closed loose complexes, because the enzyme enters into them rapidly and leaves them slowly. There is very little, if any, free core enzyme.

- There is enough sigma factor for about one third of the polymerases to exist as holoenzymes, and they are distributed between loose complexes at nonspecific sites and binary complexes (mostly closed) at promoters.
- About half of the RNA polymerases consist of core enzymes engaged in transcription.
- How much holoenzyme is free? We do not know, but we suspect that the amount is very small.

RNA polymerase must find promoters within the context of the genome. Suppose that a promoter is a stretch of ~60 bp; how is it distinguished from the  $4 \times 10^6$  bp that comprise the *E. coli* genome? The next three figures illustrate the principle of some possible models.

**Figure 9.22** shows the simplest model for promoter binding, in which RNA polymerase moves by random diffusion. Holoenzyme very rapidly associates with, and dissociates from, loose binding sites. So it could continue to make and break a series of closed complexes until (by chance) it encounters a promoter. Then its recognition of the specific sequence would allow tight binding to occur by formation of an open complex.

**Figure 9.22** The forward rate constant for RNA polymerase binding to promoters is faster than random diffusion.

For RNA polymerase to move from one binding site on DNA to another, it must dissociate from the first site, find the second site, and then associate with it. Movement from one site to another is limited by the speed of diffusion through the medium. Diffusion sets an upper limit for the rate constant for associating with a 60 bp target of  $<10^8 \text{ M}^{-1} \text{ sec}^{-1}$ . But the actual forward rate constant for some promoters *in vitro* appears to be  $\sim 10^8 \text{ M}^{-1} \text{ sec}^{-1}$ , at or above the diffusion limit. If this value applies *in vivo*, the time required for random cycles of successive association and dissociation at loose binding sites is too great to account for the way RNA polymerase finds its promoter.

RNA polymerase must therefore use some other means to seek its binding sites. **Figure 9.23** shows that the process could be speeded up if the initial target for RNA polymerase is the whole genome, not just a specific promoter sequence. By increasing the target size, the rate constant for diffusion to DNA is correspondingly

increased, and is no longer limiting.

**Figure 9.23** RNA polymerase binds very rapidly to random DNA sequences and could find a promoter by direct displacement of the bound DNA sequence.

If this idea is correct, a free RNA polymerase binds DNA and then remains in contact with it. How does the enzyme move from a random (loose) binding site on DNA to a promoter? The most likely model is to suppose that the bound sequence is directly displaced by another sequence. Having taken hold of DNA, the enzyme exchanges this sequence with another sequence very rapidly, and continues to exchange sequences until a promoter is found. Then the enzyme forms a stable, open complex, after which initiation occurs. The search process becomes much faster because association and dissociation are virtually simultaneous, and time is not spent commuting between sites. Direct displacement can give a "directed walk," in which the enzyme moves preferentially from a weak site to a stronger site.

Another idea supposes that the enzyme slides along the DNA by a one-dimensional random walk, as shown in **Figure 9.24**, being halted only when it encounters a promoter. However, there is no evidence that RNA polymerase (or other DNA-binding proteins) can function in this manner.

**Figure 9.24** RNA polymerase does not slide along DNA.

**TRANSCRIPTION****3.9.11 Sigma factor controls binding to DNA**

---

**Key Concepts**

- A change in association between sigma and holoenzyme changes binding affinity for DNA so that core enzyme can move along DNA.
- 

RNA polymerase encounters a dilemma in reconciling its needs for initiation with those for elongation. Initiation requires tight binding *only* to particular sequences (promoters), while elongation requires close association with *all* sequences that the enzyme encounters during transcription. **Figure 9.25** illustrates how the dilemma is solved by the reversible association between sigma factor and core enzyme. As mentioned previously (see *Molecular Biology 3.9.8 The association with sigma factor changes at initiation*), sigma factor is either released following initiation or changes its association with core enzyme so that it no longer participates in DNA binding (2003; 2004). Because there are fewer molecules of sigma than of core enzyme, the utilization of core enzyme requires that sigma recycles. This occurs immediately after initiation (as shown in the figure) in about one third of cases; presumably sigma and core dissociate at some later point in the other cases.

**Figure 9.25** Sigma factor and core enzyme recycle at different points in transcription.

Irrespective of the exact timing of its release from core enzyme, sigma factor is involved only in initiation. It becomes unnecessary when abortive initiation is concluded and RNA synthesis has been successfully initiated. We do not know whether the state of polymerase changes as a consequence of overcoming abortive initiation, or whether instead it is the change in state that ends abortive initiation and allows elongation to commence.

When sigma factor is released from core enzyme, it becomes immediately available for use by another core enzyme. Whether sigma is released or remains more loosely associated with core enzyme, the core enzyme in the ternary complex is bound very tightly to DNA. It is essentially "locked in" until elongation has been completed. When transcription terminates, the core enzyme is released. It is then "stored" by binding to a loose site on DNA. If it has lost its sigma factor, it must find another sigma factor in order to undertake a further cycle of transcription.

Core enzyme has a high intrinsic affinity for DNA, which is increased by the presence of nascent RNA. But its affinity for loose binding sites is too high to allow the enzyme to distinguish promoters efficiently from other sequences. By reducing the stability of the loose complexes, sigma allows the process to occur much more rapidly; and by stabilizing the association at tight binding sites, the factor drives the reaction irreversibly into the formation of open complexes. When the enzyme releases sigma (or changes its association with it), it reverts to a general affinity for all DNA, irrespective of sequence, that suits it to continue transcription.

What is responsible for the ability of holoenzyme to bind specifically to promoters? Sigma factor has domains that recognize the promoter DNA. As an independent polypeptide, sigma does not bind to DNA, but when holoenzyme forms a tight binding complex,  $\sigma$  contacts the DNA in the region upstream of the startpoint. This difference is due to a change in the conformation of sigma factor when it binds to core enzyme. The N-terminal region of free sigma factor suppresses the activity of the DNA-binding region; when sigma binds to core, this inhibition is released, and it becomes able to bind specifically to promoter sequences (see also **Figure 9.35** later). The inability of free sigma factor to recognize promoter sequences may be important: if  $\sigma$  could freely bind to promoters, it might block holoenzyme from initiating transcription.

## TRANSCRIPTION

### 3.9.12 Promoter recognition depends on consensus sequences

---

#### Key Terms

**Conserved** positions are defined when many examples of a particular nucleic acid or protein are compared and the same individual bases or amino acids are always found at particular locations.

A **consensus sequence** is an idealized sequence in which each position represents the base most often found when many actual sequences are compared.

The **-10 sequence** is the consensus sequence centered about 10 bp before the startpoint of a bacterial gene. It is involved in melting DNA during the initiation reaction.

The **-35 sequence** is the consensus sequence centered about 35 bp before the startpoint of a bacterial gene. It is involved in initial recognition by RNA polymerase.

#### Key Concepts

- A promoter is defined by the presence of short consensus sequences at specific locations.
- The promoter consensus sequences consist of a purine at the startpoint, the hexamer TATAAT centered at -10, and another hexamer centered at -35.
- Individual promoters usually differ from the consensus at one or more positions.

---

As a sequence of DNA whose function is to be *recognized by proteins*, a promoter differs from sequences whose role is to be transcribed or translated. The information for promoter function is provided directly by the DNA sequence: its structure is the signal. This is a classic example of a *cis*-acting site, as defined previously in **Figure 1.40** and **Figure 1.41**. By contrast, expressed regions gain their meaning only after the information is transferred into the form of some other nucleic acid or protein.

A key question in examining the interaction between an RNA polymerase and its promoter is how the protein recognizes a specific promoter sequence. Does the enzyme have an active site that distinguishes the chemical structure of a particular sequence of bases in the DNA double helix? How specific are its requirements?

One way to design a promoter would be for a particular sequence of DNA to be recognized by RNA polymerase. Every promoter would consist of, or at least include, this sequence. In the bacterial genome, the minimum length that could provide an adequate signal is 12 bp. (Any shorter sequence is likely to occur – just by chance – a sufficient number of additional times to provide false signals. The minimum length required for unique recognition increases with the size of genome.) The 12 bp sequence need not be contiguous. If a specific number of base pairs

separates two constant shorter sequences, their combined length could be less than 12 bp, since the *distance* of separation itself provides a part of the signal (even if the intermediate *sequence* is itself irrelevant).

Attempts to identify the features in DNA that are necessary for RNA polymerase binding started by comparing the sequences of different promoters. Any essential nucleotide sequence should be present in all the promoters. Such a sequence is said to be **conserved**. However, a conserved sequence need not necessarily be conserved at every single position; some variation is permitted. How do we analyze a sequence of DNA to determine whether it is sufficiently conserved to constitute a recognizable signal?

Putative DNA recognition sites can be defined in terms of an idealized sequence that represents the base most often present at each position. A **consensus sequence** is defined by aligning all known examples so as to maximize their homology. For a sequence to be accepted as a consensus, each particular base must be reasonably predominant at its position, and most of the actual examples must be related to the consensus by rather few substitutions, say, no more than 1-2.

The striking feature in the sequence of promoters in *E. coli* is the *lack of any extensive conservation of sequence* over the 60 bp associated with RNA polymerase. The sequence of much of the binding site is irrelevant. But some short stretches within the promoter are conserved, and they are critical for its function. *Conservation of only very short consensus sequences is a typical feature of regulatory sites (such as promoters) in both prokaryotic and eukaryotic genomes.*

There are four (perhaps five) conserved features in a bacterial promoter: the startpoint; the -10 sequence; the -35 sequence; the separation between the -10 and -35 sequences; and (sometimes) the UP element (for review see 2560):

- The startpoint is usually (>90% of the time) a purine. It is common for the startpoint to be the central base in the sequence CAT, but the conservation of this triplet is not great enough to regard it as an obligatory signal.
- Just upstream of the startpoint, a 6 bp region is recognizable in almost all promoters. The center of the hexamer generally is close to 10 bp upstream of the startpoint; the distance varies in known promoters from position -18 to -9. Named for its location, the hexamer is often called the **-10 sequence**. Its consensus is *TATAAT*, and can be summarized in the form

T<sub>80</sub> A<sub>95</sub> T<sub>45</sub> A<sub>60</sub> A<sub>50</sub> T<sub>96</sub>

where the subscript denotes the percent occurrence of the most frequently found base, varying from 45-96%. (A position at which there is no discernible preference for any base would be indicated by N.) If the frequency of occurrence indicates likely importance in binding RNA polymerase, we would expect the initial highly conserved TA and the final almost completely conserved T in the -10 sequence to be the most important bases.

- Another conserved hexamer is centered ~35 bp upstream of the startpoint. This is called the **-35 sequence**. The consensus is *TTGACA*; in more detailed form, the conservation is

T<sub>82</sub> T<sub>84</sub> G<sub>78</sub> A<sub>65</sub> C<sub>54</sub> A<sub>45</sub>

- The distance separating the -35 and -10 sites is between 16-18 bp in 90% of promoters; in the exceptions, it is as little as 15 or as great as 20 bp. *Although the actual sequence in the intervening region is unimportant, the distance is critical in holding the two sites at the appropriate separation for the geometry of RNA polymerase.*
- Some promoters have an A-T-rich sequence located farther upstream. This is called the UP element (2559). It interacts with the  $\alpha$  subunit of the RNA polymerase. It is typically found in promoters that are highly expressed, such as the promoters for rRNA genes.

The optimal promoter is a sequence consisting of the -35 hexamer, separated by 17 bp from the -10 hexamer, lying 7 bp upstream of the startpoint. The structure of a promoter, showing the permitted range of variation from this optimum, is illustrated in **Figure 9.26**.

**Figure 9.26** A typical promoter has three components, consisting of consensus sequences at -35 and -10, and the startpoint.

## TRANSCRIPTION

### 3.9.13 Promoter efficiencies can be increased or decreased by mutation

---

#### Key Terms

A **down mutation** in a promoter decreases the rate of transcription.

An **up mutation** in a promoter increases the rate of transcription.

#### Key Concepts

- Down mutations to decrease promoter efficiency usually decrease conformance to the consensus sequences, whereas up mutations have the opposite effect.
- Mutations in the  $-35$  sequence usually affect initial binding of RNA polymerase.
- Mutations in the  $-10$  sequence usually affect the melting reaction that converts a closed to an open complex.

---

Mutations are a major source of information about promoter function. Mutations in promoters affect the level of expression of the gene(s) they control, without altering the gene products themselves. Most are identified as bacterial mutants that have lost, or have very much reduced, transcription of the adjacent genes. They are known as **down mutations**. Less often, mutants are found in which there is increased transcription from the promoter. They have **up mutations**.

It is important to remember that "up" and "down" mutations are defined relative to the *usual* efficiency with which a particular promoter functions. This varies widely. So a change that is recognized as a down mutation in one promoter might never have been isolated in another (which in its wild-type state could be even less efficient than the mutant form of the first promoter). Information gained from studies *in vivo* simply identifies the overall direction of the change caused by mutation.

Is the most effective promoter one that has the actual consensus sequences? This expectation is borne out by the simple rule that up mutations usually increase homology with one of the consensus sequences or bring the distance between them closer to 17 bp. Down mutations usually decrease the resemblance of either site with the consensus or make the distance between them more distant from 17 bp. Down mutations tend to be concentrated in the most highly conserved positions, which confirms their particular importance as the main determinant of promoter efficiency (for review see 2560). However, there are occasional exceptions to these rules.

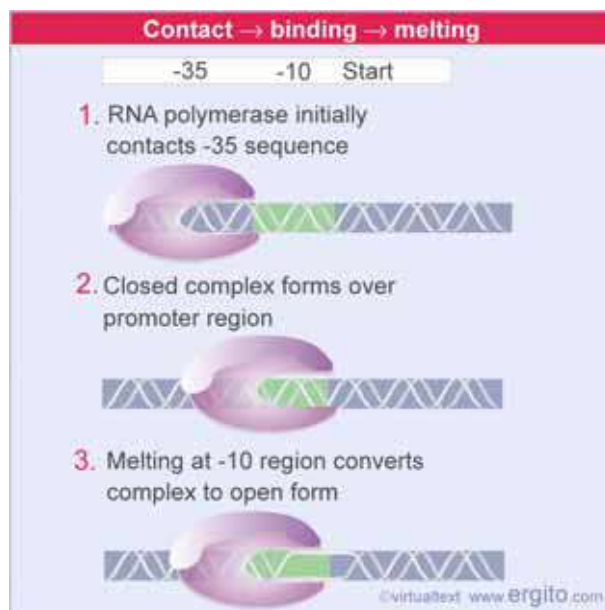

To determine the absolute effects of promoter mutations, we must measure the affinity of RNA polymerase for wild-type and mutant promoters *in vitro*. There is ~100-fold variation in the rate at which RNA polymerase binds to different promoters *in vitro*, which correlates well with the frequencies of transcription when their genes are expressed *in vivo*. Taking this analysis further, we can investigate the stage at which a mutation influences the capacity of the promoter. Does it change the

affinity of the promoter for binding RNA polymerase? Does it leave the enzyme able to bind but unable to initiate? Is the influence of an ancillary factor altered?

By measuring the kinetic constants for formation of a closed complex and its conversion to an open complex, as defined in **Figure 9.19**, we can dissect the two stages of the initiation reaction:

- Down mutations in the  $-35$  sequence reduce the rate of closed complex formation (they reduce  $K_B$ ), but do not inhibit the conversion to an open complex.
- Down mutations in the  $-10$  sequence do not affect the initial formation of a closed complex, but they slow its conversion to the open form (they reduce  $k_2$ ).

These results suggest the model shown in **Figure 9.27**. The function of the  $-35$  sequence is to provide the signal for recognition by RNA polymerase, while the  $-10$  sequence allows the complex to convert from closed to open form. We might view the  $-35$  sequence as comprising a "recognition domain," while the  $-10$  sequence comprises an "unwinding domain" of the promoter.

**Figure 9.27** The  $-35$  sequence is used for initial recognition, and the  $-10$  sequence is used for the melting reaction that converts a closed complex to an open complex.

The consensus sequence of the  $-10$  site consists exclusively of A·T base pairs, which assists the initial melting of DNA into single strands. The lower energy needed to disrupt A·T pairs compared with G·C pairs means that a stretch of A·T pairs demands the minimum amount of energy for strand separation.

The sequence immediately around the startpoint influences the initiation event. And the initial transcribed region (from +1 to +30) influences the rate at which RNA

polymerase clears the promoter, and therefore has an effect upon promoter strength. So the overall strength of a promoter cannot be predicted entirely from its  $-35$  and  $-10$  consensus sequences.

A "typical" promoter relies upon its  $-35$  and  $-10$  sequences to be recognized by RNA polymerase, but one or the other of these sequences can be absent from some (exceptional) promoters. In at least some of these cases, the promoter cannot be recognized by RNA polymerase alone, and the reaction requires ancillary proteins, which overcome the deficiency in intrinsic interaction between RNA polymerase and the promoter.

**TRANSCRIPTION****3.9.14 RNA polymerase binds to one face of DNA**

---

**Key Terms**

**Footprinting** is a technique for identifying the site on DNA bound by some protein by virtue of the protection of bonds in this region against attack by nucleases.

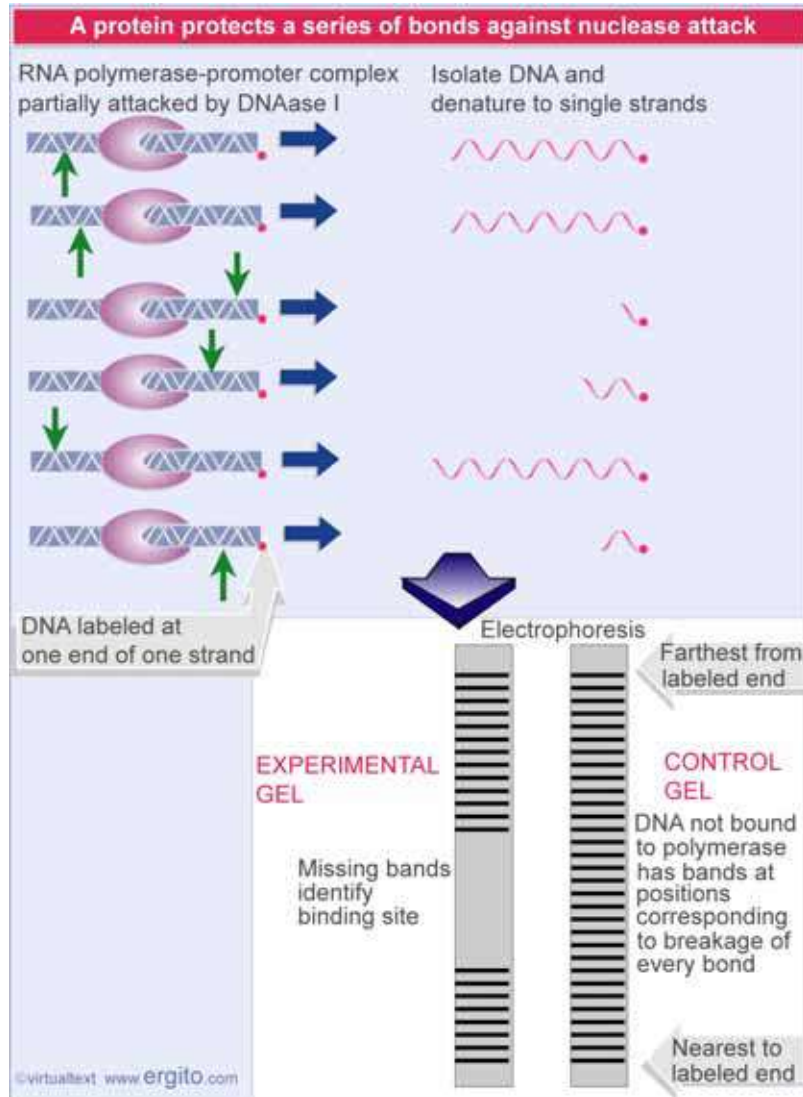

**Key Concepts**

- The consensus sequences at –35 and –10 provide most of the contact points for RNA polymerase in the promoter.
- The points of contact lie on one face of the DNA.

---

The ability of RNA polymerase (or indeed any protein) to recognize DNA can be characterized by **footprinting**. A sequence of DNA bound to the protein is *partially* digested with an endonuclease to attack individual phosphodiester bonds within the nucleic acid. Under appropriate conditions, any particular phosphodiester bond is broken in some, but not in all, DNA molecules. The positions that are cleaved are recognized by using DNA labeled on one strand at one end only. The principle is the same as that involved in DNA sequencing; partial cleavage of an end-labeled molecule at a susceptible site creates a fragment of unique length.

As **Figure 9.28** shows, following the nuclease treatment, the broken DNA fragments are recovered and electrophoresed on a gel that separates them according to length. Each fragment that retains a labeled end produces a radioactive band. The position of the band corresponds to the number of bases in the fragment. The shortest fragments move the fastest, so distance from the labeled end is counted up from the bottom of the gel.

**Figure 9.28** Footprinting identifies DNA-binding sites for proteins by their protection against nicking.

In a free DNA, every susceptible bond position is broken in one or another molecule. But when the DNA is complexed with a protein, the region covered by the DNA-binding protein is protected in every molecule. So two reactions are run in parallel: a control of DNA alone; and an experimental mixture containing molecules of DNA bound to the protein. When a bound protein blocks access of the nuclease to DNA, the bonds in the bound sequence fail to be broken in the experimental mixture.

In the control, every bond is broken, generating a series of bands, one representing each base. There are 31 bands in the figure. In the protected fragment, bonds cannot be broken in the region bound by the protein, so bands representing fragments of the corresponding sizes are not generated. The absence of bands 9-18 in the figure identifies a protein-binding site covering the region located 9-18 bases from the labeled end of the DNA. By comparing the control and experimental lanes with a sequencing reaction that is run in parallel it becomes possible to "read off" the

corresponding sequence directly, thus identifying the nucleotide sequence of the binding site.

As described previously (see **Figure 9.20**), RNA polymerase initially binds the region from  $-50$  to  $+20$ . The points at which RNA polymerase actually contacts the promoter can be identified by modifying the footprinting technique to treat RNA polymerase-promoter complexes with reagents that modify particular bases. We can perform the experiment in two ways:

- The DNA can be modified before it is bound to RNA polymerase. If the modification prevents RNA polymerase from binding, we have identified a base position where contact is essential.
- The RNA polymerase-DNA complex can be modified. Then we compare the pattern of protected bands with that of free DNA and the unmodified complex. Some bands disappear, identifying sites at which the enzyme has protected the promoter against modification. Other bands increase in intensity, identifying sites at which the DNA must be held in a conformation in which it is more exposed.

These changes in sensitivity reveal the geometry of the complex, as summarized in **Figure 9.29** for a typical promoter. The regions at  $-35$  and  $-10$  contain most of the contact points for the enzyme. Within these regions, the same sets of positions tend both to prevent binding if previously modified, and to show increased or decreased susceptibility to modification after binding. Although the points of contact do not coincide completely with sites of mutation, they occur in the same limited region.

**Figure 9.29** One face of the promoter contains the contact points for RNA.

It is noteworthy that the same *positions* in different promoters provide the contact points, even though a different base is present. This indicates that there is a common

mechanism for RNA polymerase binding, although the reaction does not depend on the presence of particular bases at some of the points of contact. This model explains why some of the points of contact are not sites of mutation. Also, not every mutation lies in a point of contact; they may influence the neighborhood without actually being touched by the enzyme (500).

It is especially significant that the experiments with prior modification identify *only* sites in the same region that is protected by the enzyme against subsequent modification. These two experiments measure different things. Prior modification identifies all those sites that the enzyme must recognize in order to bind to DNA. Protection experiments recognize all those sites that actually make contact in the binary complex. The protected sites include all the recognition sites and also some additional positions, which suggests that the enzyme first recognizes a set of bases necessary for it to "touch down," and then extends its points of contact to additional bases.

The region of DNA that is unwound in the binary complex can be identified directly by chemical changes in its availability. When the strands of DNA are separated, the unpaired bases become susceptible to reagents that cannot reach them in the double helix. Such experiments implicate positions between  $-9$  and  $+3$  in the initial melting reaction. The region unwound during initiation therefore includes the right end of the  $-10$  sequence and extends just past the startpoint.

Viewed in three dimensions, the points of contact upstream of the  $-10$  sequence all lie on one face of DNA. This can be seen in the lower drawing in **Figure 9.29**, in which the contact points are marked on a double helix viewed from one side. Most lie on the coding strand. These bases are probably recognized in the initial formation of a closed binary complex. This would make it possible for RNA polymerase to approach DNA from one side and recognize that face of the DNA. As DNA unwinding commences, further sites that originally lay on the other face of DNA can be recognized and bound.

## TRANSCRIPTION

### 3.9.15 Supercoiling is an important feature of transcription

---

#### Key Concepts

- Negative supercoiling increases the efficiency of some promoters by assisting the melting reaction.
  - Transcription generates positive supercoils ahead of the enzyme and negative supercoils behind it, and these must be removed by gyrase and topoisomerase.
- 

The importance of strand separation in the initiation reaction is emphasized by the effects of supercoiling. Both prokaryotic and eukaryotic RNA polymerases can initiate transcription more efficiently *in vitro* when the template is supercoiled, presumably because the supercoiled structure requires less free energy for the initial melting of DNA in the initiation complex.

The efficiency of some promoters is influenced by the degree of supercoiling. The most common relationship is for transcription to be aided by negative supercoiling. We understand in principle how this assists the initiation reaction. But why should some promoters be influenced by the extent of supercoiling while others are not? One possibility is that the dependence of a promoter on supercoiling is determined by its sequence. This would predict that some promoters have sequences that are easier to melt (and are therefore less dependent on supercoiling), while others have more difficult sequences (and have a greater need to be supercoiled). An alternative is that the location of the promoter might be important if different regions of the bacterial chromosome have different degrees of supercoiling.

Supercoiling also has a continuing involvement with transcription. As RNA polymerase transcribes DNA, unwinding and rewinding occurs, as illustrated in **Figure 9.4**. This requires that either the entire transcription complex rotates about the DNA or the DNA itself must rotate about its helical axis. The consequences of the rotation of DNA are illustrated in **Figure 9.30** in the *twin domain* model for transcription. As RNA polymerase pushes forward along the double helix, it generates positive supercoils (more tightly wound DNA) ahead and leaves negative supercoils (partially unwound DNA) behind. For each helical turn traversed by RNA polymerase, +1 turn is generated ahead and -1 turn behind (506).

**Figure 9.30** Transcription may generate more tightly wound (positively supercoiled) DNA ahead of RNA polymerase, while the DNA behind becomes less tightly wound (negatively supercoiled).

Transcription therefore has a significant effect on the (local) structure of DNA. As a result, the enzymes gyrase (introduces negative supercoils) and topoisomerase I (removes negative supercoils) are required to rectify the situation in front of and behind the polymerase, respectively. Blocking the activities of gyrase and topoisomerase causes major changes in the supercoiling of DNA. For example, in yeast lacking an enzyme that relaxes negative supercoils, the density of negative supercoiling doubles in a transcribed region. A possible implication of these results is that transcription is responsible for generating a significant proportion of the supercoiling that occurs in the cell.

A similar situation occurs in replication, when DNA must be unwound at a moving replication fork, so that the individual single strands can be used as templates to synthesize daughter strands. Solutions for the topological constraints associated with such reactions are indicated later in **Figure 15.20**.

## TRANSCRIPTION

**3.9.16 Substitution of sigma factors may control initiation****Key Terms**

**Heat shock genes** are a set of loci that are activated in response to an increase in temperature (and other abuses to the cell). They occur in all organisms. They usually include chaperones that act on denatured proteins.

**Key Concepts**

- *E. coli* has several sigma factors, each of which causes RNA polymerase to initiate at a set of promoters defined by specific  $-35$  and  $-10$  sequences.
- $\sigma^{70}$  is used for general transcription, and the other sigma factors are activated by special conditions.

The division of labors between a core enzyme that undertakes chain elongation and a sigma factor involved in site selection immediately raises the question of whether there is more than one type of sigma, each specific for a different class of promoters. **Figure 9.31** shows the principle of a system in which a substitution of the sigma factor changes the choice of promoter.

**Figure 9.31** The sigma factor associated with core enzyme determines the set of promoters where transcription is initiated.

*E. coli* uses alternative sigma factors to respond to general environmental changes.

They are listed in **Figure 9.32**. (They are named either by molecular weight of the product or for the gene.) The general factor, responsible for transcription of most genes under normal conditions, is  $\sigma^{70}$ . The alternative sigma factors  $\sigma^S$ ,  $\sigma^{32}$ ,  $\sigma^E$ , and  $\sigma^{54}$  are activated in response to environmental changes;  $\sigma^{28}$  is used for expression of flagellar genes during normal growth, but its level of expression responds to changes in the environment. All the sigma factors except  $\sigma^{54}$  belong to the same protein family and function in the same general manner.

<i>E. coli</i> has several sigma factors		
Gene	Factor	Use
<i>rpoD</i>	$\sigma^{70}$	general
<i>rpoS</i>	$\sigma^S$	stress
<i>rpoH</i>	$\sigma^{32}$	heat shock
<i>rpoE</i>	$\sigma^E$	heat shock
<i>rpoN</i>	$\sigma^{54}$	nitrogen
<i>fliA</i>	$\sigma^{28}$ ( $\sigma^F$ )	flagellar

**Figure 9.32** In addition to  $\sigma^{70}$ , *E. coli* has several sigma factors that are induced by particular environmental conditions. (A number in the name of a factor indicates its mass.)

Temperature fluctuation is a common type of environmental challenge. Many organisms, both prokaryotic and eukaryotic, respond in a similar way. Upon an increase in temperature, synthesis of the proteins currently being made is turned off or down, and a new set of proteins is synthesized. The new proteins are the products of the **heat shock genes**. They play a role in protecting the cell against environmental stress, and are synthesized in response to other conditions as well as heat shock. Several of the heat shock proteins are chaperones. In *E. coli*, the expression of 17 heat shock proteins is triggered by changes at transcription. The gene *rpoH* is a regulator needed to switch on the heat shock response. Its product is  $\sigma^{32}$ , which functions as an alternative sigma factor that causes transcription of the heat shock genes (499).

The heat shock response is accomplished by increasing the amount of  $\sigma^{32}$  when the temperature increases, and decreasing its activity when the temperature change is reversed. The basic signal that induces production of  $\sigma^{32}$  is the accumulation of unfolded (partially denatured) proteins that results from increase in temperature. The  $\sigma^{32}$  protein is unstable, which is important in allowing its quantity to be increased or decreased rapidly.  $\sigma^{70}$  and  $\sigma^{32}$  can compete for the available core enzyme, so that the set of genes transcribed during heat shock depends on the balance between them.

Changing sigma factors is a serious matter that has widespread implications for gene expression in the bacterium. It is not surprising, therefore, that the production of new sigma factors can be the target of many regulatory circuits. The factor  $\sigma^S$  is induced when bacteria make the transition from growth phase to stationary phase, and also in other stress conditions (for review see 3070). It is controlled at two levels. Translation of the *rpoS* mRNA is increased by low temperature or high osmolarity. Proteolysis of the protein product is inhibited by carbon starvation (the typical signal of stationary phase) and by high temperature.

Another group of heat-regulated genes is controlled by the factor  $\sigma^E$ . It responds to more extreme temperature shifts than  $\sigma^{32}$ , and is induced by accumulation of unfolded proteins in the periplasmic space or outer membrane. It is controlled by the intricate circuit summarized in **Figure 9.33**.  $\sigma^E$  binds to a protein (RseA) that is located in the inner membrane. As a result, it cannot activate transcription. The accumulation of unfolded proteins activates a protease (DegS) in the periplasmic space, which cleaves off the C-terminal end of the RseA protein. This cleavage activates another protein in the inner membrane (YaeL) which cleaves the N-terminal region of RseA (3014; 3010). When this happens, the  $\sigma^E$  factor is released, and can then activate transcription. The net result is that the accumulation of unfolded proteins at the periphery of the bacterium is responsible for activating the set of genes controlled by the sigma factor.

**Figure 9.33** RseA is synthesized as a protein in the inner membrane. Its cytoplasmic domain binds the  $\sigma^E$  factor. RseA is cleaved sequentially in the periplasmic space and then in the cytoplasm. The cytoplasmic cleavage releases  $\sigma^E$ .

This circuit has two interesting parallels with other regulatory circuits. The response to unfolded proteins in eukaryotic cells also uses a pathway in which an unfolded protein (within the endoplasmic reticulum) activates a membrane protein. In this case, the membrane protein is an endonuclease that cleaves an RNA, leading ultimately to a change in splicing that causes the production of a transcription factor (see *Molecular Biology 5.24.17 The unfolded protein response is related to tRNA splicing*). And a more direct parallel is with the first case to be discovered in which cleavage of a membrane protein activates a transcription factor. In this case, the transcription factor itself is synthesized as a membrane protein, and the level of sterols in the membrane controls the activation of proteases that release the transcription factor from the cytosolic domain of the protein (3015).

Another sigma factor is used under conditions of nitrogen starvation. *E. coli* cells contain a small amount of  $\sigma^{54}$ , which is activated when ammonia is absent from the medium. In these conditions, genes are turned on to allow utilization of alternative

nitrogen sources. Counterparts to this sigma factor have been found in a wide range of bacteria, so it represents a response mechanism that has been conserved in evolution.

Another case of evolutionary conservation of sigma factors is presented by the factor  $\sigma^F$ , which is present in small amounts and causes RNA polymerase to transcribe genes involved in chemotaxis and flagellar structure. Its counterpart in *B. subtilis* is  $\sigma_D$ , which controls flagellar and motility genes; factors with the same promoter specificity are present in many species of bacteria.

Each sigma factor causes RNA polymerase to initiate at a particular set of promoters. By analyzing the sequences of these promoters, we can show that each set is identified by unique sequence elements. Indeed, the sequence of each type of promoter ensures that it is recognized only by RNA polymerase directed by the appropriate sigma factor. We can deduce the general rules for promoter recognition from the identification of the genes responding to the sigma factors found in *E. coli* and those involved in sporulation in *B. subtilis* (see *Molecular Biology 3.9.19 Sporulation is controlled by sigma factors*).

A significant feature of the promoters for each enzyme is that *they have the same size and location relative to the startpoint, and they show conserved sequences only around the usual centers of -35 and -10.* ( $\sigma^{54}$  is an exception for which the consensus sequences are closer together, and are positioned at -24 and -12; see *Molecular Biology 3.9.17 Sigma factors directly contact DNA*.) As summarized in **Figure 9.34**, the consensus sequences for each set of promoters are different from one another at either or both of the -35 and -10 positions. This means that an enzyme containing a particular sigma factor can recognize only its own set of promoters, so that transcription of the different groups is mutually exclusive. Substitution of one sigma factor by another therefore turns off transcription of the old set of genes as well as turning on transcription of a new set of genes. (Some genes are expressed by RNA polymerases with different sigma factors because they have more than one promoter, each with a different set of consensus sequences.)

Sigma factors recognize promoters by consensus sequences				
Gene	Factor	-35 Sequence	Separation	-10 Sequence
<i>rpoD</i>	$\sigma^{70}$	TTGACA	16-18 bp	TATAAT
<i>rpoH</i>	$\sigma^{32}$	CCCTTGAA	13-15 bp	CCCGATNT
<i>rpoN</i>	$\sigma^{54}$	CTGGNA	6 bp	TTGCA
<i>fliA</i>	$\sigma^{28} (\sigma^F)$	CTAAA	15 bp	GCCGATAA
<i>sigH</i>	$\sigma^H$	AGGANPuPu	11-12 bp	GCTGAATCA

**TRANSCRIPTION****3.9.17 Sigma factors directly contact DNA**

---

**Key Concepts**

- $\sigma^{70}$  changes its structure to release its DNA-binding regions when it associates with core enzyme.
  - $\sigma^{70}$  binds both the  $-35$  and  $-10$  sequences.
- 

The definition of a series of different consensus sequences recognized at  $-35$  and  $-10$  by holoenzymes containing different sigma factors (see **Figure 9.34**) carries the immediate implication that the sigma subunit must itself contact DNA in these regions. This suggests the general principle that there is a common type of relationship between sigma and core enzyme, in which the sigma factor is positioned in such a way as to make critical contacts with the promoter sequences in the vicinity of  $-35$  and  $-10$ .

Direct evidence that sigma contacts the promoter directly at both the  $-35$  and  $-10$  consensus sequences is provided by mutations in sigma that suppress mutations in the consensus sequences. When a mutation at a particular position in the promoter prevents recognition by RNA polymerase, and a compensating mutation in sigma factor allows the polymerase to use the mutant promoter, the most likely explanation is that the relevant base pair in DNA is contacted by the amino acid that has been substituted.

Comparisons of the sequences of several bacterial sigma factors identify regions that have been conserved. Their locations in *E. coli*  $\sigma^{70}$  are summarized in **Figure 9.35** (503). The crystal structure of a sigma factor fragment from the bacterium *Thermus aquaticus* shows that these regions fold into three independent domains in the protein: domain  $\sigma_2$  contains 1.2-2.4,  $\sigma_3$  contains 3.0-1.3, and  $\sigma_4$  contains 4.1-4.2 (3071).

**Figure 9.35** A map of the *E. coli*  $\sigma^{70}$  factor identifies conserved regions. Regions 2.1 and 2.2 contact core polymerase, 2.3 is required for melting, and 2.4 and 4.2 contact the  $-10$  and  $-35$  promoter elements. The N-terminal region prevents 2.4 and 4.2 from binding to DNA in the absence of core enzyme.

**Figure 9.35** shows that two short parts of regions 2 and 4 (named 2.4 and 4.2) are involved in contacting bases in the  $-10$  and  $-35$  elements, respectively. Both of these regions form short stretches of  $\alpha$ -helix in the protein. Experiments with heteroduplexes show that  $\sigma^{70}$  makes contacts with bases principally on the coding strand, and it continues to hold these contacts after the DNA has been unwound in this region. This suggests that sigma factor could be important in the melting reaction.

The use of  $\alpha$ -helical motifs in proteins to recognize duplex DNA sequences is common (see *Molecular Biology 3.12.12 Repressor uses a helix-turn-helix motif to bind DNA*). Amino acids separated by 3-4 positions lie on the same face of an  $\alpha$ -helix and are therefore in a position to contact adjacent base pairs. **Figure 9.36** shows that amino acids lying along one face of the 2.4 region  $\alpha$ -helix contact the bases at positions  $-12$  to  $-10$  of the  $-10$  promoter sequence.

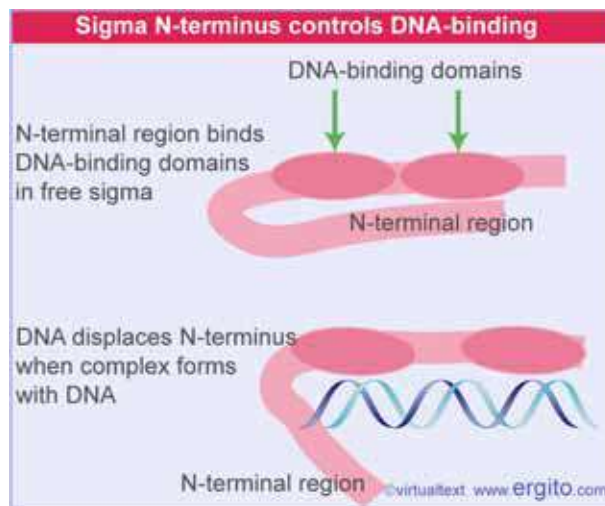

**Figure 9.36** Amino acids in the 2.4  $\alpha$ -helix of  $\sigma^{70}$  contact specific bases in the coding strand of the  $-10$  promoter sequence.

Region 2.3 resembles proteins that bind single-stranded nucleic acids, and is involved in the melting reaction. Regions 2.1 and 2.2 (which is the most highly conserved part of sigma) are involved in the interaction with core enzyme. It is assumed that all sigma factors bind the same regions of the core polymerase (ensuring that the reactions are competitive).

The N-terminal region of  $\sigma^{70}$  has important regulatory functions. If it is removed, the shortened protein becomes able to bind specifically to promoter sequences. This suggests that the N-terminal region behaves as an autoinhibition domain. It occludes the DNA-binding domains when  $\sigma^{70}$  is free. Association with core enzyme changes the conformation of sigma so that the inhibition is released, and the DNA-binding domains can contact DNA.

**Figure 9.37** schematizes the conformational change in sigma at open complex formation. When sigma binds to the core polymerase, the N-terminal domain swings  $\sim 20 \text{ \AA}$  away from the DNA-binding domains, and the DNA-binding domains separate from one another by  $\sim 15 \text{ \AA}$ , presumably to acquire a more elongated conformation appropriate for contacting DNA. Mutations in either the  $-10$  or  $-35$  sequences prevent an (N-terminal-deleted)  $\sigma^{70}$  from binding to DNA, which suggests that  $\sigma^{70}$  contacts both sequences simultaneously. This implies that the sigma factor must have a rather elongated structure, extending over the  $\sim 68 \text{ \AA}$  of two turns of DNA.

**Figure 9.37** The N-terminus of sigma blocks the DNA-binding regions from binding to DNA. When an open complex forms, the N-terminus swings  $20 \text{ \AA}$  away, and the two DNA-binding regions separate by  $15 \text{ \AA}$ .

In the free holoenzyme, the N-terminal domain is located in the active site of the core enzyme components, essentially mimicking the location that DNA will occupy when a transcription complex is formed (2405). When the holoenzyme forms an open complex on DNA, the N-terminal sigma domain is displaced from the active site. Its relationship with the rest of the protein is therefore very flexible, and changes when sigma binds to core enzyme, and again when the holoenzyme binds to DNA.

Comparisons of the crystal structures of the core enzyme and holoenzyme show that

sigma factor lies largely on the surface of the core enzyme (2509). **Figure 9.38** shows that it has an elongated structure that extends past the DNA-binding site. This places it in a position to contact DNA during the initial binding. The DNA helix has to move some 16Å from the initial position in order to enter the active site. **Figure 9.39** illustrates this movement, looking in cross-section down the helical axis of the DNA.

**Figure 9.38** Sigma factor has an elongated structure that extends along the surface of the core subunits when the holoenzyme is formed.

**Figure 9.39** DNA initially contacts sigma factor (pink) and core enzyme (gray). It moves deeper into the core enzyme to make contacts at the -10 sequence. When sigma is released, the width of the passage containing DNA increases.

An interesting difference in behavior is found with the  $\sigma^{54}$  factor. This causes RNA polymerase to recognize promoters that have a distinct consensus sequence, with a conserved element at -12 and another close by at -24 (given in the "-35" column of **Figure 9.32**). So the geometry of the polymerase-promoter complex is different

under the direction of this sigma factor. Another difference in the mechanism of regulation is that high level transcription directed by  $\sigma^{54}$  requires other activators to bind to sites that are quite distant from the promoter. This contrasts with the other types of bacterial promoter, where the regulator sites are always in close proximity to the promoter. The behavior of  $\sigma^{54}$  itself is different from other sigma factors, most notably in its ability to bind to DNA independently of core polymerase. In these regards,  $\sigma^{54}$  is more like the eukaryotic regulators we discuss in *Molecular Biology 5.21 Promoters and enhancers* than the typical prokaryotic regulators discussed in *Molecular Biology 3.10 The operon*.

**TRANSCRIPTION****3.9.18 Sigma factors may be organized into cascades**

---

**Key Terms**

**Early genes** are transcribed before the replication of phage DNA. They code for regulators and other proteins needed for later stages of infection.

**Middle genes** are phage genes that are regulated by the proteins coded by early genes. Some proteins coded by middle genes catalyze replication of the phage DNA; others regulate the expression of a later set of genes.

**Late genes** are transcribed when phage DNA is being replicated. They code for components of the phage particle.

A **cascade** is a sequence of events, each of which is stimulated by the previous one. In transcriptional regulation, as seen in sporulation and phage lytic development, it means that regulation is divided into stages, and at each stage, one of the genes that are expressed codes for a regulator needed to express the genes of the next stage.

**Key Concepts**

- A cascade of sigma factors is created when one sigma factor is required to transcribe the gene coding for the next sigma factor.
- The early genes of phage SPO1 are transcribed by host RNA polymerase.
- One of the early genes codes for a sigma factor that causes RNA polymerase to transcribe the middle genes.
- Two of the middle genes code for subunits of a sigma factor that causes RNA polymerase to transcribe the late genes.

---

Sigma factors are used extensively to control initiation of transcription in the bacterium *B. subtilis*, where ~10 different  $\sigma$  factors are known. Some are present in vegetative cells; other are produced only in the special circumstances of phage infection or the change from vegetative growth to sporulation.

The major RNA polymerase found in *B. subtilis* cells engaged in normal vegetative growth has the same structure as that of *E. coli*,  $\alpha_2 \beta \beta' \sigma$ . Its sigma factor (described as  $\sigma^{43}$  or  $\sigma^A$ ) recognizes promoters with the same consensus sequences used by the *E. coli* enzyme under direction from  $\sigma^{70}$ . Several variants of the RNA polymerase that contain other sigma factors are found in much smaller amounts. The variant enzymes recognize different promoters on the basis of consensus sequences at -35 and -10.

Transitions from expression of one set of genes to expression of another set are a common feature of bacteriophage infection. In all but the very simplest cases, the

development of the phage involves shifts in the pattern of transcription during the infective cycle. These shifts may be accomplished by the synthesis of a phage-encoded RNA polymerase or by the efforts of phage-encoded ancillary factors that control the bacterial RNA polymerase. A well characterized example of control via the production of new sigma factors occurs during infection of *B. subtilis* by phage SPO1.

The infective cycle of SPO1 passes through three stages of gene expression. Immediately on infection, the **early genes** of the phage are transcribed. After 4-5 minutes, the early genes cease transcription and the **middle genes** are transcribed. Then at 8-12 minutes, middle gene transcription is replaced by transcription of **late genes**.

The early genes are transcribed by the holoenzyme of the host bacterium. They are essentially indistinguishable from host genes whose promoters have the intrinsic ability to be recognized by the RNA polymerase  $\alpha_2 \beta \beta' \sigma^{43}$ .

Expression of phage genes is required for the transitions to middle and late gene transcription. Three regulatory genes, named 28, 33, and 34, control the course of transcription. Their functions are summarized in **Figure 9.40**. The pattern of regulation creates a **cascade**, in which the host enzyme transcribes an early gene whose product is needed to transcribe the middle genes; and then two of the middle genes code for products that are needed to transcribe the late genes.

**Figure 9.40** Transcription of phage SPO1 genes is controlled by two successive substitutions of the sigma factor that change the initiation specificity.

Mutants in the early gene 28 cannot transcribe the middle genes. The product of gene 28 (called gp28) is a protein of 26 kD that replaces the host sigma factor on the core enzyme. *This substitution is the sole event required to make the transition from early to middle gene expression.* It creates a holoenzyme that can no longer transcribe the host genes, but instead specifically transcribes the middle genes. We do not know how gp28 displaces  $\sigma^{43}$ , or what happens to the host sigma polypeptide.

Two of the middle genes are involved in the next transition. Mutations in either gene 33 or 34 prevent transcription of the late genes. The products of these genes form a dimer that replaces gp28 on the core polymerase. Again, we do not know how gp33 and gp34 exclude gp28 (or any residual host  $\sigma^{43}$ ), *but once they have bound to the core enzyme, it is able to initiate transcription only at the promoters for late genes.*

The successive replacements of sigma factor have dual consequences. Each time the subunit is changed, the RNA polymerase becomes able to recognize a new class of genes, *and* it no longer recognizes the previous class. These switches therefore constitute global changes in the activity of RNA polymerase. Probably all or virtually all of the core enzyme becomes associated with the sigma factor of the moment; and

the change is irreversible.

**TRANSCRIPTION****3.9.19 Sporulation is controlled by sigma factors**

---

**Key Terms**

**Sporulation** is the generation of a spore by a bacterium (by morphological conversion) or by a yeast (as the product of meiosis).

The **vegetative phase** describes the period of normal growth and division of a bacterium. For a bacterium that can sporulate, this contrasts with the sporulation phase, when spores are being formed.

A **phosphorelay** describes a pathway in which a phosphate group is passed along a series of proteins.

**Key Concepts**

- Sporulation divides a bacterium into a mother cell that is lysed and a spore that is released.
- Each compartment advances to the next stage of development by synthesizing a new sigma factor that displaces the previous sigma factor.
- Communication between the two compartments coordinates the timing of sigma factor substitutions.

---

Perhaps the most extensive example of switches in sigma factors is provided by **sporulation**, an alternative lifestyle available to some bacteria. At the end of the **vegetative phase** in a bacterial culture, logarithmic growth ceases because nutrients in the medium become depleted. This triggers sporulation, as illustrated in **Figure 9.41**. DNA is replicated, a genome is segregated at one end of the cell, and eventually it is surrounded by the tough spore coat. When the septum forms, it generates two independent compartments, the mother cell and the forespore. At the start of the process, one chromosome is attached to each pole of the cell. The growing septum traps part of one chromosome in the forespore, and then a translocase (SpoIIIE) pumps the rest of the chromosome into the forespore.

**Figure 9.41** Sporulation involves the differentiation of a vegetative bacterium into a mother cell that is lysed and a spore that is released.

Sporulation takes ~8 hours. It can be viewed as a primitive sort of differentiation, in which a parent cell (the vegetative bacterium) gives rise to two different daughter cells with distinct fates: the mother cell is eventually lysed, while the spore that is released has an entirely different structure from the original bacterium.

Sporulation involves a drastic change in the biosynthetic activities of the bacterium, in which many genes are involved. The basic level of control lies at transcription. Some of the genes that functioned in the vegetative phase are turned off during sporulation, but most continue to be expressed. In addition, the genes specific for sporulation are expressed only during this period. At the end of sporulation, ~40% of the bacterial mRNA is sporulation-specific.

New forms of the RNA polymerase become active in sporulating cells; they contain the same core enzyme as vegetative cells, but have different proteins in place of the vegetative  $\sigma^{43}$ . The changes in transcriptional specificity are summarized in **Figure 9.42**. The principle is that in each compartment the existing sigma factor is successively displaced by a new factor that causes transcription of a different set of genes. Communication between the compartments occurs in order to coordinate the timing of the changes in the forespore and mother cell (497; 498; for review see 72; 80).

**Figure 9.42** Sporulation involves successive changes in the sigma factors that control the initiation specificity of RNA polymerase. The cascades in the forespore (left) and the mother cell (right) are related by signals passed across the septum (indicated by horizontal arrows).

The sporulation cascade is initiated when environmental conditions trigger a **phosphorelay**, in which a phosphate group is passed along a series of proteins until it reaches SpoOA (see *Molecular Biology Supplement 32.13 Two-component signal transduction*). (Several gene products are involved in this process, whose complexity may reflect the need to avoid mistakes in triggering sporulation unnecessarily.) SpoOA is a transcriptional regulator whose activity is affected by phosphorylation. In the phosphorylated form, it activates transcription of two operons, each of which is transcribed by a different form of the host RNA polymerase. Under the direction of phosphorylated SpoOA, host enzyme utilizing the general  $\sigma^{43}$  transcribes the gene coding for the factor  $\sigma^F$ ; and host enzyme under the direction of a minor factor,  $\sigma^H$ , transcribes the gene coding for the factor pro- $\sigma^E$ . Both of these new sigma factors are produced before septum formation, but become active later.

$\sigma^F$  is the first factor to become active in the forespore compartment. It is inhibited by an anti-sigma factor that binds to it; in the forespore, an anti-anti-sigma factor removes the inhibitor. This reaction is controlled by a series of phosphorylation/dephosphorylation events. The initial determinant is a phosphatase (SpoIIE) that is an integral membrane protein, and which accumulates at the pole, with the result that its phosphatase domain becomes more concentrated in the forespore. It dephosphorylates, and thereby activates, SpoIIAA, which in turn displaces the anti-sigma factor SpoIIB from the complex of SpoIIB- $\sigma^F$ . Release of  $\sigma^F$  activates it.

Activation of  $\sigma^F$  is the start of sporulation. Under the direction of  $\sigma^F$ , RNA polymerase transcribes the first set of sporulation genes instead of the vegetative genes it was previously transcribing. The replacement reaction probably affects only part of the RNA polymerase population, since  $\sigma^F$  is produced only in small amounts. Some vegetative enzyme remains present during sporulation. The displaced  $\sigma^{43}$  is not destroyed, but can be recovered from extracts of sporulating cells.

Two regulatory events follow from the activity of  $\sigma^F$ , as detailed in **Figure 9.43**. In the forespore itself, another factor,  $\sigma^G$ , is the product of one of the early sporulation genes.  $\sigma^G$  is the factor that causes RNA polymerase to transcribe the late sporulation genes in the forespore. Another early sporulation gene product is responsible for communicating with the mother cell compartment.  $\sigma^F$  activates SpoIIR, which is secreted from the forespore. It then activates the membrane-bound protein SpoIIGA to cleave the inactive precursor pro- $\sigma^E$  into the active factor  $\sigma^E$  in the mother cell. (Any  $\sigma^E$  that is produced in the forespore is degraded by forespore-specific functions.)

**Figure 9.43**  $\sigma^F$  triggers synthesis of the next sigma factor in the forespore ( $\sigma^G$ ) and turns on SpoIIIR which causes SpoIIIGA to cleave pro- $\sigma^E$ .

The cascade continues when  $\sigma^E$  in turn is replaced by  $\sigma^K$ . (Actually the production of  $\sigma^K$  is quite complex, because first its gene must be created by a recombination event!) This factor also is synthesized as an inactive precursor (pro- $\sigma^K$ ) that is activated by a protease. Once  $\sigma^K$  has been activated, it displaces  $\sigma^E$  and causes transcription of the late genes in the mother cell. The timing of these events in the two compartments are coordinated by further signals. The activity of  $\sigma^E$  in the mother cell is necessary for activation of  $\sigma^G$  in the forespore; and in turn the activity of  $\sigma^G$  is required to generate a signal that is transmitted across the septum to activate  $\sigma^K$ .

Sporulation is thus controlled by two cascades, in which sigma factors in each compartment are successively activated, each directing the synthesis of a particular set of genes. **Figure 9.44** outlines how the two cascades are connected by the transmission of signals from one compartment to the other. As new sigma factors become active, old sigma factors are displaced, so that transitions in sigma factors turn genes off as well as on. The incorporation of each factor into RNA polymerase dictates when its set of target genes is expressed; and the amount of factor available influences the level of gene expression. More than one sigma factor may be active at any time, and the specificities of some of the sigma factors overlap. We do not know what is responsible for the ability of each sigma factor to replace its predecessor (for review see 77; 78; 81).

**Figure 9.44** The crisscross regulation of sporulation coordinates timing of events in the mother cell and forespore.

**TRANSCRIPTION****3.9.20 Bacterial RNA polymerase terminates at discrete sites**

---

**Key Terms**

A **terminator** is a sequence of DNA that causes RNA polymerase to terminate transcription.

**Antitermination** is a mechanism of transcriptional control in which termination is prevented at a specific terminator site, allowing RNA polymerase to read into the genes beyond it.

**Readthrough** at transcription or translation occurs when RNA polymerase or the ribosome, respectively, ignores a termination signal because of a mutation of the template or the behavior of an accessory factor.

**Key Concepts**

- Termination may require both recognition of the terminator sequence in DNA and the formation of a hairpin structure in the RNA product.

---

Once RNA polymerase has started transcription, the enzyme moves along the template, synthesizing RNA, until it meets a **terminator** (*t*) sequence. At this point, the enzyme stops adding nucleotides to the growing RNA chain, releases the completed product, and dissociates from the DNA template. Termination requires that all hydrogen bonds holding the RNA-DNA hybrid together must be broken, after which the DNA duplex reforms.

It is difficult to define the termination point of an RNA molecule that has been synthesized in the living cell. It is always possible that the 3' end of the molecule has been generated by *cleavage* of the primary transcript, and therefore does not represent the actual site at which RNA polymerase terminated.

The best identification of termination sites is provided by systems in which RNA polymerase terminates *in vitro*. Because the ability of the enzyme to terminate is strongly influenced by parameters such as the ionic strength, its termination at a particular point *in vitro* does not prove that this same point is a natural terminator. But we can identify authentic 3' ends when the same end is generated *in vitro* and *in vivo*.

**Figure 9.45** summarizes the two types of feature found in bacterial terminators.

**Figure 9.45** The DNA sequences required for termination are located prior to the terminator sequence. Formation of a hairpin in the RNA may be necessary.

- Terminators in bacteria and their phages have been identified as sequences that are needed for the termination reaction (*in vitro* or *in vivo*). The sequences at prokaryotic terminators show no similarities beyond the point at which the last base is added to the RNA. The responsibility for termination lies with the *sequences already transcribed* by RNA polymerase. So termination relies on scrutiny of the template or product that the polymerase is currently transcribing (for review see 69; 73; 74).
- Many terminators require a hairpin to form in the secondary structure of the RNA being transcribed. *This indicates that termination depends on the RNA product and is not determined simply by scrutiny of the DNA sequence during transcription.*

Terminators vary widely in their efficiencies of termination. At some terminators, the termination event can be *prevented* by specific ancillary factors that interact with RNA polymerase. **Antitermination** causes the enzyme to continue transcription past the terminator sequence, an event called **readthrough** (the same term used to describe a ribosome's suppression of termination codons).

In approaching the termination event, we must regard it not simply as a mechanism for generating the 3' end of the RNA molecule, but as an opportunity to control gene expression. So the stages when RNA polymerase associates with DNA (initiation) or

dissociates from it (termination) both are subject to specific control. There are interesting parallels between the systems employed in initiation and termination. Both require breaking of hydrogen bonds (initial melting of DNA at initiation, RNA-DNA dissociation at termination); and both require additional proteins to interact with the core enzyme. In fact, they are accomplished by alternative forms of the polymerase. However, whereas initiation relies solely upon the interaction between RNA polymerase and duplex DNA, the termination event involves recognition of signals in the transcript by RNA polymerase or by ancillary factors as well as the recognition of sequences in DNA.

**TRANSCRIPTION****3.9.21 There are two types of terminators in *E. coli***

---

**Key Terms**

**Intrinsic terminators** are able to terminate transcription by bacterial RNA polymerase in the absence of any additional factors.

**Rho-dependent** terminators are sequences that terminate transcription by bacterial RNA polymerase in the presence of the rho factor.

**Rho factor** is a protein involved in assisting *E. coli* RNA polymerase to terminate transcription at certain terminators (called rho-dependent terminators).

**Key Concepts**

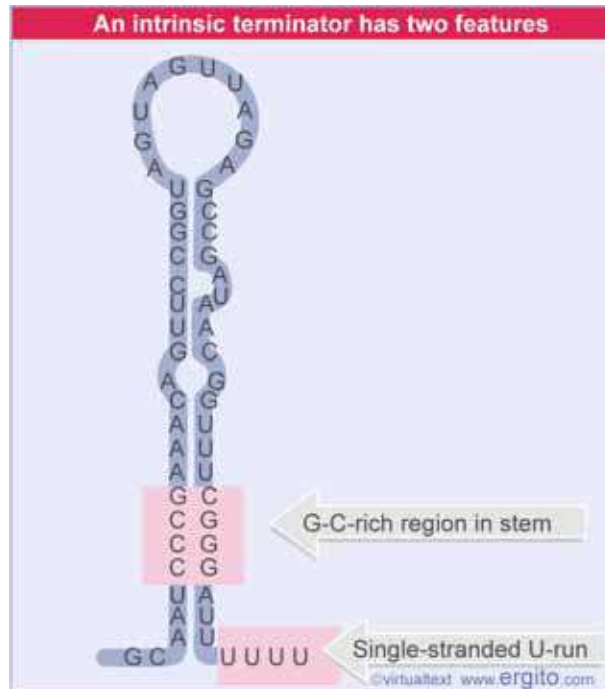

- Intrinsic terminators consist of a G-C-rich hairpin in the RNA product followed by a U-rich region in which termination occurs.

---

Terminators are distinguished in *E. coli* according to whether RNA polymerase requires any additional factors to terminate *in vitro*:

- Core enzyme can terminate *in vitro* at certain sites in the absence of any other factor. These sites are called **intrinsic terminators**.
- **Rho-dependent** terminators are defined by the need for addition of **rho factor** ( $\rho$ ) *in vitro*; and mutations show that the factor is involved in termination *in vivo*.

Intrinsic terminators have the two structural features evident in **Figure 9.46**: a hairpin in the secondary structure; and a region that is rich in U residues at the very end of the unit. Both features are needed for termination. The hairpin usually contains a G-C-rich region near the base of the stem. The typical distance between the hairpin and the U-rich region is 7-9 bases. There are ~1100 sequences in the *E. coli* genome that fit these criteria, suggesting that about half of the genes have intrinsic terminators (2830).

**Figure 9.46** Intrinsic terminators include palindromic regions that form hairpins varying in length from 7-20 bp. The stem-loop structure includes a G-C-rich region and is followed by a run of U residues.

Point mutations that prevent termination occur within the stem region of the hairpin. What is the effect of a hairpin on transcription? Probably all hairpins that form in the RNA product cause the polymerase to slow (and perhaps to pause) in RNA synthesis.

Pausing creates an opportunity for termination to occur. Pausing occurs at sites that resemble terminators but have an increased separation (typically 10-11 bases) between the hairpin and the U-run. But if the pause site does not correspond to a terminator, usually the enzyme moves on again to continue transcription. The length of the pause varies, but at a typical terminator lasts ~60 seconds.

A downstream U-rich region destabilizes the RNA-DNA hybrid when RNA polymerase pauses at the hairpin (for review see 2831). The rU·dA RNA-DNA hybrid has an unusually weak base-paired structure; it requires the least energy of any RNA-DNA hybrid to break the association between the two strands. When the polymerase pauses, the RNA-DNA hybrid unravels from the weakly bonded rU·dA terminal region. Often the actual termination event takes place at any one of several positions toward or at the end of the U-rich region, as though the enzyme "stutters" during termination. The U-rich region in RNA corresponds to an A·T-rich region in DNA, so we see that A·T-rich regions are important in intrinsic termination as well as initiation.

Both the sequence of the hairpin and the length of the U-run influence the efficiency of termination. However, termination efficiency *in vitro* varies from 2-90%, and does not correlate in any simple way with the constitution of the hairpin or the number of U residues in the U-rich region (2833). The hairpin and U-region are therefore

necessary, but not sufficient, and additional parameters influence the interaction with RNA polymerase. In particular, the sequences both upstream and downstream of the intrinsic terminator influence its efficiency (2832).

Less is known about the signals and ancillary factors involved in termination for eukaryotic polymerases. Each class of polymerase uses a different mechanism (see *Molecular Biology 5.24 RNA splicing and processing*).

## TRANSCRIPTION

## 3.9.22 How does rho factor work?

## Key Terms

**Polarity** refers to the effect of a mutation in one gene in influencing the expression (at transcription or translation) of subsequent genes in the same transcription unit.

## Key Concepts

- Rho factor is a terminator protein that binds to a *rut* site on nascent RNA and translocates along the RNA to release it from the RNA-DNA hybrid structure at the RNA polymerase.

Rho factor is an essential protein in *E. coli*. It functions solely at the stage of termination. It is a ~275 kD hexamer of identical subunits (for review see 2836). The subunit has an N-terminal RNA-binding domain and a C-terminal ATP hydrolysis domain. Rho is a member of the family of hexameric ATP-dependent helicases that function by passing nucleic acid through the hole in the middle of the hexamer formed from the RNA-binding domains of the subunits. Rho functions as an ancillary factor for RNA polymerase; typically its maximum activity *in vitro* is displayed when it is present at ~10% of the concentration of the RNA polymerase (507).

Rho-dependent terminators account for about half of *E. coli* terminators. They were discovered in phage genomes, where they have been most fully characterized. The sequences required for rho-dependent termination (sometimes called **rut** sites) are 50-90 bases long and lie upstream of the actual termination site. Their common feature is that the RNA is rich in C residues and poor in G residues. An example is given in **Figure 9.47**; C is by far the most common base (41%) and G is the least common base (14%). As a general rule the efficiency of a *rut* site increases with the length of the C-rich/G-poor region.

**Figure 9.47** A *rut* site has a sequence rich in C and poor in G preceding the actual site(s) of termination. The sequence corresponds to the 3' end of the RNA.

**Figure 9.48** shows that the structure of rho gives some indications of how it functions. It winds RNA from the 3' end around the exterior of the N-terminal domains, and pushes the 5' end of the bound region into the interior, where it is bound by a secondary RNA-binding domain in the C-terminal domains (4189). The

initial form of rho is a gapped ring, but binding of the RNA converts it to a closed ring.

**Figure 9.48** Rho has an N-terminal RNA-binding domain and a C-terminal ATPase domain. A hexamer in the form of a gapped ring binds RNA along the exterior of the N-terminal domains. The 5' end of the RNA is bound by a secondary binding site in the interior of the hexamer.

**Figure 9.49** shows that after binding to the *rut* site, it uses its helicase activity, driven by ATP hydrolysis, to translocate along RNA until it reaches the RNA-DNA hybrid stretch in RNA polymerase. Then it unwinds the duplex structure.(2835, 2834; for review see 2831). We do not know whether this action is sufficient to release the transcript or whether rho also interacts with RNA polymerase to help release RNA (for review see 79).

**Figure 9.49** Rho factor binds to RNA at a *rut* site and translocates along RNA until it reaches the RNA-DNA hybrid in RNA polymerase, where it releases the RNA from the DNA.

Rho needs to translocate along RNA from the *rut* site to the actual point of termination. This requires the factor to move faster than RNA polymerase. The enzyme pauses when it reaches a terminator, and termination occurs if rho catches it there. Pausing is therefore important in rho-dependent termination, just as in intrinsic termination, because it gives time for the other necessary events to occur.

The idea that rho moves along RNA leads to an important prediction about the relationship between transcription and translation. Rho must first have access to a binding sequence on RNA, and then must be able to move along the RNA. Either or

both of these conditions may be prevented if ribosomes are translating an RNA. So the ability of rho factor to reach RNA polymerase at a terminator depends on what is happening in translation.

This model explains a puzzling phenomenon. In some cases, a nonsense mutation in one gene of a transcription unit prevents the expression of subsequent genes in the unit. This effect is called **polarity**. A common cause is the absence of the mRNA corresponding to the subsequent (distal) parts of the unit.

Suppose that there are rho-dependent terminators *within* the transcription unit, that is, before the terminator that *usually* is used. The consequences are illustrated in **Figure 9.50**. Normally these earlier terminators are not used, because the ribosomes prevent rho from reaching RNA polymerase. But a nonsense mutation releases the ribosomes, so that rho is free to attach to and/or move along the mRNA, enabling it to act on RNA polymerase at the terminator. As a result, the enzyme is released, and the distal regions of the transcription unit are never expressed. (Why should there be internal terminators? Perhaps they are simply sequences that by coincidence mimic the usual rho-dependent terminator.) Some stable RNAs that have extensive secondary structure are preserved from polar effects, presumably because the structure impedes rho attachment or movement.

**Figure 9.50** The action of rho factor may create a link between transcription and translation when a rho-dependent terminator lies soon after a nonsense mutation.

*rho* mutations show wide variations in their influence on termination. The basic nature of the effect is a failure to terminate. But the magnitude of the failure, as seen

in the percent of readthrough *in vivo*, depends on the particular target locus. Similarly, the need for rho factor *in vitro* is variable. Some (rho-dependent) terminators require relatively high concentrations of rho, while others function just as well at lower levels. This suggests that different terminators require different levels of rho factor for termination, and therefore respond differently to the residual levels of rho factor in the mutants (*rho* mutants are usually leaky).

Some *rho* mutations can be suppressed by mutations in other genes. This approach provides an excellent way to identify proteins that interact with rho. The  $\beta$  subunit of RNA polymerase is implicated by two types of mutation. First, mutations in the *rpoB* gene can reduce termination at a rho-dependent site. Second, mutations in *rpoB* can restore the ability to terminate transcription at rho-dependent sites in *rho* mutant bacteria. However, we do not know what function the interaction plays.

**TRANSCRIPTION****3.9.23 Antitermination is a regulatory event**

---

**Key Terms**

**Antitermination** is a mechanism of transcriptional control in which termination is prevented at a specific terminator site, allowing RNA polymerase to read into the genes beyond it.

**Antitermination proteins** allow RNA polymerase to transcribe through certain terminator sites.

**Immediate early** phage genes in phage lambda are equivalent to the early class of other phages. They are transcribed immediately upon infection by the host RNA polymerase.

**Delayed early** genes in phage lambda are equivalent to the middle genes of other phages. They cannot be transcribed until regulator protein(s) coded by the immediate early genes have been synthesized.

**Key Concepts**

- Termination is prevented when antitermination proteins act on RNA polymerase to cause it to readthrough a specific terminator or terminators.
- Phage lambda has two antitermination proteins, pN and pQ, that act on different transcription units.

---

**Antitermination** is used as a control mechanism in both phage regulatory circuits and bacterial operons. **Figure 9.51** shows that antitermination controls the ability of the enzyme to read past a terminator into genes lying beyond. In the example shown in the figure, the default pathway is for RNA polymerase to terminate at the end of region 1. But antitermination allows it to continue transcription through region 2. Because the promoter does not change, both situations produce an RNA with the same 5' sequences; the difference is that after antitermination the RNA is extended to include new sequences at the 3' end.

**Figure 9.51** Antitermination can be used to control transcription by determining whether RNA polymerase terminates or reads through a particular terminator into the following region.

Antitermination was discovered in bacteriophage infections. A common feature in the control of phage infection is that very few of the phage genes (the "early" genes) can be transcribed by the bacterial host RNA polymerase. Among these genes, however, are regulator(s) whose product(s) allow the next set of phage genes to be expressed (see *Molecular Biology 3.12.4 Two types of regulatory event control the lytic cascade*). One of these types of regulator is an **antitermination protein**. **Figure 9.52** shows that it enables RNA polymerase to read through a terminator, extending the RNA transcript. In the absence of the antitermination protein, RNA polymerase terminates at the terminator (top panel). When the antitermination protein is present, it continues past the terminator (middle panel).

**Figure 9.52** An antitermination protein can act on RNA polymerase to enable it to readthrough a specific terminator.

The best characterized example of antitermination is provided by phage lambda, with which the phenomenon was discovered. It is used at two stages of phage expression. The antitermination protein produced at each stage is specific for the particular transcription units that are expressed at that stage, as summarized in the bottom panel of **Figure 9.52**.

The host RNA polymerase initially transcribes two genes, which are called the **immediate early** genes. The transition to the next stage of expression is controlled by preventing termination at the ends of the immediate early genes, with the result that the **delayed early** genes are expressed. (We discuss the overall regulation of lambda development in *Molecular Biology 3.12 Phage strategies*.)

The regulator gene that controls the switch from immediate early to delayed early expression is identified by mutations in lambda gene *N* that can transcribe *only* the immediate early genes; they proceed no further into the infective cycle. There are two transcription units of immediate early genes (transcribed from the promoters  $P_L$  and  $P_R$ ). Transcription by *E. coli* RNA polymerase itself stops at the terminators at the ends of these transcription units ( $t_L$  and  $t_R$ , respectively.) Both terminators depend on rho; in fact, these were the terminators with which rho was originally identified. The situation is changed by expression of the *N* gene. The product pN is an antitermination protein that acts on both of the immediate early transcription units,

and allows RNA polymerase to read through the terminators into the delayed early genes beyond them.

Like other phages, still another control is needed to express the late genes that code for the components of the phage particle. This switch is regulated by gene  $Q$ , itself one of the delayed early genes. Its product, pQ, is another antitermination protein, one that specifically allows RNA polymerase initiating at another site, the late promoter  $P_{R,}$ , to read through a terminator that lies between it and the late genes.

The different specificities of pN and pQ establish an important general principle: *RNA polymerase interacts with transcription units in such a way that an ancillary factor can sponsor antitermination specifically for some transcripts.* Termination can be controlled with the same sort of precision as initiation.

*This content is available online at <http://www.ergito.com/main.jsp?bcs=MBIO.3.9.23>*

---

**TRANSCRIPTION****3.9.24 Antitermination requires sites that are independent of the terminators**

---

**Key Concepts**

- The site where an antiterminator protein acts is upstream of the terminator site in the transcription unit.
- The location of the antiterminator site varies in different cases, and can be in the promoter or within the transcription unit.

---

What sites are involved in controlling the specificity of antitermination? The antitermination activity of pN is highly specific, but *the antitermination event is not determined by the terminators  $t_{L1}$  and  $t_{R1}$ ; the recognition site needed for antitermination lies upstream in the transcription unit, that is, at a different place from the terminator site at which the action eventually is accomplished.* This conclusion establishes a general principle. When we know the site on DNA at which some protein exercises its effect, we cannot assume that this coincides with the DNA sequence that it initially recognizes. They may be separate. **Figure 9.53** shows the locations of the sites required for antitermination in phage lambda.

**Figure 9.53** Host RNA polymerase transcribes lambda genes and terminates at  $t$  sites. pN allows it to read through terminators in the L and R1 units; pQ allows it to read through the R' terminator. The sites at which pN acts ( $nut$ ) and at which pQ acts ( $qut$ ) are located at different relative positions in the transcription units.

The recognition sites required for pN action are called  $nut$  (for  $N$  utilization). The sites responsible for determining leftward and rightward antitermination are described as  $nutL$  and  $nutR$ , respectively. Mapping of  $nut$  mutations locates  $nutL$  between the startpoint of  $P_L$  and the beginning of the  $N$  coding region. By contrast,  $nutR$  lies between the end of the  $cro$  gene and  $t_{L1}$ . This means that the two  $nut$  sites lie in different positions relative to the organization of their transcription units. Whereas  $nutL$  is near the promoter,  $nutR$  is near to the terminator. ( $qut$  is different yet again, and lies within the promoter.)

How does antitermination occur? When pN recognizes the  $nut$  site, it must act on RNA polymerase to ensure that the enzyme can no longer respond to the terminator. The variable locations of the  $nut$  sites indicate that this event is linked neither to

initiation nor to termination, but can occur to RNA polymerase as it elongates the RNA chain past the *nut* site. As illustrated in **Figure 9.54**, the polymerase then becomes a juggernaut that continues past the terminator, heedless of its signal. (This reaction involves antitermination at rho-dependent terminators, but pN also suppresses termination at intrinsic terminators.)

**Figure 9.54** Ancillary factors bind to RNA polymerase as it passes the *nut* site. They prevent rho from causing termination when the polymerase reaches the terminator.

Is the ability of pN to recognize a short sequence within the transcription unit an example of a more widely used mechanism for antitermination? Other phages, related to lambda, have different *N* genes and different antitermination specificities. The region of the phage genome in which the *nut* sites lie has a different sequence in each of these phages, and each phage must therefore have characteristic *nut* sites recognized specifically by its own pN. Each of these pN products must have the same general ability to interact with the transcription apparatus in an antitermination capacity, but has a different specificity for the sequence of DNA that activates the mechanism.

This content is available online at <http://www.ergito.com/main.jsp?bcs=MBIO.3.9.24>

---

**TRANSCRIPTION****3.9.25 Termination and anti-termination factors interact with RNA polymerase**

---

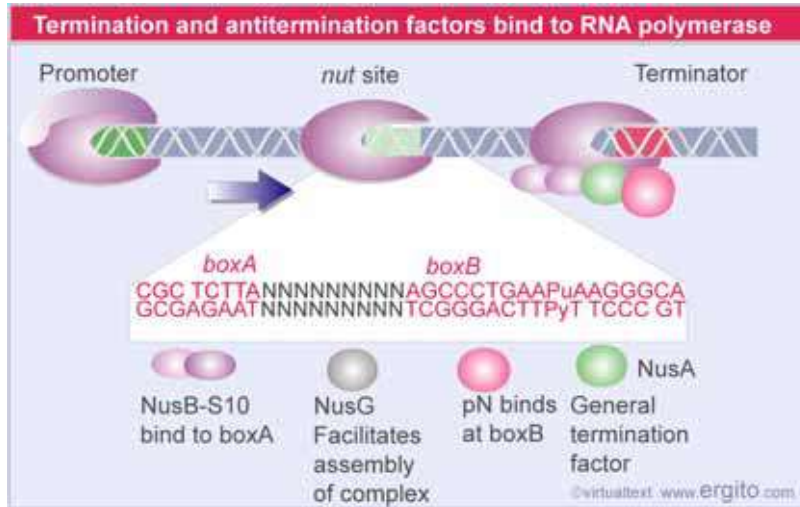

**Key Concepts**

- Several bacterial proteins are required for lambda pN to interact with RNA polymerase.
  - These proteins are also involved in antitermination in the *rrn* operons of the host bacterium.
  - The lambda antiterminator pQ has a different mode of interaction that involves binding to DNA at the promoter.
- 

Termination and antitermination are closely connected, and involve bacterial and phage proteins that interact with RNA polymerase. Several proteins concerned with termination have been identified by isolating mutants of *E. coli* in which pN is ineffective. Several of these mutations lie in the *rpoB* gene. This argues that pN (like rho factor) interacts with the  $\beta$  subunit of the core enzyme. Other *E. coli* mutations that prevent pN function identify the *nus* loci: *nusA*, *nusB*, *nusE*, and *nusG*. (The term "*nus*" is an acronym for *N* utilization substance.)

A lambda *nut* site consists of two sequence elements, called *boxA* and *boxB* (1776). Sequence elements related to *boxA* are also found in bacterial operons. *boxA* is required for binding bacterial proteins that are necessary for antitermination in both phage and bacterial operons. *boxB* is specific to the phage genome, and mutations in *boxB* abolish the ability of pN to cause antitermination.

The *nus* loci code for proteins that form part of the transcription apparatus, but that are not isolated with the RNA polymerase enzyme. The *nusA*, *nusB*, and *nusG* functions are concerned solely with the termination of transcription. *nusE* codes for ribosomal protein S10; the relationship between its location in the 30S subunit and its function in termination is not clear. The Nus proteins bind to RNA polymerase at the *nut* site, as summarized in **Figure 9.55**.

**Figure 9.55** Ancillary factors bind to RNA polymerase as it passes certain sites. The *nut* site consists of two sequences. NusB-S10 join core enzyme as it passes *boxA*. Then NusA and pN protein bind as polymerase passes *boxB*. The presence of pN allows the enzyme to read through the terminator, producing a joint mRNA that contains immediate early sequences joined to delayed early sequences.

NusA is a general transcription factor that increases the efficiency of termination, probably by enhancing RNA polymerase's tendency to pause at terminators (and indeed at other regions of secondary structure; see below). NusB and S10 form a dimer that binds specifically to RNA containing a *boxA* sequence. NusG may be concerned with the general assembly of all the Nus factors into a complex with RNA polymerase.

Intrinsic and rho-dependent terminators have different requirements for the Nus factors. NusA is required for termination at intrinsic terminators, and the reaction can be prevented by pN. At rho-dependent terminators, all 4 Nus proteins are required, and again pN alone can inhibit the reaction (for review see 102). The common feature of pN at both types of terminator is to prevent the role of NusA in termination (1779). Binding of pN to NusA inhibits the ability of NusA to bind RNA, which is necessary for termination.

Antitermination occurs in the *rrn* (rRNA) operons of *E. coli*, and involves the same *nus* functions. The leader regions of the *rrn* operons contain *boxA* sequences; NusB-S10 dimers recognize these sequences and bind to RNA polymerase as it elongates past *boxA*. This changes the properties of RNA polymerase in such a way that it can now read through rho-dependent terminators that are present within the transcription unit.

The *boxA* sequence of lambda RNA does not bind NusB-S10, and is probably enabled to do so by the presence of NusA and pN; the *boxB* sequence could be required to stabilize the reaction. So variations in *boxA* sequences may determine which particular set of factors is required for antitermination. The consequences are the same: when RNA polymerase passes the *nut* site, it is modified by addition of appropriate factors, and fails to terminate when it subsequently encounters the terminator sites.

Antitermination in lambda requires pN to bind to RNA polymerase in a manner that depends on the sequence of the transcription unit. Does pN recognize the *boxB* site in DNA or in the RNA transcript? It does not bind independently to either type of sequence, but does bind to a transcription complex when core enzyme passes the *boxB* site. pN has separate domains that recognize the *boxB* RNA sequence and the NusA protein (1777; 1778). After joining the transcription complex, pN remains associated with the core enzyme, in effect becoming an additional subunit whose presence changes recognition of terminators. It is possible that pN in fact continues to bind to both the *boxB* RNA sequence and to RNA polymerase, maintaining a loop in the RNA; thus the role of *boxB* RNA would partly be to tether pN in the vicinity, effectively increasing its local concentration.

pQ, which prevents termination later in phage infection by acting at *qut*, has a different mode of action. The *qut* sequence lies at the start of the late transcription unit. The upstream part of *qut* lies within the promoter, while the downstream part lies at the beginning of the transcribed region. This implies that pQ action involves recognition of DNA, and implies that its mechanism of action, at least concerning the initial binding to the complex, must be different from that of pN. pQ interacts with the holoenzyme during the initiation phase. In fact,  $\sigma^{70}$  is required for the interaction with pQ. This reinforces the view of RNA polymerase as an interactive structure in which conformational changes induced at one phase may affect its activity at a later phase.

The basic action of pQ is to interfere with pausing; and once pQ has acted upon RNA polymerase, the enzyme shows much reduced pausing at all sites, including rho-dependent and intrinsic terminators. So pQ does not act directly on termination *per se*, but instead allows the enzyme to pass the terminator more quickly, thus depriving the core polymerase and/or accessory factor of the opportunity to cause termination.

The general principle is that RNA polymerase may exist in forms that are competent to undertake particular stages of transcription, and its activities at these stages can be changed only by modifying the appropriate form. So substitutions of sigma factors may change one initiation-competent form into another; and additions of Nus factors may change the properties of termination-competent forms.

Termination seems to be closely connected with the mode of elongation. In its basic transcription mode, core polymerase is subject to many pauses during elongation; and pausing at a terminator site is the prerequisite for termination to occur. Under the influence of factors such as NusA, pausing becomes extended, increasing the efficiency of termination; while under the influence of pN or pQ, pausing is abbreviated, decreasing the efficiency of termination. Because recognition sites for these factors are found only in certain transcription units, pausing and consequently termination are altered only in those units.

**TRANSCRIPTION****3.9.26 Summary**

---

A transcription unit comprises the DNA between a promoter, where transcription initiates, and a terminator, where it ends. One strand of the DNA in this region serves as a template for synthesis of a complementary strand of RNA. The RNA-DNA hybrid region is short and transient, as the transcription "bubble" moves along DNA. The RNA polymerase holoenzyme that synthesizes bacterial RNA can be separated into two components. Core enzyme is a multimer of structure  $\alpha_2 \beta \beta'$  that is responsible for elongating the RNA chain. Sigma factor ( $\sigma$ ) is a single subunit that is required at the stage of initiation for recognizing the promoter.

Core enzyme has a general affinity for DNA. The addition of sigma factor reduces the affinity of the enzyme for nonspecific binding to DNA, but increases its affinity for promoters. The rate at which RNA polymerase finds its promoters is too great to be accounted for by diffusion and random contacts with DNA; direct exchange of DNA sequences held by the enzyme may be involved.

Bacterial promoters are identified by two short conserved sequences centered at  $-35$  and  $-10$  relative to the startpoint. Most promoters have sequences that are well related to the consensus sequences at these sites. The distance separating the consensus sequences is 16-18 bp. RNA polymerase initially "touches down" at the  $-35$  sequence and then extends its contacts over the  $-10$  region. The enzyme covers  $\sim 77$  bp of DNA. The initial "closed" binary complex is converted to an "open" binary complex by melting of a sequence of  $\sim 12$  bp that extends from the  $-10$  region to the startpoint. The A·T-rich base pair composition of the  $-10$  sequence may be important for the melting reaction.

The binary complex is converted to a ternary complex by the incorporation of ribonucleotide precursors. There are multiple cycles of abortive initiation, during which RNA polymerase synthesizes and releases very short RNA chains without moving from the promoter. At the end of this stage, there is a change in structure, and the core enzyme contracts to cover  $\sim 50$  bp. Sigma factor is either released (30% of cases) or changes its form of association with the core enzyme. Then core enzyme moves along DNA, synthesizing RNA. A locally unwound region of DNA moves with the enzyme. The enzyme contracts further in size to cover only 30-40 bp when the nascent chain has reached 15-20 nucleotides; then it continues to the end of the transcription unit.

The "strength" of a promoter describes the frequency at which RNA polymerase initiates transcription; it is related to the closeness with which its  $-35$  and  $-10$  sequences conform to the ideal consensus sequences, but is influenced also by the sequences immediately downstream of the startpoint. Negative supercoiling increases the strength of certain promoters. Transcription generates positive supercoils ahead of RNA polymerase and leaves negative supercoils behind the enzyme.

The core enzyme can be directed to recognize promoters with different consensus sequences by alternative sigma factors. In *E. coli*, these sigma factors are activated by adverse conditions, such as heat shock or nitrogen starvation. *B. subtilis* contains

a single major sigma factor with the same specificity as the *E. coli* sigma factor, and also contains a variety of minor sigma factors. Another series of factors is activated when sporulation is initiated; sporulation is regulated by two cascades in which sigma factor replacements occur in the forespore and mother cell. A cascade for regulating transcription by substitution of sigma factors is also used by phage SPO1.

The geometry of RNA polymerase-promoter recognition is similar for holoenzymes containing all sigma factors (except  $\sigma^{54}$ ). Each sigma factor causes RNA polymerase to initiate transcription at a promoter that conforms to a particular consensus at -35 and -10. Direct contacts between sigma and DNA at these sites have been demonstrated for *E. coli*  $\sigma^{70}$ . The  $\sigma^{70}$  factor of *E. coli* has an N-terminal autoinhibitory domain that prevents the DNA-binding regions from recognizing DNA. The autoinhibitory region is displaced by DNA when the holoenzyme forms an open complex.

Bacterial RNA polymerase terminates transcription at two types of sites. Intrinsic terminators contain a G-C-rich hairpin followed by a U-rich region. They are recognized *in vitro* by core enzyme alone. Rho-dependent terminators require rho factor both *in vitro* and *in vivo*; rho binds to *rut* sites that are rich in C and poor in G residues and that precede the actual site of termination. Rho is a hexameric ATP-dependent helicase activity that translocates along the RNA until it reaches the RNA-DNA hybrid region in the transcription bubble of RNA polymerase, where it dissociates the RNA from DNA. In both types of termination, pausing by RNA polymerase is important in order to allow time for the actual termination event to occur.

The Nus factors are required for termination. NusA is required for intrinsic terminators, and in addition NusB-S10 is required for rho-dependent terminators. The NusB-S10 dimer recognizes the *boxA* sequence of a *nut* site in the elongating RNA; NusA joins subsequently.

Antitermination is used by some phages to regulate progression from one stage of gene expression to the next. The lambda gene *N* codes for an antitermination protein (pN) that is necessary to allow RNA polymerase to read through the terminators located at the ends of the immediate early genes. Another antitermination protein, pQ, is required later in phage infection. pN and pQ act on RNA polymerase as it passes specific sites (*nut* and *qut*, respectively). These sites are located at different relative positions in their respective transcription units. pN recognizes RNA polymerase carrying NusA when the enzyme passes the sequence *boxB*. pN then binds to the complex and prevents termination by antagonizing the action of NusA when the polymerase reaches the rho-dependent terminator.

## THE OPERON

### 3.10.1 Introduction

---

#### Key Terms

A **trans-acting** product can function on any copy of its target DNA. This implies that it is a diffusible protein or RNA.

A **cis-acting** site affects the activity only of sequences on its own molecule of DNA (or RNA); this property usually implies that the site does not code for protein.

A **structural gene** codes for any RNA or protein product other than a regulator.

A **regulator gene** codes for a product (typically protein) that controls the expression of other genes (usually at the level of transcription).

---

Gene expression can be controlled at any of several stages, which we divide broadly into transcription, processing, and translation:

- Transcription often is controlled at the stage of initiation. Transcription is not usually controlled at elongation, but may be controlled at termination to determine whether RNA polymerase is allowed to proceed past a terminator to the gene(s) beyond.
- In eukaryotic cells, processing of the RNA product may be regulated at the stages of modification, splicing, transport, or stability. In bacteria, an mRNA is in principle available for translation as soon as (or even while) it is being synthesized, and these stages of control are not available.
- Translation may be regulated, usually at the stages of initiation and termination (like transcription). Regulation of initiation is formally analogous to the regulation of transcription: the circuitry can be drawn in similar terms for regulating initiation of transcription on DNA or initiation of translation on RNA.

The basic concept for how transcription is controlled in bacteria was provided by the classic formulation of the model for control of gene expression by Jacob and Monod in 1961 (508). They distinguished between two types of sequences in DNA: sequences that code for **trans-acting** products; and **cis-acting** sequences that function exclusively within the DNA. Gene activity is regulated by the specific interactions of the *trans-acting* products (usually proteins) with the *cis-acting* sequences (usually sites in DNA). In more formal terms:

- A gene is a sequence of DNA that codes for a diffusible product. This product may be protein (as in the case of the majority of genes) or may be RNA (as in the case of genes that code for tRNA and rRNA). *The crucial feature is that the product diffuses away from its site of synthesis to act elsewhere.* Any gene product that is free to diffuse to find its target is described as *trans-acting*.
  - The description *cis-acting* applies to any sequence of DNA that is not converted
-

into any other form, but that functions exclusively as a DNA sequence *in situ*, affecting only the DNA to which it is physically linked. (In some cases, a *cis*-acting sequence functions in an RNA rather than in a DNA molecule.)

To help distinguish between the components of regulatory circuits and the genes that they regulate, we sometimes use the terms structural gene and regulator gene. A **structural gene** is simply any gene that codes for a protein (or RNA) product. Structural genes represent an enormous variety of protein structures and functions, including structural proteins, enzymes with catalytic activities, and regulatory proteins. A **regulator gene** simply describes a gene that codes for a protein (or an RNA) involved in regulating the expression of other genes.

The simplest form of the regulatory model is illustrated in **Figure 10.1**: a regulator gene codes for a protein that controls transcription by binding to particular site(s) on DNA. This interaction can regulate a target gene in either a positive manner (the interaction turns the gene on) or in a negative manner (the interaction turns the gene off). The sites on DNA are usually (but not exclusively) located just upstream of the target gene.

**Figure 10.1** A regulator gene codes for a protein that acts at a target site on DNA.

The sequences that mark the beginning and end of the transcription unit, the promoter and terminator, are examples of *cis*-acting sites. A *promoter serves to initiate transcription only of the gene or genes physically connected to it on the same stretch of DNA*. In the same way, a terminator can terminate transcription only by an RNA polymerase that has traversed the preceding gene(s). In their simplest forms, promoters and terminators are *cis*-acting elements that are recognized by the same *trans*-acting species, that is, by RNA polymerase (although other factors also participate at each site).

Additional *cis*-acting regulatory sites are often juxtaposed to, or interspersed with, the promoter. A bacterial promoter may have one or more such sites located close by, that is, in the immediate vicinity of the startpoint. A eukaryotic promoter is likely to have a greater number of sites, spread out over a longer distance.

## THE OPERON

### 3.10.2 Regulation can be negative or positive

---

#### Key Terms

A **repressor** is a protein that inhibits expression of a gene. It may act to prevent transcription by binding to an operator site in DNA, or to prevent translation by binding to RNA.

The **operator** is the site on DNA at which a repressor protein binds to prevent transcription from initiating at the adjacent promoter.

A **transcription factor** is required for RNA polymerase to initiate transcription at specific promoter(s), but is not itself part of the enzyme.

#### Key Concepts

- In negative regulation a repressor protein binds to an operator to prevent a gene from being expressed.
- In positive regulation a transcription factor is required to bind at the promoter in order to enable RNA polymerase to initiate transcription.

---

A classic mode of control in bacteria is *negative*: a **repressor** protein prevents a gene from being expressed. **Figure 10.2** shows that the "default state" for such a gene is to be expressed via the recognition of its promoter by RNA polymerase. Close to the promoter is another *cis*-acting site called the **operator**, which is the target for the repressor protein. When the repressor binds to the operator, RNA polymerase is prevented from initiating transcription, and *gene expression is therefore turned off*.

**Figure 10.2** In negative control, a trans-acting repressor binds to the *cis*-acting operator to turn off transcription.

An alternative mode of control is *positive*. This is used in bacteria (probably) with about equal frequency to negative control, and it is the most common mode of control in eukaryotes. A **transcription factor** is required to assist RNA polymerase in initiating at the promoter. **Figure 10.3** shows that the typical default state of a eukaryotic gene is inactive: RNA polymerase cannot by itself initiate transcription at the promoter. Several *trans*-acting factors have target sites in the vicinity of the promoter, and *binding of some or all of these factors enables RNA polymerase to initiate transcription*.

**Figure 10.3** In positive control, *trans*-acting factors must bind to *cis*-acting sites in order for RNA polymerase to initiate transcription at the promoter.

The unifying theme is that regulatory proteins are *trans*-acting factors that recognize *cis*-acting elements (usually) upstream of the gene. The consequences of this recognition are to activate or to repress the gene, depending on the individual type of regulatory protein. A typical feature is that the protein functions by recognizing a very short sequence in DNA, usually <10 bp in length, although the protein actually binds over a somewhat greater distance of DNA. The bacterial promoter is an example: although RNA polymerase covers >70 bp of DNA at initiation, the crucial sequences that it recognizes are the hexamers centered at -35 and -10.

A significant difference in gene organization between prokaryotes and eukaryotes is that structural genes in bacteria are organized in clusters, while those in eukaryotes occur individually. Clustering of structural genes allows them to be coordinately controlled by means of interactions at a single promoter: as a result of these interactions, the entire set of genes is either transcribed or not transcribed. In this chapter, we discuss this mode of control and its use by bacteria (for review see 82). The means employed to coordinate control of dispersed eukaryotic genes are discussed in *Molecular Biology 5.22 Activating transcription*.

## THE OPERON

### 3.10.3 Structural gene clusters are coordinately controlled

#### Key Terms

An **operon** is a unit of bacterial gene expression and regulation, including structural genes and control elements in DNA recognized by regulator gene product(s).

#### Key Concepts

- Genes coding for proteins that function in the same pathway may be located adjacent to one another and controlled as a single unit that is transcribed into a polycistronic mRNA.

Bacterial structural genes are often organized into clusters that include genes coding for proteins whose functions are related. It is common for the genes coding for the enzymes of a metabolic pathway to be organized into such a cluster. In addition to the enzymes actually involved in the pathway, other related activities may be included in the unit of coordinate control; for example, the protein responsible for transporting the small molecule substrate into the cell.

The cluster of the three *lac* structural genes, *lacZYA*, is typical. **Figure 10.4** summarizes the organization of the structural genes, their associated *cis*-acting regulatory elements, and the *trans*-acting regulatory gene. *The key feature is that the cluster is transcribed into a single polycistronic mRNA from a promoter where initiation of transcription is regulated.*

**Figure 10.4** The *lac* operon occupies ~6000 bp of DNA. At the left the *lacI* gene has its own promoter and terminator. The end of the *lacI* region is adjacent to the promoter, *P*. The operator, *O*, occupies the first 26 bp of the transcription unit. The long *lacZ* gene starts at base 39, and is followed by the *lacY* and *lacA* genes and a terminator.

The protein products enable cells to take up and metabolize  $\beta$ -galactosides, such as lactose. The roles of the three structural genes are:

- *lacZ* codes for the enzyme  $\beta$ -galactosidase, whose active form is a tetramer of ~500 kD. The enzyme breaks a  $\beta$ -galactoside into its component sugars. For example, lactose is cleaved into glucose and galactose (which are then further metabolized).
- *lacY* codes for the  $\beta$ -galactoside permease, a 30 kD membrane-bound protein constituent of the transport system. This transports  $\beta$ -galactosides into the cell.
- *lacA* codes for  $\beta$ -galactoside transacetylase, an enzyme that transfers an acetyl group from acetyl-CoA to  $\beta$ -galactosides.

Mutations in either *lacZ* or *lacY* can create the *lac* genotype, in which cells cannot utilize lactose. (The genotypic description "*lac*" without a qualifier indicates loss-of-function.) The *lacZ* mutations abolish enzyme activity, directly preventing metabolism of lactose. The *lacY* mutants cannot take up lactose from the medium. (No defect is identifiable in *lacA* cells, which is puzzling. It is possible that the acetylation reaction gives an advantage when the bacteria grow in the presence of certain analogs of  $\beta$ -galactosides that cannot be metabolized, because the modification results in detoxification and excretion.)

The entire system, including structural genes and the elements that control their expression, forms a common unit of regulation; this is called an **operon**. The activity of the operon is controlled by regulator gene(s), whose protein products interact with the *cis*-acting control elements.

*This content is available online at <http://www.ergito.com/main.jsp?bcs=MBIO.3.10.3>*

---

## THE OPERON

### 3.10.4 The *lac* genes are controlled by a repressor

---

#### Key Terms

The default state of genes that are controlled by **negative regulation** is to be expressed. A specific intervention is required to turn them off.

#### Key Concepts

- Transcription of the *lacZYA* gene cluster is controlled by a repressor protein that binds to an operator that overlaps the promoter at the start of the cluster.
- The repressor protein is a tetramer of identical subunits coded by the gene *lacI*.

---

We can distinguish between structural genes and regulator genes by the effects of mutations. A mutation in a structural gene deprives the cell of the particular protein for which the gene codes. But a mutation in a regulator gene influences the expression of all the structural genes that it controls. The consequences of a regulatory mutation reveal the type of regulation (508; for review see 84).

Transcription of the *lacZYA* genes is controlled by a regulator protein synthesized by the *lacI* gene. It happens that *lacI* is located adjacent to the structural genes, but it comprises an independent transcription unit with its own promoter and terminator. Since *lacI* specifies a diffusible product, in principle it need not be located near the structural genes; it can function equally well if moved elsewhere, or carried on a separate DNA molecule (the classic test for a *trans*-acting regulator).

The *lac* genes are controlled by **negative regulation**: *they are transcribed unless turned off by the regulator protein*. A mutation that inactivates the regulator causes the structural genes to remain in the expressed condition. The product of *lacI* is called the *Lac repressor*, because its function is to prevent the expression of the structural genes.

The repressor is a tetramer of identical subunits of 38 kD each. There are ~10 tetramers in a wild-type cell. The regulator gene is not controlled by the availability of lactose. It is transcribed into a monocistronic mRNA at a rate that appears to be governed simply by the affinity of its promoter for RNA polymerase.

The repressor functions by binding to an operator (formally denoted  $O_{lac}$ ) at the start of the *lacZYA* cluster. The operator lies between the promoter ( $P_{lac}$ ) and the structural genes (*lacZYA*). *When the repressor binds at the operator, it prevents RNA polymerase from initiating transcription at the promoter.* **Figure 10.5** expands our view of the region at the start of the *lac* structural genes. The operator extends from position -5 just upstream of the mRNA startpoint to position +21 within the transcription unit. So it overlaps the right end of the promoter. We discuss the relationship between repressor and RNA polymerase in more detail in *Molecular Biology 3.10.10 Repressor protein binds to the operator* and *Molecular*

Biology 3.10.16 Repressor binds to three operators and interacts with RNA polymerase (for review see 83; 85; 86; 87).

**Figure 10.5** Repressor and RNA polymerase bind at sites that overlap around the transcription startpoint of the *lac* operon.

## THE OPERON

### 3.10.5 The *lac* operon can be induced

---

#### Key Terms

**Induction** refers to the ability of bacteria (or yeast) to synthesize certain enzymes only when their substrates are present; applied to gene expression, it refers to switching on transcription as a result of interaction of the inducer with the regulator protein.

The level of response from a system in the absence of a stimulus is its **basal level**. (The basal level of transcription of a gene is the level that occurs in the absence of any specific activation.)

**Repression** describes the ability of bacteria to prevent synthesis of certain enzymes when their products are present; more generally, refers to inhibition of transcription (or translation) by binding of repressor protein to a specific site on DNA (or mRNA).

An **inducer** is a small molecule that triggers gene transcription by binding to a regulator protein.

A **corepressor** is a small molecule that triggers repression of transcription by binding to a regulator protein.

#### Key Concepts

- Small molecules that induce an operon are identical with or related to the substrate for its enzymes.
- $\beta$ -galactosides are the substrates for the enzymes coded by *lacZYA*.
- In the absence of  $\beta$ -galactosides the *lac* operon is expressed only at a very low (basal) level.
- Addition of  $\beta$ -galactosides induces transcription of all three genes of the operon.
- Because the *lac* mRNA is extremely unstable, induction can be rapidly reversed.
- The same types of systems that allow substrates to induce operons coding for metabolic enzymes can be used to allow end-products to repress the operons that code for biosynthetic enzymes.

---

Bacteria need to respond swiftly to changes in their environment. Fluctuations in the supply of nutrients can occur at any time; survival depends on the ability to switch from metabolizing one substrate to another. Yet economy also is important, since a bacterium that indulges in energetically expensive ways to meet the demands of the environment is likely to be at a disadvantage. So a bacterium avoids synthesizing the enzymes of a pathway in the absence of the substrate; but is ready to produce the enzymes if the substrate should appear.

The synthesis of enzymes in response to the appearance of a specific substrate is

called **induction**. This type of regulation is widespread in bacteria, and occurs also in unicellular eukaryotes (such as yeasts). The lactose system of *E. coli* provides the paradigm for this sort of control mechanism.

When cells of *E. coli* are grown in the absence of a  $\beta$ -galactoside, there is no need for  $\beta$ -galactosidase, and they contain very few molecules of the enzyme – say,  $<5$ . When a suitable substrate is added, the enzyme activity appears very rapidly in the bacteria. Within 2-3 minutes some enzyme is present, and soon there are  $\sim 5000$  molecules of enzyme per bacterium. (Under suitable conditions,  $\beta$ -galactosidase can account for 5-10% of the total soluble protein of the bacterium.) If the substrate is removed from the medium, the synthesis of enzyme stops as rapidly as it had originally started.

**Figure 10.6** summarizes the essential features of induction. Control of transcription of the *lac* genes responds very rapidly to the inducer, as shown in the upper part of the figure. In the absence of inducer, the operon is transcribed at a very low **basal level**. Transcription is stimulated as soon as inducer is added; the amount of *lac* mRNA increases rapidly to an induced level that reflects a balance between synthesis and degradation of the mRNA.

**Figure 10.6** Addition of inducer results in rapid induction of *lac* mRNA, and is followed after a short lag by synthesis of the enzymes; removal of inducer is followed by rapid cessation of synthesis.

The *lac* mRNA is extremely unstable, and decays with a half-life of only  $\sim 3$  minutes. This feature allows induction to be reversed rapidly. Transcription ceases as soon as the inducer is removed; and in a very short time all the *lac* mRNA has been destroyed, and the cellular content has returned to the basal level.

The production of protein is followed in the lower part of the figure. Translation of the *lac* mRNA produces  $\beta$ -galactosidase (and the products of the other *lac* genes). There is a short lag between the appearance of *lac* mRNA and appearance of the first completed enzyme molecules (it is ~2 min after rise of mRNA from basal level before protein begins to increase). There is a similar lag between reaching maximal induced levels of mRNA and protein. When inducer is removed, synthesis of enzyme ceases almost immediately (as the mRNA is degraded), but the  $\beta$ -galactosidase in the cell is more stable than the mRNA, so the enzyme activity remains at the induced level for longer.

This type of rapid response to changes in nutrient supply not only provides the ability to metabolize new substrates, but also is used to shut off endogenous synthesis of compounds that suddenly appear in the medium. For example, *E. coli* synthesizes the amino acid tryptophan through the action of the enzyme tryptophan synthetase. But if tryptophan is provided in the medium on which the bacteria are growing, the production of the enzyme is immediately halted. This effect is called **repression**. It allows the bacterium to avoid devoting its resources to unnecessary synthetic activities.

Induction and repression represent the same phenomenon. In one case the bacterium adjusts its ability to use a given substrate (such as lactose) for growth; in the other it adjusts its ability to synthesize a particular metabolic intermediate (such as an essential amino acid). The trigger for either type of adjustment is the small molecule that is the substrate for the enzyme, or the product of the enzyme activity, respectively. Small molecules that cause the production of enzymes able to metabolize them are called **inducers**. Those that prevent the production of enzymes able to synthesize them are called **corepressors**.

*This content is available online at <http://www.ergito.com/main.jsp?bcs=MBIO.3.10.5>*

---

## THE OPERON

### 3.10.6 Repressor is controlled by a small molecule inducer

---

#### Key Terms

**Gratuitous inducers** resemble authentic inducers of transcription but are not substrates for the induced enzymes.

**Allosteric** regulation describes the ability of a protein to change its conformation (and therefore activity) at one site as the result of binding a small molecule to a second site located elsewhere on the protein.

**Coordinate regulation** refers to the common control of a group of genes.

#### Key Concepts

- An inducer functions by converting the repressor protein into an inactive form.
- Repressor has two binding sites, one for the operator and another for the inducer.
- Repressor is inactivated by an allosteric interaction in which binding of inducer at its site changes the properties of the DNA-binding site.

---

The ability to act as inducer or corepressor is highly specific. Only the substrate/product or a closely related molecule can serve. *But the activity of the small molecule does not depend on its interaction with the target enzyme.* Some inducers resemble the natural inducers of the *lac* operon, but cannot be metabolized by the enzyme. The example *par excellence* is isopropylthiogalactoside (IPTG), one of several thiogalactosides with this property. Although it is not recognized by  $\beta$ -galactosidase, IPTG is a very efficient inducer of the *lac* genes.

Molecules that induce enzyme synthesis but are not metabolized are called **gratuitous inducers**. They are extremely useful because they remain in the cell in their original form. (A real inducer would be metabolized, interfering with study of the system.) The existence of gratuitous inducers reveals an important point. *The system must possess some component, distinct from the target enzyme, that recognizes the appropriate substrate; and its ability to recognize related potential substrates is different from that of the enzyme.*

The component that responds to the inducer is the repressor protein coded by *lacI*. The *lacZYA* structural genes are transcribed into a single mRNA from a promoter just upstream of *lacZ*. The state of the repressor determines whether this promoter is turned off or on:

- **Figure 10.7** shows that in the absence of an inducer, the genes are not transcribed, because repressor protein is in an active form that is bound to the operator.

- **Figure 10.8** shows that when an inducer is added, the repressor is converted into an inactive form that leaves the operator. Then transcription starts at the promoter and proceeds through the genes to a terminator located beyond the 3' end of *lacA*.

**Figure 10.7** Repressor maintains the *lac* operon in the inactive condition by binding to the operator. The shape of the repressor is represented as a series of connected domains as revealed by its crystal structure (see later).

*This is a static version of an interactive figure; see <http://www.ergito.com/main.jsp?bcs=MBIO.3.10.6> to view properly.*

**Figure 10.8** Addition of inducer converts repressor to an inactive form that cannot bind the operator. This allows RNA polymerase to initiate transcription.

The crucial features of the control circuit reside in the dual properties of the repressor: it can prevent transcription; and it can recognize the small-molecule inducer. The repressor has two binding sites, one for the operator and one for the inducer. When the inducer binds at its site, it changes the conformation of the protein in such a way as to influence the activity of the operator-binding site. The ability of one site in the protein to control the activity of another is called **allosteric** control (see *Molecular Biology Supplement 32.7 Allostery*).

Induction accomplishes a **coordinate regulation**: *all the genes are expressed (or not expressed) in unison*. The mRNA is translated sequentially from its 5' end, which explains why induction always causes the appearance of  $\beta$ -galactosidase,  $\beta$ -galactoside permease, and  $\beta$ -galactoside transacetylase, in that order. Translation of a common mRNA explains why the relative amounts of the three enzymes always remain the same under varying conditions of induction.

Induction throws a switch that causes the genes to be transcribed. Inducers vary in their effectiveness, and other factors influence the absolute level of transcription or translation, but the relationship between the three genes is predetermined by their organization.

We notice a potential paradox in the constitution of the operon. The lactose operon contains the structural gene (*lacZ*) coding for the  $\beta$ -galactosidase activity needed to metabolize the sugar; it also includes the gene (*lacY*) that codes for the protein needed to transport the substrate into the cell. But if the operon is in a repressed state, how does the inducer enter the cell to start the process of induction?

Two features ensure that there is always a minimal amount of the protein present in

the cell, enough to start the process off. There is a basal level of expression of the operon: even when it is not induced, it is expressed at a residual level (0.1% of the induced level). And some inducer enters anyway via another uptake system.

## THE OPERON

### 3.10.7 *cis*-acting constitutive mutations identify the operator

---

#### Key Terms

An **uninducible** mutant is one where the affected gene(s) cannot be expressed.

A **constitutive** process is one that occurs all the time, unchanged by any form of stimulus or external condition.

A ***cis*-dominant** site or mutation affects the properties only of its own molecule of DNA. *cis*-dominance is taken to indicate that a site does not code for a diffusible product. (A rare exception is that a protein is *cis*-dominant when it is constrained to act only on the DNA or RNA from which it was synthesized.)

#### Key Concepts

- Mutations in the operator cause constitutive expression of all three *lac* structural genes.
- They are *cis*-acting and affect only those genes on the contiguous stretch of DNA.

---

Mutations in the regulatory circuit may either abolish expression of the operon or cause unregulated expression. Mutants that cannot be expressed at all are called **uninducible**. The continued expression of a gene that does not respond to regulation is called **constitutive** gene expression, and mutants with this property are called constitutive mutants.

Components of the regulatory circuit of the operon can be identified by mutations that *affect the expression of all the structural genes and map outside them*. They fall into two classes. The promoter and the operator are identified as targets for the regulatory proteins (RNA polymerase and repressor, respectively) by *cis*-acting mutations. And the locus *lacI* is identified as the gene that codes for the repressor protein by mutations that eliminate the *trans*-acting product.

The operator was originally identified by constitutive mutations, denoted  $O^c$ , whose distinctive properties provided the first evidence for *an element that functions without being represented in a diffusible product*.

The structural genes contiguous with an  $O^c$  mutation are expressed constitutively because the mutation changes the operator so that the repressor no longer binds to it. So the repressor cannot prevent RNA polymerase from initiating transcription. The operon is transcribed constitutively, as illustrated in **Figure 10.9**.

**Figure 10.9** Operator mutations are constitutive because the operator is unable to bind repressor protein; this allows RNA polymerase to have unrestrained access to the promoter. The  $O^c$  mutations are *cis*-acting, because they affect only the contiguous set of structural genes.

*The operator can control only the lac genes that are adjacent to it.* If a second *lac* operon is introduced into the bacterium on an independent molecule of DNA, it has its own operator. Neither operator is influenced by the other. So if one operon has a wild-type operator, it will be repressed under the usual conditions, while a second operon with an  $O^c$  mutation will be expressed in its characteristic fashion.

These properties define the operator as a typical *cis*-acting site, whose function depends upon recognition of its DNA sequence by some *trans*-acting factor. The operator controls the adjacent genes irrespective of the presence in the cell of other alleles of the site. A mutation in such a site, for example, the  $O^c$  mutation, is formally described as ***cis*-dominant**.

A mutation in a *cis*-acting site cannot be assigned to a complementation group. (The ability to complement defines genes that are expressed as diffusible products.) When two *cis*-acting sites lie close together – for example, a promoter and an operator – we cannot classify the mutations by a complementation test. We are restricted to distinguishing them by their effects on the phenotype.

*cis*-dominance is a characteristic of any site that is *physically contiguous with the sequences it controls*. If a control site functions as part of a polycistronic mRNA, mutations in it will display *exactly the same pattern* of *cis*-dominance as they would if functioning in DNA. The critical feature is that the control site cannot be physically separated from the genes that it regulates. From the genetic point of view, it does not matter whether the site and genes are together on DNA or on RNA.

---

*This content is available online at <http://www.ergito.com/main.jsp?bcs=MBIO.3.10.7>*

**THE OPERON****3.10.8 *trans*-acting mutations identify the regulator gene****Key Concepts**

- Mutations in the *lacI* gene are *trans*-acting and affect expression of all *lacZYA* clusters in the bacterium.
- Mutations that eliminate *lacI* function cause constitutive expression and are recessive.
- Mutations in the DNA-binding site of the repressor are constitutive because the repressor cannot bind the operator.
- Mutations in the inducer-binding site of the repressor prevent it from being inactivated and cause uninducibility.
- Mutations in the promoter are uninducible and *cis*-acting.

Constitutive transcription is also caused by mutations of the *lacI* type, which are caused by loss of function (including deletions of the gene). When the repressor is inactive or absent, transcription can initiate at the promoter. **Figure 10.10** shows that the *lacI* mutants express the structural genes all the time (constitutively), *irrespective of whether the inducer is present or absent*, because the repressor is inactive.

**Figure 10.10** Mutations that inactivate the *lacI* gene cause the operon to be constitutively expressed, because the mutant repressor protein cannot bind to the operator.

The two types of constitutive mutations can be distinguished genetically.  $O^c$  mutants are *cis*-dominant, whereas *lacI*<sup>-</sup> mutants are recessive. This means that the introduction of a normal, *lacI*<sup>+</sup> gene restores control, irrespective of the presence of the defective *lacI*<sup>-</sup> gene.

Mutants of the operon that are uninducible fall into the same two types of genetic classes as the constitutive mutants:

- Promoter mutations are *cis*-acting. If they prevent RNA polymerase from binding at  $P_{lac}$ , they render the operon nonfunctional because it cannot be transcribed.
- Mutations that abolish the ability of repressor to bind the inducer are described as *lacI*<sup>s</sup>. They are *trans*-acting. The repressor is "locked in" to the active form that recognizes the operator and prevents transcription. The addition of inducer has no effect because its binding site is absent, and therefore it is impossible to convert the repressor to the inactive form. The mutant repressor binds to all *lac* operators in the cell to prevent their transcription, and cannot be pried off, irrespective of the properties of any wild-type repressor protein that is present, so it is genetically dominant.

The two types of mutations in *lacI* can be used to identify the individual active sites in the repressor protein. The *DNA-binding site* recognizes the sequence of the operator. It is identified by constitutive point mutations that prevent repressor from binding to DNA to block RNA polymerase. The *inducer-binding site* is identified by point mutations that cause uninducibility, because inducer cannot bind to trigger the allosteric change in the DNA-binding site.

## THE OPERON

### 3.10.9 Multimeric proteins have special genetic properties

---

#### Key Terms

**Interallelic complementation (intragenic complementation)** describes the change in the properties of a heteromultimeric protein brought about by the interaction of subunits coded by two different mutant alleles; the mixed protein may be more or less active than the protein consisting of subunits only of one or the other type.

**Negative complementation** occurs when interallelic complementation allows a mutant subunit to suppress the activity of a wild-type subunit in a multimeric protein.

A **dominant negative** mutation results in a mutant gene product that prevents the function of the wild-type gene product, causing loss or reduction of gene activity in cells containing both the mutant and wild-type alleles. The effect may result from the titration of another factor that interacts with the gene product or by an inhibiting interaction of the mutant subunit on the multimer.

#### Key Concepts

- Active repressor is a tetramer of identical subunits.
- When mutant and wild-type subunits are present, a single  $lacI^d$  mutant subunit can inactivate a tetramer whose other subunits are wild-type.
- $lacI^d$  mutations occur in the DNA-binding site. Their effect is explained by the fact that repressor activity requires all DNA-binding sites in the tetramer to be active.

---

An important feature of the repressor is that it is multimeric. Repressor subunits associate at random in the cell to form the active protein tetramer. When two different alleles of the *lacI* gene are present, the subunits made by each can associate to form a heterotetramer, whose properties differ from those of either homotetramer. This type of interaction between subunits is a characteristic feature of multimeric proteins and is described as **interallelic complementation** (see *Molecular Biology Supplement 32.9 Complementation*).

**Negative complementation** occurs between some repressor mutants, as seen in the combination of  $lacI^d$  with  $lacI^+$  genes. The  $lacI^d$  mutation alone results in the production of a repressor that cannot bind the operator, and is therefore constitutive like the *lacI* alleles. Because the *lacI* type of mutation inactivates the repressor, it is usually recessive to the wild type. However, the  $-d$  notation indicates that this variant of the negative type is dominant when paired with a wild-type allele. Such mutations are called **dominant negative** (see *Molecular Biology Supplement 32.9 Complementation*).

**Figure 10.11** explains this phenomenon. The reason for the dominance is that the

$lacI^d$  allele produces a "bad" subunit, which is not only itself unable to bind to operator DNA, but is also able as part of a tetramer to prevent any "good" subunits from binding. This demonstrates that the repressor tetramer as a whole, rather than the individual monomer, is needed to achieve repression. In fact, we may reverse the argument to say that, whenever a protein has a dominant negative form, this must mean it functions as part of a multimer. The production of dominant negative proteins has become an important technique in eukaryotic genetics.

**Figure 10.11** A  $lacI^d$  mutant gene makes a monomer that has a damaged DNA binding site (shown by the red circle). When it is present in the same cell as a wild-type gene, multimeric repressors are assembled at random from both types of subunits. It only requires one of the subunits of the multimer to be of the  $lacI^d$  type to block repressor function. This explains the dominant negative behavior of the  $lacI^{>d}$  mutation.

## THE OPERON

### 3.10.10 Repressor protein binds to the operator

---

#### Key Terms

A **palindrome** is a DNA sequence that reads the same on each strand of DNA when the strand is read in the 5' to 3' direction. It consists of adjacent inverted repeats.

#### Key Concepts

- Repressor protein binds to the double-stranded DNA sequence of the operator.
- The operator is a palindromic sequence of 26 bp.
- Each inverted repeat of the operator binds to the DNA-binding site of one repressor subunit.

---

The repressor was isolated originally by purifying the component able to bind the gratuitous inducer IPTG (509; see *Great Experiments 2.1 Isolation of repressor*). (Because the amount of repressor in the cell is so small, in order to obtain enough material it was necessary to use a promoter up mutation to increase *lacI* transcription, and to place this *lacI* locus on a DNA molecule present in many copies per cell. This results in an overall overproduction of 100-1000-fold.)

The repressor binds to double-stranded DNA containing the sequence of the wild-type *lac* operator. The repressor does not bind DNA from an  $O^c$  mutant. The addition of IPTG releases the repressor from operator DNA *in vitro*. The *in vitro* reaction between repressor protein and operator DNA therefore displays the characteristics of control inferred *in vivo*; so it can be used to establish the basis for repression (510).

How does the repressor recognize the specific sequence of operator DNA? The operator has a feature common to many recognition sites for bacterial regulator proteins: it is a **palindrome**. The inverted repeats are highlighted in **Figure 10.12**. Each repeat can be regarded as a half-site of the operator.

**Figure 10.12** The *lac* operator has a symmetrical sequence. The sequence is numbered relative to the startpoint for transcription at +1. The pink arrows to left and right identify the two dyad repeats. The green blocks indicate the positions of identity.

We can use the same approaches to define the points that the repressor contacts in the operator that we used for analyzing the polymerase-promoter interaction (see *Molecular Biology 3.9.14 RNA polymerase binds to one face of DNA*). Deletions of material on either side define the end points of the region; constitutive point mutations identify individual base pairs that must be crucial. Experiments in which DNA bound to repressor is compared with unbound DNA for its susceptibility to methylation or UV crosslinking identify bases that are either protected or more susceptible when associated with the protein.

**Figure 10.13** shows that the region of DNA protected from nucleases by bound repressor lies within the region of symmetry, comprising the 26 bp region from -5 to +21. The area identified by constitutive mutations is even smaller. Within a central region extending over the 13 bp from +5 to +17, there are eight sites at which single base-pair substitutions cause constitutivity. This emphasizes the same point made by the promoter mutations summarized earlier in **Figure 9.29**. *A small number of essential specific contacts within a larger region can be responsible for sequence-specific association of DNA with protein.*

**Figure 10.13** Bases that contact the repressor can be identified by chemical crosslinking or by experiments to see whether modification prevents binding. They identify positions on both strands of DNA extending from +1 to +23. Constitutive mutations occur at 8 positions in the operator between +5 and +17.

The symmetry of the DNA sequence reflects the symmetry in the protein. Each of the identical subunits in a repressor tetramer has a DNA-binding site. Two of these sites contact the operator in such a way that each inverted repeat of the operator makes the same pattern of contacts with a repressor monomer. This is shown by symmetry in the contacts that repressor makes with the operator (the pattern between +1 and +6 is identical with that between +21 and +16) and by matching constitutive mutations in each inverted repeat. (However, the operator is not perfectly symmetrical; the left side binds more strongly than the right side to the repressor. A stronger operator would be created by a perfect inverted duplication of the left side.)

**THE OPERON****3.10.11 Binding of inducer releases repressor from the operator****Key Concepts**

- Inducer binding causes a change in repressor conformation that reduces its affinity for DNA and releases it from the operator.

Various inducers cause characteristic reductions in the affinity of the repressor for the operator *in vitro*. These changes correlate with the effectiveness of the inducers *in vivo*. This suggests that induction results from a reduction in the attraction between operator and repressor. So when inducer enters the cell, it binds to free repressors and in effect prevents them from finding their operators. But consider a repressor tetramer that is already bound tightly to the operator. How does inducer cause this repressor to be released?

Two models for repressor action are illustrated in **Figure 10.14**:

**Figure 10.14** Does the inducer bind to free repressor to upset an equilibrium (left) or directly to repressor bound at the operator (right)?

- The equilibrium model (left) calls for repressor bound to DNA to be in rapid equilibrium with free repressor. Inducer would bind to the free form of repressor, and thus unbalance the equilibrium by preventing reassociation with DNA.
- But the rate of dissociation of the repressor from the operator is much too slow to be compatible with this model (the half-life *in vitro* in the absence of inducer is >15 min). This means that instead the *inducer must bind directly to repressor protein complexed with the operator*. As indicated in the model on the right, inducer binding must produce a change in the repressor that makes it release the operator. Indeed, addition of IPTG causes an immediate destabilization of the repressor-operator complex *in vitro*.

Binding of the repressor-IPTG complex to the operator can be studied by using greater concentrations of the protein in the methylation protection/enhancement assay. The large amount compensates for the low affinity of the repressor-IPTG complex for the operator. The complex makes exactly the same pattern of contacts with DNA as the free repressor. An analogous result is obtained with mutant repressors whose affinity for operator DNA is increased; they too make the same pattern of contacts.

Overall, a range of repressor variants whose affinities for the operator span seven orders of magnitude all make the same contacts with DNA. *Changes in the affinity of the repressor for DNA must therefore occur by influencing the general conformation of the protein in binding DNA, not by making or breaking one or a few individual bonds.*

*This content is available online at <http://www.ergito.com/main.jsp?bcs=MBIO.3.10.11>*

## THE OPERON

### 3.10.12 The repressor monomer has several domains

#### Key Terms

The **headpiece** is the DNA-binding domain of the *lac* repressor.

#### Key Concepts

- A single repressor subunit can be divided into the N-terminal DNA-binding domain, a hinge, and the core of the protein.
- The DNA-binding domain contains two short  $\alpha$ -helical regions that bind the major groove of DNA.
- The inducer-binding site and the regions responsible for multimerization are located in the core.

The repressor has several domains. The DNA-binding domain occupies residues 1-59. It is known as the **headpiece**. It can be cleaved from the remainder of the monomer, which is known as the *core*, by trypsin. The crystal structure illustrated in **Figure 10.15** offers a more detailed account of these regions (512; 513).

**Figure 10.15** The structure of a monomer of Lac repressor identifies several independent domains. Photograph kindly provided by Mitchell Lewis.

The N-terminus of the monomer consists of two  $\alpha$ -helices separated by a turn. This

is a common DNA-binding motif, known as the HTH (helix-turn-helix); the two  $\alpha$ -helices fit into the major groove of DNA, where they make contacts with specific bases (see *Molecular Biology 3.12.12 Repressor uses a helix-turn-helix motif to bind DNA*). This region is connected by a *hinge* to the main body of the protein. In the DNA-binding form of repressor, the hinge forms a small  $\alpha$ -helix (as shown in the figure); but when the repressor is not bound to DNA, this region is disordered. The HTH and hinge together correspond to the headpiece.

The bulk of the core consists of two regions with similar structures (core domains 1 and 2). Each has a six-stranded parallel  $\beta$ -sheet sandwiched between two  $\alpha$ -helices on either side. The inducer binds in a cleft between the two regions .

At the C-terminus, there is an  $\alpha$ -helix that contains two leucine heptad repeats. This is the oligomerization domain. The oligomerization helices of four monomers associate to maintain the tetrameric structure.

## THE OPERON

### 3.10.13 Repressor is a tetramer made of two dimers

---

#### Key Concepts

- Monomers form a dimer by making contacts between core domain 2 and between the oligomerization helices.
  - Dimers form a tetramer by interactions between the oligomerization helices.
- 

**Figure 10.16** shows the structure of the tetrameric core (using a different modeling system from **Figure 10.15**). It consists in effect of two dimers. The body of the dimer contains a loose interface between the N-terminal regions of the core monomers, a cleft at which inducer binds, and a hydrophobic core (top). The C-terminal regions of each monomer protrude as parallel helices. (The headpiece would join on to the N-terminal regions at the top.) Together the dimers interact to form a tetramer (center) that is held together by a C-terminal bundle of four helices.

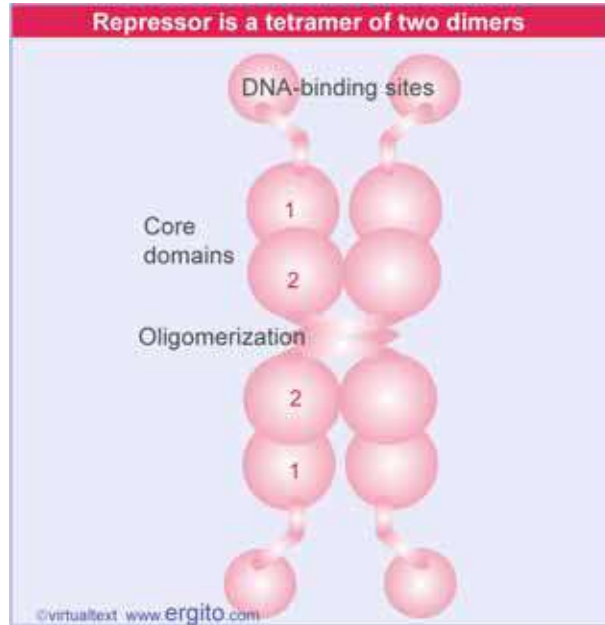

**Figure 10.16** The crystal structure of the core region of Lac repressor identifies the interactions between monomers in the tetramer. Each monomer is identified by a different color. Mutations are colored as: dimer interface - yellow; inducer-binding blue; oligomerization - white and purple. Photographs kindly provided by Alan Friedman.

Sites of mutations are shown by beads on the structure at the bottom.  $lacI^s$  mutations make the repressor unresponsive to the inducer, so that the operon is uninducible. They map in two groups: gray shows those in the inducer-binding cleft, and yellow shows those that affect the dimer interface. The first group abolish the inducer binding site; the second group prevent the effects of inducer binding from being transmitted to the DNA-binding site.  $lacI^{-d}$  mutations that affect oligomerization map in two groups. White shows mutations in core domain 2 that prevent dimer

formation. Purple shows those in the oligomerization helix that prevent tetramer formation from dimers.

From these data we can derive the schematic of **Figure 10.17**, which shows how the monomers are organized into the tetramer. Two monomers form a dimer by means of contacts at core domain 2 and in the oligomerization helix. The dimer has two DNA-binding domains at one end of the structure, and the oligomerization helices at the other end. Two dimers then form a tetramer by interactions at the oligomerization interface.

**Figure 10.17** The repressor tetramer consists of two dimers. Dimers are held together by contacts involving core domain 2 as well as by the oligomerization helix. The dimers are linked into the tetramer by the oligomerization interface.

## THE OPERON

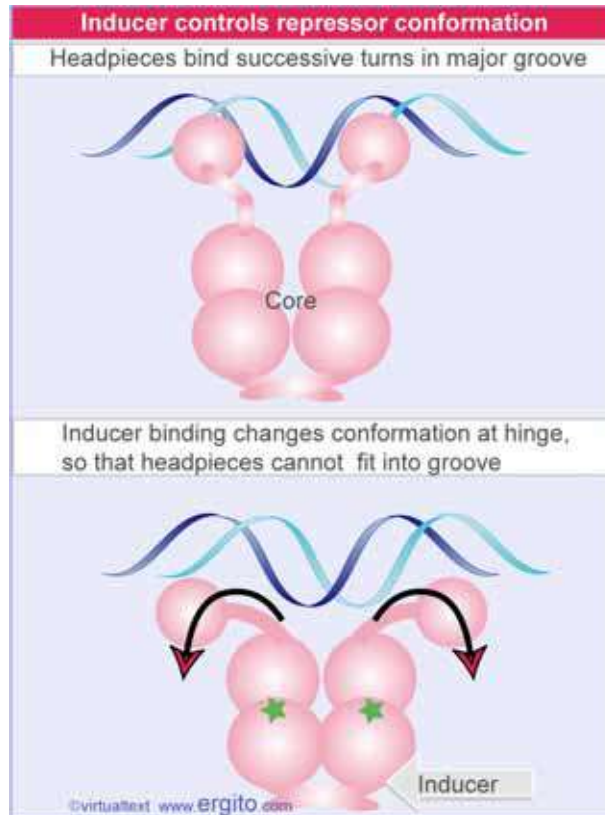

### 3.10.14 DNA-binding is regulated by an allosteric change in conformation

---

#### Key Concepts

- The DNA-binding domain of a monomer inserts into the major groove of DNA.
  - Active repressor has a conformation in which the two DNA-binding domains of a dimer can insert into successive turns of the double helix.
  - Inducer binding changes the conformation so that the two DNA-binding sites are not in the right geometry to make simultaneous contacts.
- 

Early work suggested a model in which the headpiece is relatively independent of the core. It can bind to operator DNA by making the same pattern of contacts with a half-site as intact repressor. However, its affinity for DNA is many orders of magnitude less than that of intact repressor. The reason for the difference is that the dimeric form of intact repressor allows two headpieces to contact the operator simultaneously, each binding to one half-site. **Figure 10.18** shows that the two DNA-binding domains in a dimeric unit contact DNA by inserting into successive turns of the major groove. This enormously increases affinity for the operator.

**Figure 10.18** Inducer changes the structure of the core so that the headpieces of a repressor dimer are no longer in an orientation that permits binding to DNA.

Binding of inducer causes an immediate conformational change in the repressor protein. Binding of two molecules of inducer to the repressor tetramer is adequate to release repression. Binding of inducer changes the orientation of the headpieces relative to the core, with the result that the two headpieces in a dimer can no longer bind DNA simultaneously. This eliminates the advantage of the multimeric repressor, and reduces the affinity for the operator.

*Last updated on 7-29-2002*

*This content is available online at <http://www.ergito.com/main.jsp?bcs=MBIO.3.10.14>*

## THE OPERON

**3.10.15 Mutant phenotypes correlate with the domain structure****Key Concepts**

- Different types of mutations occur in different domains of the repressor subunit.

Mutations in the Lac repressor identified the existence of different domains even before the structure was known (2568; 2569). We can now explain the nature of the mutations more fully by reference to the structure, as summarized in **Figure 10.19** (for review see 2567).

**Figure 10.19** The locations of three type of mutations in lactose repressor are mapped on the domain structure of the protein. Recessive  $lacI^-$  mutants that cannot repress can map anywhere in the protein. Dominant negative  $lacI^{-d}$  mutants that cannot repress map to the DNA-binding domain. Dominant  $lacI^s$  mutants that cannot induce because they do not bind inducer map to core domain 1.

Recessive mutations of the  $lacI^-$  type can occur anywhere in the bulk of the protein. Basically any mutation that inactivates the protein will have this phenotype. The more detailed mapping of mutations on to the crystal structure in **Figure 10.16** identifies specific impairments for some of these mutations, for example, those that affect oligomerization.

The special class of dominant-negative  $lacI^d$  mutations lie in the DNA-binding site

of the repressor subunit (see *Molecular Biology 3.10.9 Multimeric proteins have special genetic properties*). This explains their ability to prevent mixed tetramers from binding to the operator; a reduction in the number of binding sites reduces the specific affinity for the operator. The role of the N-terminal region in specifically binding DNA is shown also by its location as the site of occurrence of "tight binding" mutations. These increase the affinity of the repressor for the operator, sometimes so much that it cannot be released by inducer. They are rare.

Uninducible *lacI<sup>s</sup>* mutations map in a region of the core domain 1 extending from the inducer-binding site to the hinge. One group lies in amino acids that contact the inducer, and these mutations function by preventing binding of inducer. The remaining mutations lie at sites that must be involved in transmitting the allosteric change in conformation to the hinge when inducer binds.

## THE OPERON

### 3.10.16 Repressor binds to three operators and interacts with RNA polymerase

---

#### Key Concepts

- Each dimer in a repressor tetramer can bind an operator, so that the tetramer can bind two operators simultaneously.
  - Full repression requires the repressor to bind to an additional operator downstream or upstream as well as to the operator at *lacZ*.
  - Binding of repressor at the operator stimulates binding of RNA polymerase at the promoter.
- 

The allosteric transition that results from binding of inducer occurs in the repressor dimer. So why is a tetramer required to establish full repression?

Each dimer can bind an operator sequence. This enables the intact repressor to bind to two operator sites simultaneously. In fact, there are two further operator sites in the initial region of the *lac* operon. The original operator, *O1*, is located just at the start of the *lacZ* gene. It has the strongest affinity for repressor. Weaker operator sequences (sometimes called pseudo-operators) are located on either side; *O2* is 410 bp downstream of the startpoint, and *O3* is 83 bp upstream of it.

**Figure 10.20** shows what happens when a DNA-binding protein can bind simultaneously to two separated sites on DNA. The DNA between the two sites forms a loop from a base where the protein has bound the two sites. The length of the loop depends on the distance between the two binding sites. When Lac repressor binds simultaneously to *O1* and to one of the other operators, it causes the DNA between them to form a rather short loop, significantly constraining the DNA structure. A scale model for binding of tetrameric repressor to two operators is shown in **Figure 10.21** (511).

**Figure 10.20** If both dimers in a repressor tetramer bind to DNA, the DNA between the two binding sites is held in a loop.

**Figure 10.21** When a repressor tetramer binds to two operators, the stretch of DNA between them is forced into a tight loop. (The blue structure in the center of the looped DNA represents CAP, another regulator protein that binds in this region). Photograph kindly provided by Mitchell Lewis.

Binding at the additional operators affects the level of repression. Elimination of either the downstream operator ( $O_2$ ) or the upstream operator ( $O_3$ ) reduces the efficiency of repression by 2-4 $\times$ . However, if *both*  $O_2$  and  $O_3$  are eliminated, repression is reduced 100 $\times$ . *This suggests that the ability of the repressor to bind to one of the two other operators as well as to  $O_1$  is important for establishing repression.* We do not know how and why this simultaneous binding increases repression.

We know most about the direct effects of binding of repressor to the operator ( $O_1$ ). It was originally thought that repressor binding would occlude RNA polymerase from binding to the promoter. However, we now know that the two proteins may be bound to DNA simultaneously, and *the binding of repressor actually enhances the binding of RNA polymerase!* But the bound enzyme is prevented from initiating transcription.

The equilibrium constant for RNA polymerase binding alone to the *lac* promoter is  $1.9 \times 10^7 \text{ M}^{-1}$ . The presence of repressor increases this constant by two orders of magnitude to  $2.5 \times 10^9 \text{ M}^{-1}$ . In terms of the range of values for the equilibrium constant  $K_B$  given in **Figure 9.20**, repressor protein effectively converts the formation of closed complex by RNA polymerase at the *lac* promoter from a weak to a strong interaction.

What does this mean for induction of the operon? The higher value for  $K_B$  means that, when occupied by repressor, the promoter is 100 times more likely to be bound by an RNA polymerase. And by allowing RNA polymerase to be bound at the same time as repressor, it becomes possible for transcription to begin immediately upon induction, instead of waiting for an RNA polymerase to be captured.

The repressor in effect causes RNA polymerase to be stored at the promoter. The complex of RNA polymerase-repressor-DNA is blocked at the closed stage. When inducer is added, the repressor is released, and the closed complex is converted to an open complex that initiates transcription. The overall effect of repressor has been to speed up the induction process.

Does this model apply to other systems? The interaction between RNA polymerase, repressor, and the promoter/operator region is distinct in each system, because the operator does not always overlap with the same region of the promoter (see **Figure 10.26**). For example, in phage lambda, the operator lies in the upstream region of the promoter, and binding of repressor occludes the binding of RNA polymerase (see *Molecular Biology 3.12 Phage strategies*). So a bound repressor does not interact with RNA polymerase in the same way in all systems.

## THE OPERON

## 3.10.17 Repressor is always bound to DNA

## Key Concepts

- Proteins that have a high affinity for a specific DNA sequence also have a low affinity for other DNA sequences.
- Every base pair in the bacterial genome is the start of a low-affinity binding-site for repressor.
- The large number of low-affinity sites ensures that all repressor protein is bound to DNA.
- Repressor binds to the operator by moving from a low-affinity site rather than by equilibrating from solution.

Probably all proteins that have a high affinity for a specific sequence also possess a low affinity for any (random) DNA sequence. A large number of low-affinity sites will compete just as well for a repressor tetramer as a small number of high-affinity sites. There is only one high-affinity site in the *E. coli* genome: the operator. The remainder of the DNA provides low-affinity binding sites. Every base pair in the genome starts a new low-affinity site. (Just moving one base pair along the genome, out of phase with the operator itself, creates a low-affinity site!) So there are  $4.2 \times 10^6$  low-affinity sites.

The large number of low-affinity sites means that, even in the absence of a specific binding site, all or virtually all repressor is bound to DNA; none is free in solution. **Figure 10.22** shows how the equation of describing the equilibrium between free repressor and DNA-bound repressor can be rearranged to give the proportion of free repressor.

**Repressor + DNA  $\rightleftharpoons$  Repressor-DNA**

The equilibrium for repressor binding to (random) DNA is described by the equation:

$$K_A = \frac{[\text{Repressor-DNA}]}{[\text{Free repressor}] [\text{DNA}]}$$

The proportion of free repressor is given by rearranging the equation:

$$\frac{[\text{Free repressor}]}{[\text{Repressor-DNA}]} = \frac{1}{K_A \times [\text{DNA}]}$$

©virtualtext www.ergito.com

**Figure 10.22** Repressor binding to random sites is governed by an equilibrium equation.

Applying the parameters for the *lac* system, we find that:

- The nonspecific equilibrium binding constant is  $K_A = 2 \times 10^6 \text{ M}^{-1}$ .
- The concentration of nonspecific binding sites is  $4 \times 10^6$  in a bacterial volume of  $10^{-15}$  liter, which corresponds to  $[\text{DNA}] = 7 \times 10^{-3} \text{ M}$  (a very high concentration).

Substituting these values gives: Free / Bound repressor =  $10^{-4}$ .

*So all but 0.01% of repressor is bound to (random) DNA.* Since there are ~10 molecules of repressor per cell, this is tantamount to saying that there is no free repressor protein. This has an important implication for the interaction of repressor with the operator: it means that we are concerned with the *partitioning* of the repressor on DNA, in which the single high-affinity site of the operator *competes* with the large number of low-affinity sites.

In this competition, the absolute values of the association constants for operator and random DNA are not important; what is important is the ratio of  $K_{sp}$  (the constant for binding a specific site) to  $K_{nsp}$  (the constant for binding any random DNA sequence), that is, the specificity.

---

## THE OPERON

### 3.10.18 The operator competes with low-affinity sites to bind repressor

---

#### Key Concepts

- In the absence of inducer, the operator has an affinity for repressor that is  $10^7\times$  that of a low affinity site.
- The level of 10 repressor tetramers per cell ensures that the operator is bound by repressor 96% of the time.
- Induction reduces the affinity for the operator to  $10^4\times$  that of low-affinity sites, so that only 3% of operators are bound.
- Induction causes repressor to move from the operator to a low-affinity site by direct displacement.
- These parameters could be changed by a reduction in the effective concentration of DNA *in vivo*.

---

We can define the parameters that influence the ability of a regulator protein to saturate its target site by comparing the equilibrium equations for specific and nonspecific binding. As might be expected intuitively, the important parameters are:

- The size of the genome dilutes the ability of a protein to bind specific target sites.
- The specificity of the protein counters the effect of the mass of DNA.
- The amount of protein that is required increases with the total amount of DNA in the genome and decreases with the specificity.
- The amount of protein also must be in reasonable excess of the total number of specific target sites, so we expect regulators with many targets to be found in greater quantities than regulators with fewer targets.

**Figure 10.23** compares the equilibrium constants for *lac* repressor/operator binding with repressor/general DNA binding. From these constants, we can deduce how repressor is partitioned between the operator and the rest of DNA, and what happens to the repressor when inducer causes it to dissociate from the operator.

Repressor specifically binds operator DNA		
DNA	Repressor	Repressor + inducer
Operator	$2 \times 10^{13}$	$2 \times 10^{10}$
Other DNA	$2 \times 10^6$	$2 \times 10^6$
Specificity	$10^7$	$10^4$
Operators bound	96%	3%
Operon is:	repressed	induced

©virtualtext www.ergito.com

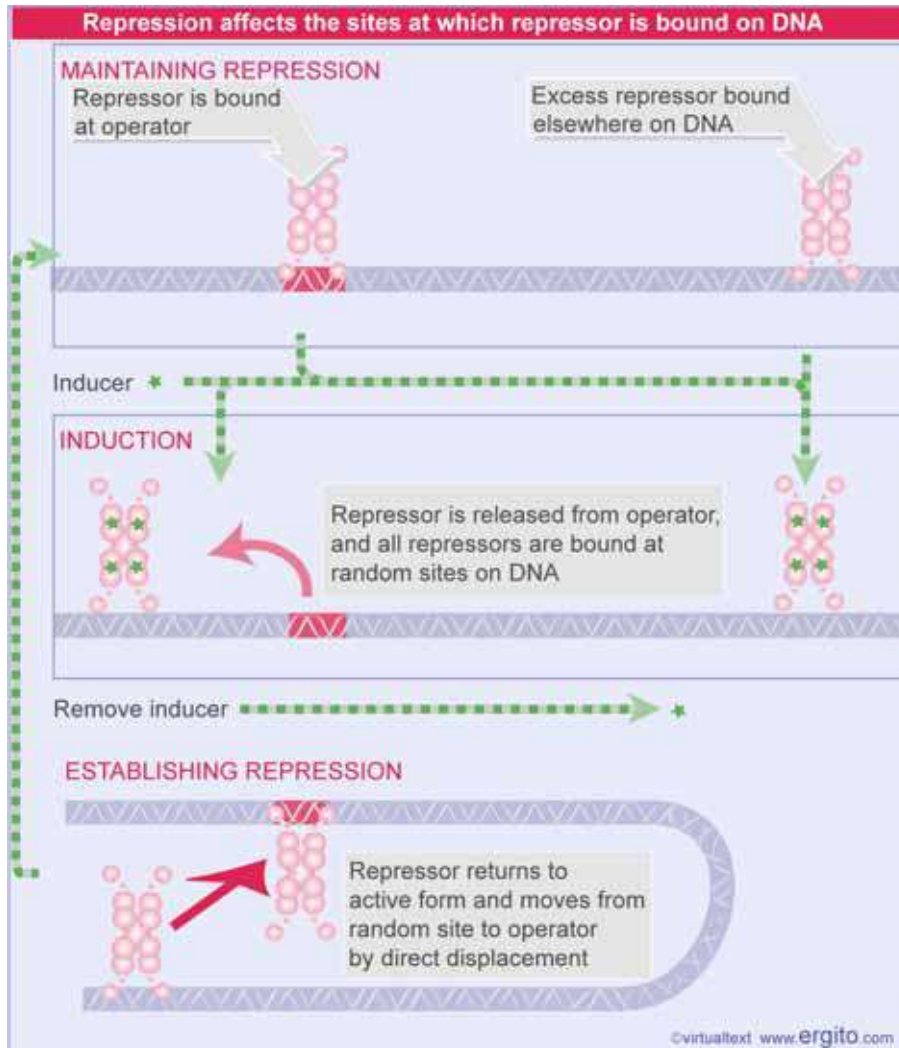

**Figure 10.23** Lac repressor binds strongly and specifically to its operator, but is released by inducer. All equilibrium constants are in  $M^{-1}$ .

Repressor binds  $\sim 10^7$  times better to operator DNA than to any random DNA sequence of the same length. So the operator comprises a single high-affinity site that will compete for the repressor  $10^7$  better than any low-affinity (random) site. How does this ensure that the repressor can maintain effective control of the operon?

Using the specificity, we can calculate the distribution between random sites and the operator, and can express this in terms of occupancy of the operator. If there are 10 molecules of *lac* repressor per cell with a specificity for the operator of  $10^7$ , the operator will be bound by repressor 96% of the time. The role of specificity explains two features of the *lac* repressor-operator interaction:

- When inducer binds to the repressor, the affinity for the operator is reduced by  $\sim 10^3$ -fold. The affinity for general DNA sequences remains unaltered. So the specificity is now only  $10^4$ , which is insufficient to capture the repressor against competition from the excess of  $4.2 \times 10^6$  low-affinity sites. Only 3% of operators would be bound under these conditions.
- Mutations that reduce the affinity of the operator for the repressor by as little as 20-30 $\times$  have sufficient effect to be constitutive. Within the genome, the mutant operators can be overwhelmed by the preponderance of random sites. The occupancy of the operator is reduced to  $\sim 50\%$  if the repressor's specificity is reduced just 10 $\times$ .

The consequence of these affinities is that in an uninduced cell, one tetramer of repressor usually is bound to the operator. All or almost all of the remaining tetramers are bound at random to other regions of DNA, as illustrated in **Figure 10.24**. There are likely to be very few or no repressor tetramers free within the cell.

**Figure 10.24** Virtually all the repressor in the cell is bound to DNA.

The addition of inducer abolishes the ability of repressor to bind specifically at the operator. Those repressors bound at the operator are released, and bind to random (low-affinity) sites. So in an induced cell, the repressor tetramers are "stored" on random DNA sites. In a noninduced cell, a tetramer is bound at the operator, while the remaining repressor molecules are bound to nonspecific sites. *The effect of induction is therefore to change the distribution of repressor on DNA, rather than to generate free repressor.*

When inducer is removed, repressor recovers its ability to bind specifically to the operator, and does so very rapidly. This must involve its movement from a nonspecific "storage" site on DNA. What mechanism is used for this rapid movement? The ability to bind to the operator very rapidly is not consistent with the time that would be required for multiple cycles of dissociation and reassociation with nonspecific sites on DNA. The discrepancy excludes random-hit mechanisms for finding the operator, suggesting that the repressor can move directly from a random site on DNA to the operator. This is the same issue that we encountered previously with the ability of RNA polymerase to find its promoters (see **Figure 9.22** and

**Figure 9.23).** The same solution is likely: movement could be accomplished by direct displacement from site to site (as indicated in **Figure 10.24**). A displacement reaction might be aided by the presence of more binding sites per tetramer (four) than are actually needed to contact DNA at any one time (two).

The parameters involved in finding a high-affinity operator in the face of competition from many low-affinity sites pose a dilemma for repressor. Under conditions of repression, there must be high specificity for the operator. But under conditions of induction, this specificity must be relieved. Suppose, for example, that there were 1000 molecules of repressor per cell. Then only 0.04% of operators would be free under conditions of repression. But upon induction only 40% of operators would become free. We therefore see an inverse correlation between the ability to achieve complete repression and the ability to relieve repression effectively. We assume that the number of repressors synthesized *in vivo* has been subject to selective forces that balance these demands.

The difference in expression of the lactose operon between its induced and repressed states *in vivo* is actually  $10^3\times$ . In other words, even when inducer is absent, there is a basal level of expression of  $\sim 0.1\%$  of the induced level. This would be reduced if there were more repressor protein present, increased if there were less. So it could be impossible to establish tight repression if there were fewer repressors than the 10 found per cell; and it might become difficult to induce the operon if there were too many (514).

It is possible to introduce the *lac* operator-repressor system into the mouse. When the *lac* operator is connected to a tyrosinase reporter gene, the enzyme is induced by the addition of IPTG (2240). This means that the repressor is finding its target in a genome  $10^3$  times larger than that of *E. coli*. Induction occurs at approximately the same concentration of IPTG as in bacteria. However, we do not know the concentration of Lac repressor and how effectively the target is induced.

In order to extrapolate *in vivo* from the affinity of a DNA-protein interaction *in vitro*, we need to know the effective concentration of DNA *in vivo*. The "effective concentration" differs from the mass/volume because of several factors. The effective concentration is increased, for example, by molecular crowding, which occurs when polyvalent cations neutralize  $\sim 90\%$  of the charges on DNA, and the nucleic acid collapses into condensed structures. The major force that decreases the effective concentration is the inaccessibility of DNA that results from occlusion or sequestration by DNA-binding proteins.

One way to determine the effective concentration is to compare the rate of a reaction *in vitro* and *in vivo* that depends on DNA concentration. This has been done using intermolecular recombination between two DNA molecules. To provide a control, the same reaction is followed as an intramolecular recombination, that is, the two recombining sites are presented on the same DNA molecule. We assume that concentration is the same *in vivo* and *in vitro* for the *intramolecular* reaction, and therefore any difference in the ratio of intermolecular/ intramolecular recombination rates can be attributed to a change in the effective concentration *in vivo*. The results of such a comparison suggest that the effective concentration of DNA is reduced  $>10$ -fold *in vivo* (516).

This could affect the rates of reactions that depend on DNA concentration, including DNA recombination, and protein-DNA binding. It emphasizes the problem encountered by all DNA-binding proteins in finding their targets with sufficient speed, and reinforces the conclusion that diffusion is not adequate (see **Figure 9.22**).

## THE OPERON

### 3.10.19 Repression can occur at multiple loci

---

#### Key Terms

**Autogenous** control describes the action of a gene product that either inhibits (negative autogenous control) or activates (positive autogenous control) expression of the gene coding for it.

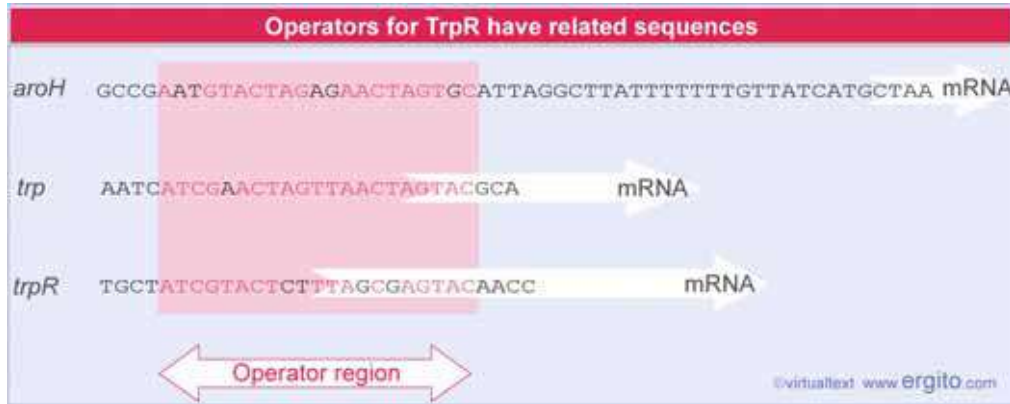

#### Key Concepts

- A repressor will act on all loci that have a copy of its target operator sequence.
- 

The *lac* repressor acts only on the operator of the *lacZYA* cluster. However, some repressors control dispersed structural genes by binding at more than one operator. An example is the *trp* repressor, which controls three unlinked sets of genes:

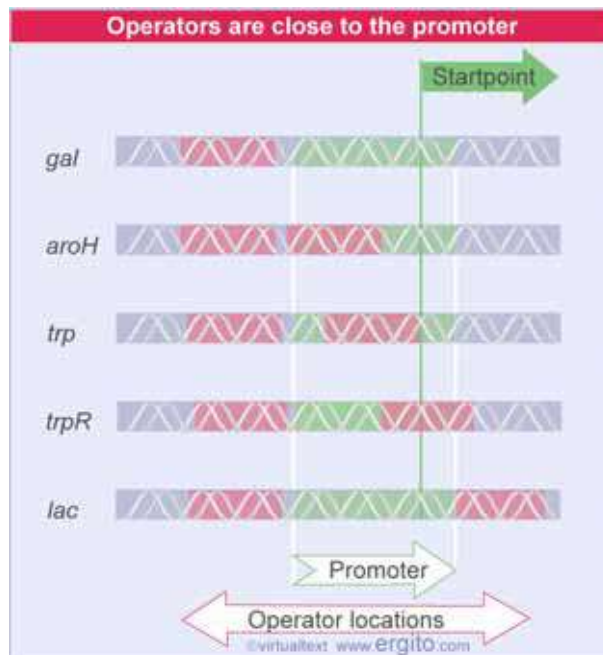

- An operator at the cluster of structural genes *trpEDBCA* controls coordinate synthesis of the enzymes that synthesize tryptophan from chorismic acid.
- An operator at another locus controls the *aroH* gene, which codes for one of the three enzymes that catalyze the initial reaction in the common pathway of aromatic amino acid biosynthesis.
- The *trpR* regulator gene is repressed by its own product, the *trp* repressor. So the repressor protein acts to reduce its own synthesis. This circuit is an example of **autogenous** control. Such circuits are quite common in regulatory genes, and may be either negative or positive (see *Molecular Biology 3.11.11 r-protein synthesis is controlled by autogenous regulation* and *Molecular Biology 3.12.9 Repressor maintains an autogenous circuit*).

A related 21 bp operator sequence is present at each of the three loci at which the *trp* repressor acts. The conservation of sequence is indicated in **Figure 10.25**. Each operator contains appreciable (but not identical) dyad symmetry. The features conserved at all three operators include the important points of contact for *trp* repressor. This explains how one repressor protein acts on several loci: *each locus has a copy of a specific DNA-binding sequence recognized by the repressor* (just as each promoter shares consensus sequences with other promoters).

**Figure 10.25** The *trp* repressor recognizes operators at three loci. Conserved bases are shown in red. The location of the startpoint and mRNA varies, as indicated by the white arrows.

**Figure 10.26** summarizes the variety of relationships between operators and promoters. A notable feature of the dispersed operators recognized by TrpR is their presence at different locations within the promoter in each locus. In *trpR* the operator lies between positions -12 and +9, while in the *trp* operon it occupies positions -23 to -3, but in the *aroH* locus it lies farther upstream, between -49 and -29. In other cases, the operator lies downstream from the promoter (as in *lac*), or apparently just upstream of the promoter (as in *gal*, where the nature of the repressive effect is not quite clear). The ability of the repressors to act at operators whose positions are different in each target promoter suggests that there could be differences in the exact mode of repression, the common feature being that RNA polymerase is prevented from initiating transcription at the promoter.

**Figure 10.26** Operators may lie at various positions relative to the promoter.

## THE OPERON

### 3.10.20 Summary

---

Transcription is regulated by the interaction between *trans*-acting factors and *cis*-acting sites. A *trans*-acting factor is the product of a regulator gene. It is usually protein but can be RNA. Because it diffuses in the cell, it can act on any appropriate target gene. A *cis*-acting site in DNA (or RNA) is a sequence that functions by being recognized *in situ*. It has no coding function and can regulate only those sequences that are physically contiguous with it. Bacterial genes coding for proteins whose functions are related, such as successive enzymes in a pathway, may be organized in a cluster that is transcribed into a polycistronic mRNA from a single promoter. Control of this promoter regulates expression of the entire pathway. The unit of regulation, containing structural genes and *cis*-acting elements, is called the operon.

Initiation of transcription is regulated by interactions that occur in the vicinity of the promoter. The ability of RNA polymerase to initiate at the promoter is prevented or activated by other proteins. Genes that are active unless they are turned off are said to be under negative control. Genes that are active only when specifically turned on are said to be under positive control. The type of control can be determined by the dominance relationships between wild type and mutants that are constitutive/derepressed (permanently on) or uninducible/super-repressed (permanently off).

A repressor protein prevents RNA polymerase either from binding to the promoter or from activating transcription. The repressor binds to a target sequence, the operator, that usually is located around or upstream of the startpoint. Operator sequences are short and often are palindromic. The repressor is often a homomultimer whose symmetry reflects that of its target.

The ability of the repressor protein to bind to its operator is regulated by a small molecule. An inducer prevents a repressor from binding; a corepressor activates it. Binding of the inducer or corepressor to its site produces a change in the structure of the DNA-binding site of the repressor. This allosteric reaction occurs in both free repressor proteins and directly in repressor proteins already bound to DNA.

The lactose pathway operates by induction, when an inducer  $\beta$ -galactoside prevents the repressor from binding its operator; transcription and translation of the *lacZ* gene then produce  $\beta$ -galactosidase, the enzyme that metabolizes  $\beta$ -galactosides. The tryptophan pathway operates by repression; the corepressor (tryptophan) activates the repressor protein, so that it binds to the operator and prevents expression of the genes that code for the enzymes that biosynthesize tryptophan. A repressor can control multiple targets that have copies of an operator consensus sequence.

A protein with a high affinity for a particular target sequence in DNA has a lower affinity for all DNA. The ratio defines the specificity of the protein. Because there are many more nonspecific sites (any DNA sequence) than specific target sites in a genome, a DNA-binding protein such as a repressor or RNA polymerase is "stored" on DNA; probably none or very little is free. The specificity for the target sequence must be great enough to counterbalance the excess of nonspecific sites over specific

sites. The balance for bacterial proteins is adjusted so that the amount of protein and its specificity allow specific recognition of the target in "on" conditions, but allow almost complete release of the target in "off" conditions.

---

## REGULATORY CIRCUITS

### 3.11.1 Introduction

---

The basic concept of genetic regulation in bacteria is that the expression of a gene may be controlled by a regulator that interacts with a specific sequence or structure in DNA or mRNA at some stage prior to the synthesis of protein. This is an extremely flexible idea with many ramifications. The stage of expression that is controlled can involve transcription, when the target for regulation is DNA; or it can be at translation, when the target for regulation is RNA. When transcription is involved, the level of control can be at initiation or at termination. The regulator can be a protein or an RNA. "Controlled" can mean that the regulator turns off (represses) the target or that it turns on (activates) the target. Expression of many genes can be coordinately controlled by a single regulator gene on the principle that each target contains a copy of the sequence or structure that the regulator recognizes. Regulators may themselves be regulated, most typically in response to small molecules whose supply responds to environmental conditions. Regulators may be controlled by other regulators to make complex circuits.

Let's compare the ways that different types of regulators work.

Protein regulators work on the principle of allostery (see *Molecular Biology Supplement 32.7 Allostery*). The protein has two binding sites, one for a nucleic acid target, the other for a small molecule. Binding of the small molecule to its site changes the conformation in such a way as to alter the affinity of the other site for the nucleic acid. The way in which this happens is known in detail for the Lac repressor (see *Molecular Biology 3.10.14 DNA-binding is regulated by an allosteric change in conformation*). Protein regulators are often multimeric, with a symmetrical organization that allows two subunits to contact a palindromic target on DNA. This can generate cooperative binding effects that create a more sensitive response to regulation.

RNA regulators use changes in secondary structure as the guiding principle. An RNA regulator recognizes its target by the familiar principle of complementary base pairing. **Figure 11.1** shows that the regulator is usually a small RNA molecule with extensive secondary structure, but with a single-stranded region(s) that is complementary to a single-stranded region in its target. The formation of a double helical region between regulator and target can have two types of consequence:

**Figure 11.1** A regulator RNA is a small RNA with a single-stranded region that can pair with a single-stranded region in a target RNA.

- Formation of the double helical structure may itself be sufficient. In some cases, protein(s) can bind only to the single-stranded form of the target sequence, and are therefore prevented by acting by duplex formation. In other cases, the duplex region becomes a target for binding, for example, by nucleases that degrade the RNA and therefore prevent its expression.
- Duplex formation may be important because it sequesters a region of the target RNA that would otherwise participate in some alternative secondary structure.

Going beyond the interactions in which a protein or RNA regulates expression of a single gene, we find that bacteria have responses in which the expression of many genes is coordinated. The simplest form of regulating multiple genes occurs when they all have a copy of the same *cis*-acting regulatory elements. Genes that have a copy of the same operator sequence are coordinately repressed by a single repressor protein. Genes that have the same type of promoter are coordinately activated by the production of a sigma factor that causes RNA polymerase to use that promoter.

Regulatory networks are created when one regulator is required for the production of another. This happens in situations in which an ordered temporal expression of genes is required, for example, during phage infection (see *Molecular Biology 3.12.3 Lytic development is controlled by a cascade*) or during the development of a new cell type, such as a spore (see *Molecular Biology 3.9.18 Sigma factors may be organized into cascades*). These use one of the simplest relationships between regulators, in which one regulator is necessary for expression of the next regulator in a series, creating a cascade.

Another type of relationship occurs when one regulator directly regulates the activity of another regulator. For example, a protein that represses or activates expression of a gene may itself be inhibited by an "anti-regulator" that responds to some other signal. **Figure 11.2** shows an example. A series of such relationships can be

extended indefinitely. Some circuits are controlled by a series of regulators each of which antagonizes another. Such circuits allow the cell to control the target set of genes in response to multiple stimuli, since each stimulus can feed into the regulatory circuit at a different point.

**Figure 11.2** A protein that antagonizes a repressor can turn a gene on.

A special type of circuit is created when a protein regulates expression of the gene that codes for it. This is called autogenous control. It allows a protein to regulate its own level of expression without reference to any other circuit. It is often used for regulating levels of proteins that are assembled into macromolecular complexes.

## REGULATORY CIRCUITS

### 3.11.2 Distinguishing positive and negative control

---

#### Key Terms

An **activator** is a protein that stimulates the expression of a gene, typically by acting at a promoter to stimulate RNA polymerase. In eukaryotes, the sequence to which it binds in the promoter is called a response element.

An **inducible** operon is expressed only in the presence of a specific small molecule (the inducer).

A **repressible** operon is expressed unless the small molecule co-repressor is present.

The **derepressed** state describes a gene that is turned on because a small molecule corepressor is absent. It has the same effect as the induced state that is produced by a small molecule inducer for a gene that is regulated by induction. In describing the effect of a mutation, derepressed and constitutive have the same meaning.

**Super-repressed** is a mutant condition in which a repressible operon cannot be de-repressed, so it is always turned off.

The level of response from a system in the absence of a stimulus is its **basal level**. (The basal level of transcription of a gene is the level that occurs in the absence of any specific activation.)

#### Key Concepts

- Induction can be achieved by inactivating a repressor or activating an activator.
- Repression can be achieved by activating a repressor or inactivating an activator.

---

Positive and negative control systems are defined by the response of the operon when no regulator protein is present. The characteristics of the two types of control system are mirror images.

*Genes under negative control are expressed unless they are switched off by a repressor protein (see **Figure 10.2**). Any action that interferes with gene expression can provide a negative control. Typically a repressor protein either binds to DNA to prevent RNA polymerase from initiating transcription, or binds to mRNA to prevent a ribosome from initiating translation.*

Negative control provides a fail-safe mechanism: if the regulator protein is inactivated, the system functions and so the cell is not deprived of these enzymes. It is easy to see how this might evolve. Originally a system functions constitutively, but then cells able to interfere specifically with its expression acquire a selective advantage by virtue of their increased efficiency.

*For genes under positive control, expression is possible only when an active regulator protein is present. The mechanism for controlling an individual operon is*

an exact counterpart of negative control, but instead of *interfering* with initiation, the regulator protein is *essential* for it. It interacts with DNA and with RNA polymerase to *assist the initiation event* (see **Figure 10.3**). The use of sigma factors to regulate transcription formally is an example of positive control. A positive regulator protein that responds to a small molecule is usually called an **activator**.

It is less obvious how positive control evolved, since the cell must have had the ability to express the regulated genes even before any control existed. Presumably some component of the control system must have changed its role. Perhaps originally it was used as a regular part of the apparatus for gene expression; then later it became restricted to act only in a particular system or systems.

Operons are defined as **inducible** or **repressible** by the nature of their response to the small molecule that regulates their expression. Inducible operons function only in the *presence* of the small-molecule inducer. Repressible operons function only in the *absence* of the small-molecule corepressor (so called to distinguish it from the repressor protein).

The terminology used for repressible systems describes the active state of the operon as **derepressed**; this has the same meaning as *induced*. The condition in which a (mutant) operon cannot be derepressed is sometimes called **super-repressed**; this is the exact counterpart of *uninducible*.

Either positive or negative control could be used to achieve either induction or repression by utilizing appropriate interactions between the regulator protein and the small-molecule inducer or corepressor. **Figure 11.3** summarizes four simple types of control circuit. Induction is achieved when an inducer inactivates a repressor protein or activates an activator protein. Repression is accomplished when a corepressor activates a repressor protein or inactivates an activator protein.

**Figure 11.3** Control circuits are versatile and can be designed to allow positive or negative control of induction or repression.

The *trp* operon is a repressible system. Tryptophan is the end product of the reactions catalyzed by a series of biosynthetic enzymes. Both the activity and the synthesis of the tryptophan enzymes are controlled by the level of tryptophan in the cell.

Tryptophan functions as a corepressor that activates a repressor protein. This is the classic mechanism for repression, as seen in **Figure 11.3** (lower left). In conditions when the supply of tryptophan is plentiful, the operon is repressed because the repressor protein-corepressor complex is bound at the operator. When tryptophan is in short supply, the corepressor is inactive, therefore has reduced specificity for the operator, and is stored elsewhere on DNA.

Deprivation of repressor causes ~70-fold increase in the frequency of initiation events at the *trp* promoter. Even under repressing conditions, the structural genes

continue to be expressed at a low **basal level** (sometimes also called the repressed level). The efficiency of repression at the operator is much lower than in the *lac* operon (where the basal level is only ~1/1000 of the induced level).

We have treated both induction and repression as phenomena that rely upon allosteric changes induced in regulator proteins by small molecules. Other types of interactions also can be used to control the activities of regulator proteins. One example is OxyR, a transcriptional activator of genes induced by hydrogen peroxide. The OxyR protein is directly activated by oxidation, so it provides a sensitive measure of oxidative stress. Another common type of signal is phosphorylation of a regulator protein.

*This content is available online at <http://www.ergito.com/main.jsp?bcs=MBIO.3.11.2>*

---

## REGULATORY CIRCUITS

### 3.11.3 Glucose repression controls use of carbon sources

---

#### Key Terms

**Glucose repression (Catabolite repression)** describes the decreased expression of many bacterial operons that results from addition of glucose.

**Inducer exclusion** describes the inhibition of uptake of other carbon sources into the cell that is caused by uptake of glucose.

#### Key Concepts

- *E. coli* uses glucose in preference to other carbon sources when it has a choice.
- Glucose prevents uptake of alternative carbon sources from the medium.
- Exclusion of the alternative carbon sources from the cell prevents expression of the operons coding for the enzymes that metabolize them.

---

Bacteria have distinct preferences among potential carbon sources when they are offered a choice. When glucose is available as an energy source, it is used in preference to other sugars. So when *E. coli* finds (for example) both glucose and lactose in the medium, it metabolizes the glucose and represses the use of lactose. The phenomenon of **glucose repression** follows from the ability of glucose to prevent the use of alternative carbon sources. It describes the general repression of transcription of the operons (such as *lac*, *gal*, and *ara*) coding for the enzymes required to metabolize the alternative carbon sources. The same effect is found in many bacteria, although different molecular mechanisms may be responsible in different classes of bacteria (for review see 2563).

The basis for glucose repression in *E. coli* appears to be largely indirect. It involves two mechanisms:

- **Inducer exclusion** describes the ability of glucose to prevent alternative carbon sources from being taken up from the medium. These include the inducers of the operons coding for the alternative metabolic systems. As a result of the exclusion of the small molecule inducers from the cell, the operons cannot be transcribed.
- A general system for activating many operons is provided by the activator protein CRP, which is activated by the small molecule cyclic AMP (see *Molecular Biology 3.11.5 CRP functions in different ways in different target operons*). It was thought for many years that this system is inactivated by glucose, with the result that its target operons are not expressed under conditions of glucose repression. However, this view has been challenged recently, and the exact way in which it is controlled by glucose is not clear.

**Figure 11.4** outlines the interactions involved in inducer exclusion. The key molecular component in inducer exclusion is the PTS (phosphoenolpyruvate:glycose phosphotransferase system), a complex of proteins in the bacterial membrane, which simultaneously phosphorylates and transports sugars into the cell (for review see 2561). One of the proteins of this complex ( $\text{IIA}^{\text{Glc}}$ , which is coded by the *crr* gene) becomes dephosphorylated as a result of glucose transport. It then binds to the Lac permease and prevents it from importing lactose into the cell.

**Figure 11.4** Glucose is imported through the Pts system. This causes the Lac permease to be inactivated. The absence of lactose means that the *lac* repressor switches off the operon. When glucose is absent, lactose can be imported, and inactivates the *lac* repressor, so the operon is switched on.

## REGULATORY CIRCUITS

### 3.11.4 Cyclic AMP is an inducer that activates CRP to act at many operons

---

#### Key Terms

**CRP activator (CAP activator)** is a positive regulator protein activated by cyclic AMP. It is needed for RNA polymerase to initiate transcription of many operons of *E. coli*.

**Adenylate cyclase** is an enzyme that uses ATP as a substrate to generate cyclic AMP, in which 5' and 3' positions of the sugar ring are connected via a phosphate group.

#### Key Concepts

- CRP is an activator protein that binds to a target sequence at a promoter.
- A dimer of CRP is activated by a single molecule of cyclic AMP.

---

So far we have dealt with the promoter as a DNA sequence that is competent to bind RNA polymerase, which then initiates transcription. But there are some promoters at which RNA polymerase cannot initiate transcription without assistance from an ancillary protein. Such proteins are positive regulators, because their presence is necessary to switch on the transcription unit. Typically the activator overcomes a deficiency in the promoter, for example, a poor consensus sequence at  $-35$  or  $-10$ .

One of the most widely acting activators is a protein called **CRP activator** that controls the activity of a large set of operons in *E. coli*. The protein is a positive control factor whose presence is necessary to initiate transcription at dependent promoters. CRP is active *only in the presence of cyclic AMP*, which behaves as the classic small-molecule inducer (see **Figure 11.3**; upper right).

Cyclic AMP is synthesized by the enzyme **adenylate cyclase**. The reaction uses ATP as substrate and introduces a 3'–5' link via phosphodiester bonds, generating the structure drawn in **Figure 11.5**. Mutations in the gene coding for adenylate cyclase (*cya*) do not respond to changes in glucose levels.

**Figure 11.5** Cyclic AMP has a single phosphate group connected to both the 3' and 5' positions of the sugar ring.

The level of cyclic AMP is inversely related to the level of glucose. The basis for this effect lies with the same component of the Pts system that is responsible for controlling lactose uptake. The phosphorylated form of protein IIA<sup>Glc</sup> stimulates adenylate cyclase. When glucose is imported, the dephosphorylation of IIA<sup>Glc</sup> leads to a fall in adenylate cyclase activity.

**Figure 11.6** shows that reducing the level of cyclic AMP renders the (wild-type) protein unable to bind to the control region, which in turn prevents RNA polymerase from initiating transcription. So the effect of glucose in reducing cyclic AMP levels is to deprive the relevant operons of a control factor necessary for their expression.

**Figure 11.6** By reducing the level of cyclic AMP, glucose inhibits the transcription of operons that require CRP activity.

## REGULATORY CIRCUITS

### 3.11.5 CRP functions in different ways in different target operons

#### Key Concepts

- CRP-binding sites lie at highly variable locations relative to the promoter.
- CRP interacts with RNA polymerase, but the details of the interaction depend on the relative locations of the CRP-binding site and the promoter.

The CRP factor binds to DNA, and complexes of cyclic AMP·CRP·DNA can be isolated at each promoter at which it functions. The factor is a dimer of two identical subunits of 22.5 kD, which can be activated by a single molecule of cyclic AMP. A CRP monomer contains a DNA-binding region and a transcription-activating region (for review see 99).

A CRP dimer binds to a site of ~22 bp at a responsive promoter. The binding sites include variations of the consensus sequence given in **Figure 11.7**. Mutations preventing CRP action usually are located within the well conserved pentamer **TGTGA**, which appears to be the essential element in recognition. CRP binds most **ACACT**

strongly to sites that contain two (inverted) versions of the pentamer, because this enables both subunits of the dimer to bind to the DNA. Many binding sites lack the second pentamer, however, and in these the second subunit must bind a different sequence (if it binds to DNA). The hierarchy of binding affinities for CRP helps to explain why different genes are activated by different levels of cyclic AMP *in vivo*.

**Figure 11.7** The consensus sequence for CRP contains the well conserved pentamer TGTGA and (sometimes) an inversion of this sequence (TCANA).

The action of CRP has the curious feature that its binding sites lie at different locations relative to the startpoint in the various operons that it regulates. And the TGTGA pentamer may lie in either orientation. The three examples summarized in **Figure 11.8** encompass the range of locations:

**Figure 11.8** The CRP protein can bind at different sites relative to RNA polymerase.

- The CRP-binding site is adjacent to the promoter, as in the *lac* operon, in which the region of DNA protected by CRP is centered on  $-61$ . It is possible that two dimers of CRP are bound. The binding pattern is consistent with the presence of CRP largely on one face of DNA, the same face that is bound by RNA polymerase. This location would place the two proteins just about in reach of each other.
- Sometimes the CRP-binding site lies within the promoter, as in the *gal* locus, where the CRP-binding site is centered on  $-41$ . It is likely that only a single CRP dimer is bound, probably in quite intimate contact with RNA polymerase, since the CRP-binding site extends well into the region generally protected by the RNA polymerase.
- In other operons, the CRP-binding site lies well upstream of the promoter. In the *ara* region, the binding site for a single CRP is the farthest from the startpoint, centered at  $-92$ .

Dependence on CRP is related to the intrinsic efficiency of the promoter. No CRP-dependent promoter has a good  $-35$  sequence and some also lack good  $-10$  sequences. In fact, we might argue that effective control by CRP would be difficult if the promoter had effective  $-35$  and  $-10$  regions that interacted independently with RNA polymerase.

There are in principle two ways in which CRP might activate transcription: it could interact directly with RNA polymerase; or it could act upon DNA to change its structure in some way that assists RNA polymerase to bind. In fact, CRP has effects upon both RNA polymerase and DNA (for review see 101).

Binding sites for CRP at most promoters resemble either *lac* (centered at  $-61$ ) or *gal* (centered at  $-41$  bp). The basic difference between them is that in the first type (called class I) the CRP-binding site is entirely upstream of the promoter, whereas in the second type (called class II) the CRP-binding site overlaps the binding site for RNA polymerase. (The interactions at the *ara* promoter may be different.)

In both types of promoter, the CRP binding site is centered an integral number of turns of the double helix from the startpoint. This suggests that CRP is bound to the same face of DNA as RNA polymerase. However, the nature of the interaction between CRP and RNA polymerase is different at the two types of promoter.

When the  $\alpha$  subunit of RNA polymerase has a deletion in the C-terminal end, transcription appears normal except for the loss of ability to be activated by CRP. CRP has an "activating region", which consists of a small exposed loop of  $\sim 10$  amino acids, that is required for activating both types of its promoters. The activating region is a small patch of amino acids that interacts directly with the  $\alpha$  subunit of RNA polymerase to stimulate the enzyme (2565). At class I promoters, this interaction is sufficient. At class II promoters, a second interaction is also required, involving another region of CRP and the N-terminal region of the RNA polymerase  $\alpha$  subunit (2564).

Experiments using CRP dimers in which only one of the subunits has a functional transcription-activating region shows that, when CRP is bound at the *lac* promoter, only the activating region of the subunit nearer the startpoint is required, presumably because it touches RNA polymerase (2566). This offers an explanation for the lack of dependence on the orientation of the binding site: the dimeric structure of CRP ensures that one of the subunits is available to contact RNA polymerase, no matter which subunit binds to DNA and in which orientation.

The effect upon RNA polymerase binding depends on the relative locations of the two proteins. At class I promoters, where CRP binds adjacent to the promoter, it increases the rate of initial binding to form a closed complex. At class II promoters, where CRP binds within the promoter, it increases the rate of transition from the closed to open complex.

## REGULATORY CIRCUITS

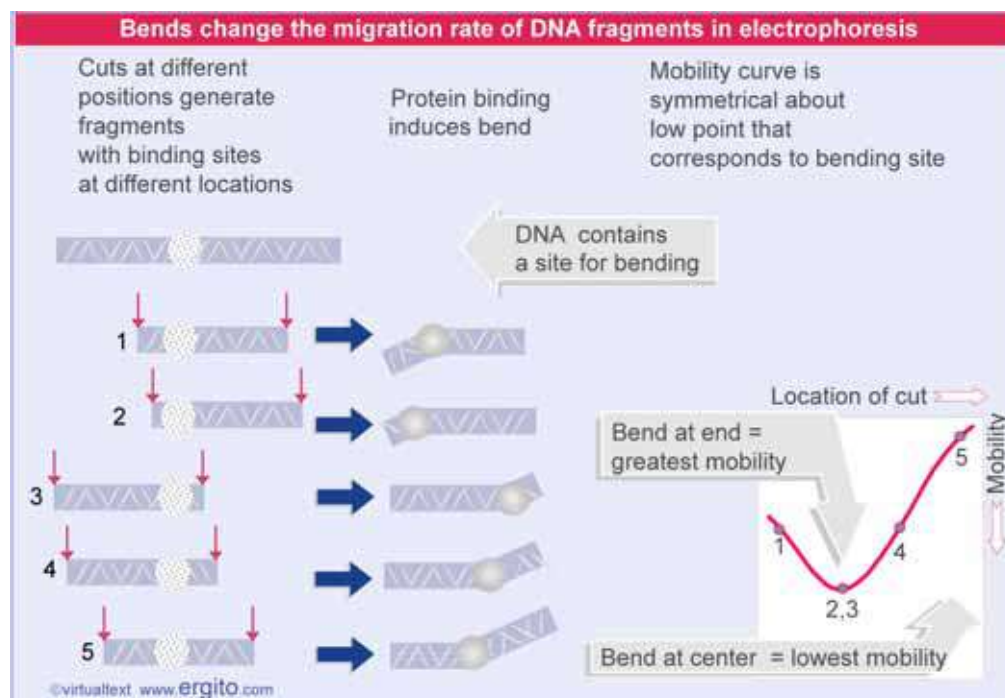

### 3.11.6 CRP bends DNA

#### Key Concepts

- CRP introduces a 90° bend into DNA at its binding site.

The structure of the CRP-DNA complex is interesting: *the DNA has a bend*. Proteins may distort the double helical structure of DNA when they bind, and several regulator proteins induce a bend in the axis.

**Figure 11.9** illustrates a technique that can be used to measure the extent and location of a bend. A target sequence containing the site is cut with different restriction enzymes to generate a set of fragments all of the same length, but each containing the protein-binding site at a different location.

**Figure 11.9** Gel electrophoresis can be used to analyze bending.

The fragments move at different speeds in an electrophoretic gel, depending on the position of the bend. (If there is no bend, all fragments move at the same rate.) The greatest impediment to motion, causing the lowest mobility, happens when the bend is in the center of the DNA fragment. The least impediment to motion, allowing the greatest mobility, happens when the bend is at one end.

The results are analyzed by plotting mobility against the site of restriction cutting. The low point on the curve identifies the situation in which the restriction enzyme

has cut the sequence immediately adjacent to the site of bending.

For the interaction of CRP with the *lac* promoter, this point lies at the center of dyad symmetry. The bend is quite severe,  $>90^\circ$ , as illustrated in the model of **Figure 11.10**. There is therefore a dramatic change in the organization of the DNA double helix when CRP protein binds. The mechanism of bending is to introduce a sharp kink within the TGTGA consensus sequence. When there are inverted repeats of the consensus, the two kinks in each copy present in a palindrome cause the overall  $90^\circ$  bend. It is possible that the bend has some direct effect upon transcription, but it could be the case that it is needed simply to allow CRP to contact RNA polymerase at the promoter (518).

**Figure 11.10** CRP bends DNA  $>90^\circ$  around the center of symmetry.

Whatever the exact means by which CRP activates transcription at various promoters, it accomplishes the same general purpose: to turn off alternative metabolic pathways when they become unnecessary because the cell has an adequate supply of glucose. Again, this makes the point that coordinate control, of either negative or positive type, can extend over dispersed loci by repetition of binding sites for the regulator protein.

## REGULATORY CIRCUITS

### 3.11.7 The stringent response produces (p)ppGpp

---

#### Key Terms

**Stringent response** refers to the ability of a bacterium to shut down synthesis of tRNA and ribosomes in a poor-growth medium.

An **alarmone** is a small molecule in bacteria that is produced as a result of stress and which acts to alter the state of gene expression. The unusual nucleotides ppGpp and pppGpp are examples.

**ppGpp** is guanosine tetraphosphate. Diphosphate groups are attached to both the 5' and 3' positions.

**pppGpp** is a guanosine pentaphosphate, with a triphosphate attached to the 5' position and a diphosphate attached to the 3' position.

#### Key Concepts

- Poor growth conditions cause bacteria to produce the small molecule regulators ppGpp and pppGpp.

---

When bacteria find themselves in such poor growth conditions that they lack a sufficient supply of amino acids to sustain protein synthesis, they shut down a wide range of activities. This is called the **stringent response**. We can view it as a mechanism for surviving hard times: the bacterium husbands its resources by engaging in only the minimum of activities until nutrient conditions improve, when it reverses the response and again engages its full range of metabolic activities.

The stringent response causes a massive (10-20×) reduction in the synthesis of rRNA and tRNA. This alone is sufficient to reduce the total amount of RNA synthesis to ~5-10% of its previous level. The synthesis of certain mRNAs is reduced, leading to an overall reduction of ~3× in mRNA synthesis. The rate of protein degradation is increased. Many metabolic adjustments occur, as seen in reduced synthesis of nucleotides, carbohydrates, lipids, etc.

The stringent response causes the accumulation of two unusual nucleotides (sometimes called **alarmones**). **ppGpp** is guanosine tetraphosphate, with diphosphates attached to both 5' and 3' positions. **pppGpp** is guanosine pentaphosphate, with a 5' triphosphate group and a 3' diphosphate. These nucleotides are typical small-molecule effectors that function by binding to target proteins to alter their activities. Sometimes they are known collectively as (p)ppGpp (520; for review see 94).

(p)ppGpp functions to regulate coordinately a large number of cellular activities. Its production is controlled in two ways. A drastic increase in (p)ppGpp is triggered by the stringent response. And there is also a general inverse correlation between (p)ppGpp levels and the bacterial growth rate, which is controlled by some unknown means.

## REGULATORY CIRCUITS

### 3.11.8 (p)ppGpp is produced by the ribosome

---

#### Key Terms

The **idling reaction** results in the production of pppGpp and ppGpp by ribosomes when an uncharged tRNA is present in the A site; this triggers the stringent response.

**Relaxed mutants** of *E. coli* do not display the stringent response to starvation for amino acids (or other nutritional deprivation).

The **stringent factor** is the protein RelA, which is associated with ribosomes. It synthesizes ppGpp and pppGpp when uncharged aminoacyl-tRNA enters the A site.

#### Key Concepts

- The stringent factor RelA is a (p)ppGpp synthetase that is associated with ~5% of ribosomes.
- RelA is activated when the A site is occupied by an uncharged tRNA.
- One (p)ppGpp is produced every time an uncharged tRNA enters the A site.

---

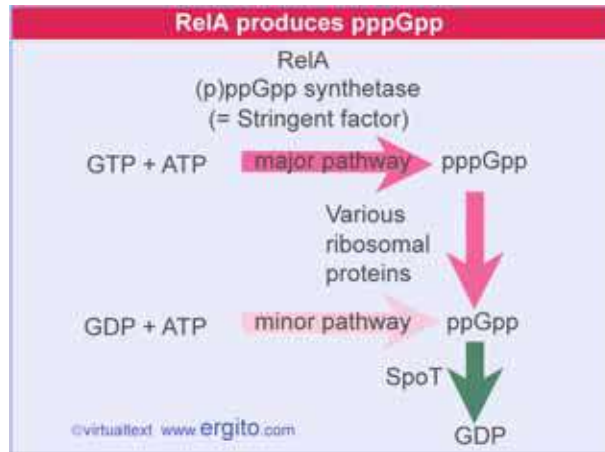

Deprivation of any one amino acid, or mutation to inactivate any aminoacyl-tRNA synthetase, is sufficient to initiate the stringent response. The trigger that sets the entire series of events in train is *the presence of uncharged tRNA in the A site of the ribosome*. Under normal conditions, of course, only aminoacyl-tRNA is placed in the A site by EF-Tu (see *Molecular Biology 2.6.10 Elongation factor Tu loads aminoacyl-tRNA into the A site*). But when there is no aminoacyl-tRNA available to respond to a particular codon, the uncharged tRNA becomes able to gain entry. Of course, this blocks any further progress by the ribosome; and it triggers an **idling reaction**.

The components involved in producing (p)ppGpp via the idling reaction have been identified through the existence of **relaxed** (*rel*) mutants. *rel* mutations abolish the stringent response, so that starvation for amino acids does not cause any reduction in stable RNA synthesis or alter any of the other reactions that are usually seen.

The most common site of relaxed mutation lies in the gene *relA*, which codes for a protein called the **stringent factor**. This factor is associated with the ribosomes, although the amount is rather low – say, <1 molecule for every 200 ribosomes. So perhaps only a minority of the ribosomes are able to produce the stringent response.

Ribosomes obtained from stringent bacteria can synthesize ppGpp and pppGpp *in vitro*, provided that the A site is occupied by an uncharged tRNA *specifically responding to the codon*. Ribosomes extracted from relaxed mutants cannot perform this reaction; but they are able to do so if the stringent factor is added.

**Figure 11.11** shows the pathways for synthesis of (p)ppGpp. The stringent factor (RelA) is an enzyme that catalyzes the synthetic reaction in which ATP is used to donate a pyrophosphate group to the 3' position of either GTP or GDP. The formal name for this activity is (p)ppGpp synthetase.

**Figure 11.11** Stringent factor catalyzes the synthesis of pppGpp and ppGpp; ribosomal proteins can dephosphorylate pppGpp to ppGpp.

How is ppGpp removed when conditions return to normal? A gene called *spoT* codes for an enzyme that provides the major catalyst for ppGpp degradation. The activity of this enzyme causes ppGpp to be rapidly degraded, with a half-life of ~20 sec; so the stringent response is reversed rapidly when synthesis of (p)ppGpp ceases. *spoT* mutants have elevated levels of ppGpp, and grow more slowly as a result.

The RelA enzyme uses GTP as substrate more frequently, so that pppGpp is the predominant product. However, pppGpp is converted to ppGpp by several enzymes; among those able to perform this dephosphorylation are the translation factors EF-Tu and EF-G. The production of ppGpp via pppGpp is the most common route, *and ppGpp is the usual effector of the stringent response.*

The response of the ribosome to entry of uncharged tRNA is compared with normal protein synthesis in **Figure 11.12**. When EF-Tu places aminoacyl-tRNA in the A site, peptide bond synthesis is followed by ribosomal movement. But when uncharged tRNA is paired with the codon in the A site, the ribosome remains stationary and engages in the idling reaction (521).

**Figure 11.12** In normal protein synthesis, the presence of aminoacyl-tRNA in the A site is a signal for peptidyl transferase to transfer the polypeptide chain, followed by movement catalyzed by EF-G; but under stringent conditions, the presence of uncharged tRNA causes RelA protein to synthesize (p)ppGpp and to expel the tRNA.

How does the state of the ribosome control the activity of RelA enzyme? An indication of the nature of the interaction is revealed by relaxed mutations in another locus, originally called *relC*, which turns out to be the same as *rplK*, which codes for the 50S subunit protein L11. This protein is located in the vicinity of the A and P sites, in a position to respond to the presence of a properly paired but uncharged tRNA in the A site. A conformational change in this protein or some other component could activate the RelA enzyme, so that the idling reaction occurs instead of polypeptide transfer from the peptidyl-tRNA.

One round of (p)ppGpp synthesis is associated with release of the uncharged tRNA from the A site, so that synthesis of (p)ppGpp is a continuing response to the level of uncharged tRNA. So under limiting conditions, a ribosome stalls when no aminoacyl-tRNA is available to respond to the codon in the A site. Entry of uncharged tRNA triggers the synthesis of a (p)ppGpp molecule, and the resulting expulsion of the uncharged tRNA allows the situation to be reassessed. Depending upon the availability of aminoacyl-tRNA, the ribosome resumes polypeptide synthesis or undertakes another idling reaction.

## REGULATORY CIRCUITS

### 3.11.9 pGpp has many effects

---

#### Key Concepts

- ppGpp inhibits transcription of rRNA.
- 

What does ppGpp do? It is an effector for controlling several reactions, including the inhibition of transcription. Many effects have been reported, among which two stand out:

- *Initiation of transcription is specifically inhibited at the promoters of operons coding for rRNA.* Mutations of stringently regulated promoters can abolish stringent control, which suggests that the effect requires an interaction with specific promoter sequences.
- *The elongation phase of transcription of many or most templates is reduced by ppGpp.* The cause is increased pausing by RNA polymerase. This effect is responsible for the general reduction in transcription efficiency when ppGpp is added *in vitro*.

The use of ppGpp is just one aspect of a more general regulatory network that relates production of ribosomes to the growth rate. The level of protein synthesis increases in proportion with the growth rate. This is accomplished by increasing the production of ribosomes as cells grow more rapidly. The cell therefore needs some general indicator of growth rate that can be used to control the synthesis of ribosomes. The indicator appears to be NTP levels, and the target for their action is the control of transcription of rRNA.

**Figure 11.13** summarizes the systems that are used to control rRNA transcription in response to growth rate. Under conditions of starvation, ppGpp is produced, and (among its various actions) inhibits initiation at the promoters of the *rrn* loci that code for rRNA. As growth rate increases, the levels of ATP and GTP increase. These increase the rate of initiation at the *rrn* promoters (for review see 103).

**Figure 11.13** Nucleotide levels control initiation of rRNA transcription.

The *rrn* promoters in *E. coli* form atypical open complexes with RNA polymerase. The open complexes are unusually unstable. The result is that the main factor governing the rate of initiation becomes the decay rate of the open complex. Increased concentration of the initiating nucleotide (which is ATP at six of the *rrn* promoters and GTP at the seventh) drives the initiation reaction forward by stabilizing the open complex.

The level of rRNA controls the production of ribosomes (by a feedback loop in which the absence of rRNA inhibits synthesis of ribosomal proteins, see **Figure 11.18**). This means that the production of ribosomes, and thus the level of protein synthesis, in turn respond to the levels of ATP and GTP, which reflect the nutritional condition of the cell. So concentrations of particular nucleotides control ribosome synthesis in response to normal changes in growth rate and the more extreme conditions of starvation.

## REGULATORY CIRCUITS

### 3.11.10 Translation can be regulated

#### Key Concepts

- A repressor protein can regulate translation by preventing a ribosome from binding to an initiation codon.
- Accessibility of initiation codons in a polycistronic mRNA can be controlled by changes in the structure of the mRNA that occur as the result of translation.

Translational control is a notable feature of operons coding for components of the protein synthetic apparatus. The operon provides an arrangement for *coordinate* regulation of a group of structural genes. But, superimposed on it, further controls, such as those at the level of translation, may create *differences* in the extent to which individual genes are expressed.

A similar type of mechanism is used to achieve translational control in several systems. *Repressor function is provided by a protein that binds to a target region on mRNA to prevent ribosomes from recognizing the initiation region.* Formally this is equivalent to a repressor protein binding to DNA to prevent RNA polymerase from utilizing a promoter. **Figure 11.14** illustrates the most common form of this interaction, in which the regulator protein binds directly to a sequence that includes the AUG initiation codon, thereby preventing the ribosome from binding.

**Figure 11.14** A regulator protein may block translation by binding to a site on mRNA that overlaps the ribosome-binding site at the initiation codon.

*This is a static version of an interactive figure; see <http://www.ergito.com/main.jsp?bcs=MBIO.3.11.10> to view properly.*

Some examples of translational repressors and their targets are summarized in **Figure 11.15**. A classic example is the coat protein of the RNA phage R17; it binds to a hairpin that encompasses the ribosome binding site in the phage mRNA. Similarly the T4 RegA protein binds to a consensus sequence that includes the AUG initiation codon in several T4 early mRNAs; and T4 DNA polymerase binds to a sequence in its own mRNA that includes the Shine-Dalgarno element needed for ribosome binding.

Translational repressors bind to mRNA		
Repressor	Target Gene	Site of Action
R17 coat protein	R17 replicase	hairpin that includes ribosome binding site
T4 RegA	early T4 mRNAs	various sequences including initiation codon
T4 DNA polymerase	T4 DNA polymerase	Shine-Dalgarno sequence
T4 p32	gene 32	single-stranded 5' leader

©virtualtext www.ergito.com

**Figure 11.15** Proteins that bind to sequences within the initiation regions of mRNAs may function as translational repressors.

Another form of translational control occurs when translation of one cistron requires changes in secondary structure that depend on translation of a preceding cistron. This happens during translation of the RNA phages, whose cistrons always are expressed in a set order. **Figure 11.16** shows that the phage RNA takes up a secondary structure in which only one initiation sequence is accessible; the second cannot be recognized by ribosomes because it is base paired with other regions of the RNA. However, translation of the first cistron disrupts the secondary structure, allowing ribosomes to bind to the initiation site of the next cistron. In this mRNA, secondary structure controls translatability.

**Figure 11.16** Secondary structure can control initiation. Only one initiation site is available in the RNA phase, but translation of the first cistron changes the conformation of the RNA so that other initiation site(s) become available.

*This is a static version of an interactive figure; see*

*<http://www.ergito.com/main.jsp?bcs=MBIO.3.11.10> to view properly.*

## REGULATORY CIRCUITS

### 3.11.11 r-protein synthesis is controlled by autogenous regulation

---

#### Key Terms

An **r-protein** is one of the proteins of the ribosome.

**Autogenous** control describes the action of a gene product that either inhibits (negative autogenous control) or activates (positive autogenous control) expression of the gene coding for it.

#### Key Concepts

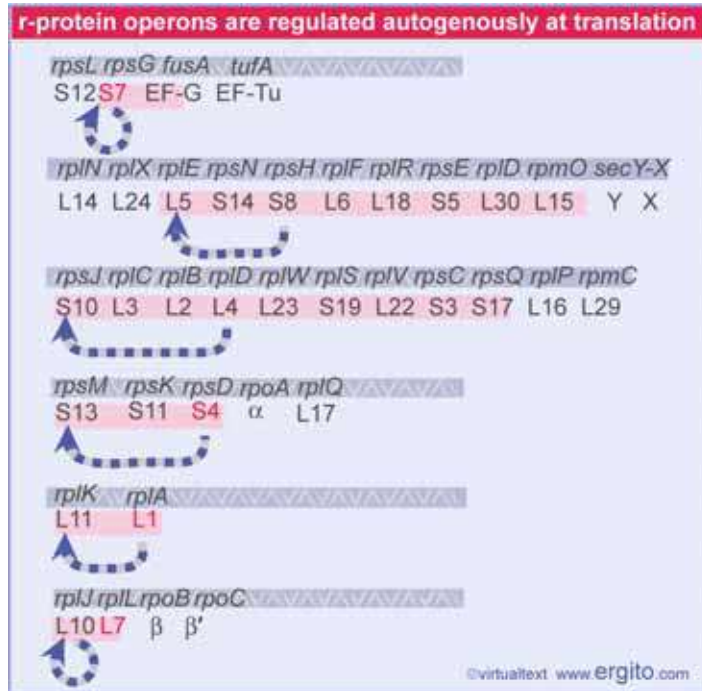

- Translation of an r-protein operon can be controlled by a product of the operon that binds to a site on the polycistronic mRNA.

---

About 70 or so proteins constitute the apparatus for bacterial gene expression. The ribosomal proteins are the major component, together with the ancillary proteins involved in protein synthesis. The subunits of RNA polymerase and its accessory factors make up the remainder. The genes coding for ribosomal proteins, protein-synthesis factors, and RNA polymerase subunits all are intermingled and organized into a small number of operons. Most of these proteins are represented only by single genes in *E. coli*.

Coordinate controls ensure that these proteins are synthesized in amounts appropriate for the growth conditions: when bacteria grow more rapidly, they devote a greater proportion of their efforts to the production of the apparatus for gene expression. An array of mechanisms is used to control the expression of the genes coding for this apparatus and to ensure that the proteins are synthesized at comparable levels that are related to the levels of the rRNAs.

The organization of six operons is summarized in **Figure 11.17**. About half of the genes for ribosomal proteins (**r-proteins**) map in four operons that lie close together (named *str*, *spc*, *S10*, and  $\alpha$  simply for the first one of the functions to have been identified in each case). The *rif* and *L11* operons lie together at another location.

**Figure 11.17** Genes for ribosomal proteins, protein synthesis factors, and RNA polymerase subunits are interspersed in a small number of operons that are autonomously regulated. The regulator is named in red; the proteins that are regulated are shaded in pink.

Each operon codes for a variety of functions. The *str* operon has genes for small subunit ribosomal proteins as well as for EF-Tu and EF-G. The *spc* and *S10* operons have genes interspersed for both small and large ribosomal subunit proteins. The  $\alpha$  operon has genes for proteins of both ribosomal subunits as well as for the  $\alpha$  subunit of RNA polymerase. The *rif* locus has genes for large subunit ribosomal proteins and for the  $\beta$  and  $\beta'$  subunits of RNA polymerase.

All except one of the ribosomal proteins are needed in equimolar amounts, which must be coordinated with the level of rRNA. The dispersion of genes whose products must be equimolar, and their intermingling with genes whose products are needed in different amounts, pose some interesting problems for coordinate regulation.

A feature common to all of the operons described in **Figure 11.17** is regulation of some of the genes by one of the products. In each case, the gene coding for the regulatory product is itself one of the targets for regulation. **Autogenous** regulation occurs whenever a protein (or RNA) regulates its own production. In the case of the r-protein operons, the regulatory protein inhibits expression of a contiguous set of genes within the operon, so this is an example of negative autogenous regulation.

In each case, *accumulation of the protein inhibits further synthesis of itself and of some other gene products*. The effect often is exercised at the level of translation of the polycistronic mRNA. Each of the regulators is a ribosomal protein that binds directly to rRNA. *Its effect on translation is a result of its ability also to bind to its own mRNA*. The sites on mRNA at which these proteins bind either overlap the sequence where translation is initiated or lie nearby and probably influence the

accessibility of the initiation site by inducing conformational changes. For example, in the S10 operon, protein L4 acts at the very start of the mRNA to inhibit translation of S10 and the subsequent genes. The inhibition may result from a simple block to ribosome access, as illustrated previously in **Figure 11.15**, or it may prevent a subsequent stage of translation. In two cases (including S4 in the  $\alpha$  operon), the regulatory protein stabilizes a particular secondary structure in the mRNA that prevents the initiation reaction from continuing after the 30S subunit has bound (517).

The use of r-proteins that bind rRNA to establish autogenous regulation immediately suggests that this provides a mechanism to link r-protein synthesis to rRNA synthesis. A generalized model is depicted in **Figure 11.18**. Suppose that the binding sites for the autogenous regulator r-proteins on rRNA are much stronger than those on the mRNAs. Then so long as any free rRNA is available, the newly synthesized r-proteins will associate with it to start ribosome assembly. There will be no free r-protein available to bind to the mRNA, so its translation will continue. But as soon as the synthesis of rRNA slows or stops, free r-proteins begin to accumulate. Then they are available to bind their mRNAs, repressing further translation. This circuit ensures that each r-protein operon responds in the same way to the level of rRNA: as soon as there is an excess of r-protein relative to rRNA, synthesis of the protein is repressed (for review see 92).

**Figure 11.18** Translation of the r-protein operons is autogenously controlled and responds to the level of rRNA. This is a static version of an interactive figure; see <http://www.ergito.com/main.jsp?bcs=MBIO.3.11.11> to view properly.

## REGULATORY CIRCUITS

**3.11.12 Phage T4 p32 is controlled by an autogenous circuit****Key Concepts**

- p32 binds to its own mRNA to prevent initiation of translation.

Autogenous regulation has been placed on a quantitative basis for gene 32 of phage T4. The protein (p32) plays a central role in genetic recombination, DNA repair, and replication, in which its function is exercised by virtue of its ability to bind to single-stranded DNA. Nonsense mutations cause the inactive protein to be overproduced. *So when the function of the protein is prevented, more of it is made.* This effect occurs at the level of translation; the gene 32 mRNA is stable, and remains so irrespective of the behavior of the protein product.

**Figure 11.19** presents a model for the gene 32 control circuit. When single-stranded DNA is present in the phage-infected cell, it sequesters p32. However, in the absence of single-stranded DNA, or at least in conditions in which there is a surplus of p32, the protein prevents translation of its own mRNA. The effect is mediated directly by p32 binding to mRNA to prevent initiation of translation. Probably this occurs at an A·T-rich region that surrounds the ribosome binding site.

**Figure 11.19** Excess gene 32 protein (p32) binds to its own mRNA to prevent ribosomes from initiating translation.

Two features of the binding of p32 to the site on mRNA are required to make the control loop work effectively:

- The affinity of p32 for the site on gene 32 mRNA must be significantly lower than its affinity for single-stranded DNA. The equilibrium constant for binding RNA is in fact almost two orders of magnitude below that for single-stranded DNA.
- But the affinity of p32 for the mRNA must be significantly greater than the affinity for other RNA sequences. It is influenced by base composition and by secondary structure; an important aspect of the binding to gene 32 mRNA is that the regulatory region has an extended sequence lacking secondary structure.

Using the known equilibrium constants, we can plot the binding of p32 to its target sites as a function of protein concentration. **Figure 11.20** shows that at concentrations below  $10^{-6}$  M, p32 binds to single-stranded DNA. At concentrations  $>10^{-6}$  M, it binds to gene 32 mRNA. At yet greater concentrations, it binds to other mRNA sequences, with a range of affinities.

**Figure 11.20** Gene 32 protein binds to various substrates with different affinities, in the order single-stranded DNA, its own mRNA, and other mRNAs. Binding to its own mRNA prevents the level of p32 from rising  $>10^{-6}$  M.

These results imply that the level of p32 should be autoregulated to be  $<10^{-6}$  M, which corresponds to  $\sim 2000$  molecules per bacterium. This fits well with the measured level of 1000-2000 molecules/cell.

A feature of autogenous control is that each regulatory interaction is unique: a protein acts only on the mRNA responsible for its own synthesis. Phage T4 provides an example of a more general translational regulator, coded by the gene *regA*, which represses the expression of several genes that are transcribed during early infection. RegA protein prevents the translation of mRNAs for these genes by competing with 30S subunits for the initiation sites on the mRNA. Its action is a direct counterpart to the function of a repressor protein that binds multiple operators.

## REGULATORY CIRCUITS

### 3.11.13 Autogenous regulation is often used to control synthesis of macromolecular assemblies

---

#### Key Concepts

- The precursor to microtubules, free tubulin protein, inhibits translation of tubulin mRNA.
- 

Autogenous regulation is a common type of control among proteins that are incorporated into macromolecular assemblies. The assembled particle itself may be unsuitable as a regulator, because it is too large, too numerous, or too restricted in its location. But the need for synthesis of its components may be reflected in the pool of free precursor subunits. If the assembly pathway is blocked for any reason, free subunits accumulate and shut off the unnecessary synthesis of further components (for review see 98).

Eukaryotic cells have a common system in which autogenous regulation of this type occurs. Tubulin is the monomer from which microtubules, a major filamentous system of all eukaryotic cells, are synthesized. The production of tubulin mRNA is controlled by the free tubulin pool. When this pool reaches a certain concentration, the production of further tubulin mRNA is prevented. Again, the principle is the same: tubulin sequestered into its macromolecular assembly plays no part in regulation, but the level of the free precursor pool determines whether further monomers are added to it.

The target site for regulation is a short sequence at the start of the coding region. We do not know yet what role this sequence plays, but two models are illustrated in **Figure 11.21**. Tubulin may bind directly to the mRNA; or it may bind to the nascent polypeptide representing this region. Whichever model applies, excess tubulin causes tubulin mRNA that is located on polysomes to be degraded, so the consequence of the reaction is to make the tubulin mRNA unstable.

**Figure 11.21** Tubulin is assembled into microtubules when it is synthesized. Accumulation of excess free tubulin induces instability in the tubulin mRNA by acting at a site at the start of the reading frame in mRNA or at the corresponding position in the nascent protein.

Autogenous control is an *intrinsically* self-limiting system, by contrast with the *extrinsic* control that we discussed previously. A repressor protein's ability to bind an operator may be controlled by the level of an extraneous small molecule, which activates or inhibits its activity. But in the case of autogenous regulation, the critical parameter is the concentration of the protein itself.

## REGULATORY CIRCUITS

### 3.11.14 Alternative secondary structures control attenuation

---

#### Key Terms

**Attenuation** describes the regulation of bacterial operons by controlling termination of transcription at a site located before the first structural gene.

An **attenuator** is a terminator sequence at which attenuation occurs.

#### Key Concepts

- Termination of transcription can be attenuated by controlling formation of the necessary hairpin structure in RNA.
- The most direct mechanisms for attenuation involve proteins that either stabilize or destabilize the hairpin.

---

RNA structure provides an opportunity for regulation in both prokaryotes and eukaryotes. Its most common role occurs when an RNA molecule can take up alternative secondary structures by utilizing different schemes for intramolecular base pairing. The properties of the alternative conformations may be different. This type of mechanism can be used to regulate the termination of transcription, when the alternative structures differ in whether they permit termination. Another means of controlling conformation (and thereby function) is provided by the cleavage of an RNA; by removing one segment of an RNA, the conformation of the rest may be altered. It is possible also for a (small) RNA molecule to control the activity of a target RNA by base pairing with it; the role of the small RNA is directly analogous to that of a regulator protein (see *Molecular Biology 3.11.19 Small RNA molecules can regulate translation*). The ability of an RNA to shift between different conformations with regulatory consequences is the nucleic acid's alternative to the allosteric changes of conformation that regulate protein function. Both these mechanisms allow an interaction at one site in the molecule to affect the structure of another site.

Several operons are regulated by **attenuation**, a mechanism that controls the ability of RNA polymerase to read through an **attenuator**, which is an intrinsic terminator located at the beginning of a transcription unit. *The principle of attenuation is that some external event controls the formation of the hairpin needed for intrinsic termination.* If the hairpin is allowed to form, termination prevents RNA polymerase from transcribing the structural genes. If the hairpin is prevented from forming, RNA polymerase elongates through the terminator, and the genes are expressed. Different types of mechanisms are used in different systems for controlling the structure of the RNA.

Attenuation may be regulated by proteins that bind to RNA, either to stabilize or to destabilize formation of the hairpin required for termination. **Figure 11.22** shows an example in which a protein prevents formation of the terminator hairpin. The activity

of such a protein may be intrinsic or may respond to a small molecule in the same manner as a repressor protein responds to corepressor.

**Figure 11.22** Attenuation occurs when a terminator hairpin in RNA is prevented from forming.

## REGULATORY CIRCUITS

### 3.11.15 Termination of *B. subtilis* trp genes is controlled by tryptophan and by tRNA<sup>Trp</sup>

---

#### Key Concepts

- A terminator protein called TRAP is activated by tryptophan to prevent transcription of trp genes.
  - Activity of TRAP is (indirectly) inhibited by uncharged tRNA<sup>Trp</sup>.
- 

The circuitry that controls transcription via termination can use both direct and indirect means to respond to the level of small molecule products or substrates.

In *B. subtilis*, a protein called TRAP (formerly called MtrB) is activated by tryptophan to bind to a sequence in the leader of the nascent transcript (915, 919; for review see 920). TRAP forms a multimer of 11 subunits. Each subunit binds a single tryptophan amino acid and a trinucleotide (GAG or UAG) of RNA. The RNA is wound in a circle around the protein (921). **Figure 11.23** shows that the result is to ensure the availability of the regions that are required to form the terminator hairpin. The termination of transcription then prevents production of the tryptophan biosynthetic enzymes. In effect, TRAP is a terminator protein that responds to the level of tryptophan. In the absence of TRAP, an alternative secondary structure precludes the formation of the terminator hairpin.

**Figure 11.23** TRAP is activated by tryptophan and binds to trp mRNA. This allows the termination hairpin to form, with the result that RNA polymerase terminates, and the genes are not expressed. In the absence of tryptophan, TRAP does not bind, and the mRNA adopts a structure that prevents the terminator hairpin from forming.

However, the TRAP protein in turn is also controlled by tRNA<sup>Trp</sup>. **Figure 11.24** shows that uncharged tRNA<sup>Trp</sup> binds to the mRNA for a protein called anti-TRAP (AT). This suppresses formation of a termination hairpin in the mRNA. The uncharged tRNA<sup>Trp</sup> also increases the translation of the mRNA. The combined result of these two actions to increase synthesis of anti-TRAP, which binds to TRAP, and prevents it from repressing the tryptophan operon. By this complex series of events, the absence of tryptophan generates the uncharged tRNA, which causes synthesis of anti-TRAP, which prevents function of TRAP, which causes expression of tryptophan genes (2068).

**Figure 11.24** Under normal conditions (in the presence of tryptophan) transcription terminates before the anti-TRAP gene. When tryptophan is absent, uncharged tRNA<sup>Trp</sup> base pairs with the anti-TRAP mRNA, preventing formation of the terminator hairpin, thus causing expression of anti-TRAP.

Expression of the *B. subtilis trp* genes is therefore controlled by both tryptophan and tRNA<sup>Trp</sup>. When tryptophan is present, there is no need for it to be synthesized. This is accomplished when tryptophan activates TRAP and therefore inhibits expression of the enzymes that synthesize tryptophan. The presence of uncharged tRNA<sup>Trp</sup> indicates that there is a shortage of tryptophan. The uncharged tRNA activates the anti-TRAP, and thereby activates transcription of the *trp* genes.

## REGULATORY CIRCUITS

### 3.11.16 The *E. coli* tryptophan operon is controlled by attenuation

---

#### Key Concepts

- An attenuator (intrinsic terminator) is located between the promoter and the first gene of the *trp* cluster.
- The absence of tryptophan suppresses termination and results in a 10× increase in transcription.

---

A complex regulatory system is used in *E. coli* (where attenuation was originally discovered). The changes in secondary structure that control attenuation are determined by the position of the ribosome on mRNA. **Figure 11.25** shows that termination requires that *the ribosome can translate a leader segment that precedes the trp genes in the mRNA*. When the ribosome translates the leader region, a termination hairpin forms at terminator 1. But when the ribosome is prevented from translating the leader, the termination hairpin does not form, and RNA polymerase transcribes the coding region. *This mechanism of antitermination therefore depends upon the ability of external circumstances to influence ribosome movement in the leader region* (for review see 89).

**Figure 11.25** Termination can be controlled via changes in RNA secondary structure that are determined by ribosome movement.

The *trp* operon consists of five structural genes arranged in a contiguous series, coding for the three enzymes that convert chorismic acid to tryptophan. **Figure 11.26** shows that transcription starts at a promoter at the left end of the cluster. *trp* operon expression is controlled by two separate mechanisms. Repression of expression is exercised by a repressor protein (coded by the unlinked gene *trpR*) that binds to an operator that is adjacent to the promoter. Attenuation controls the progress of RNA polymerase into the operon by regulating whether termination occurs at a site preceding the first structural gene.

**Figure 11.26** The *trp* operon consists of five contiguous structural genes preceded by a control region that includes a promoter, operator, leader peptide coding region, and attenuator.

Attenuation was first revealed by the observation that deleting a sequence between the operator and the *trpE* coding region can increase the expression of the structural genes. This effect is independent of repression: both the basal and derepressed levels of transcription are increased. So this site influences events that occur *after* RNA polymerase has set out from the promoter (irrespective of the conditions prevailing at initiation).

An attenuator (intrinsic terminator) is located between the promoter and the *trpE* gene. It provides a barrier to transcription into the structural genes. RNA polymerase terminates there, either *in vivo* or *in vitro*, to produce a 140-base transcript.

Termination at the attenuator responds to the level of tryptophan, as illustrated in **Figure 11.27**. In the presence of adequate amounts of tryptophan, termination is efficient. But in the absence of tryptophan, RNA polymerase can continue into the structural genes.

**Figure 11.27** An attenuator controls the progression of RNA polymerase into the *trp* genes. RNA polymerase initiates at the promoter and then proceeds to position 90, where it pauses before proceeding to the attenuator at position 140. In the absence of tryptophan, the polymerase continues into the structural genes (*trpE* starts at +163). In the presence of tryptophan there is ~90% probability of termination to release the 140-base leader RNA.

Repression and attenuation respond in the same way to the level of tryptophan. When tryptophan is present, the operon is repressed; and most of the RNA polymerases that escape from the promoter then terminate at the attenuator. When tryptophan is removed, RNA polymerase has free access to the promoter, and also is no longer compelled to terminate prematurely.

Attenuation has  $\sim 10\times$  effect on transcription. When tryptophan is present, termination is effective, and the attenuator allows only  $\sim 10\%$  of the RNA polymerases to proceed. In the absence of tryptophan, attenuation allows virtually all of the polymerases to proceed. Together with the  $\sim 70\times$  increase in initiation of transcription that results from the release of repression, this allows an  $\sim 700$ -fold range of regulation of the operon.

## REGULATORY CIRCUITS

### 3.11.17 Attenuation can be controlled by translation

---

#### Key Terms

The **leader peptide** is the product that would result from translation of a short coding sequence used to regulate transcription of the tryptophan operon by controlling ribosome movement.

**Ribosome stalling** describes the inhibition of movement that occurs when a ribosome reaches a codon for which there is no corresponding charged aminoacyl-tRNA.

#### Key Concepts

- The leader region of the *trp* operon has a 14 codon open reading frame that includes two codons for tryptophan.
- The structure of RNA at the attenuator depends on whether this reading frame is translated.
- In the presence of tryptophan, the leader is translated, and the attenuator is able to form the hairpin that causes termination.
- In the absence of tryptophan, the ribosome stalls at the tryptophan codons and an alternative secondary structure prevents formation of the hairpin, so that transcription continues.

---

How can termination of transcription at the attenuator respond to the level of tryptophan? The sequence of the leader region suggests a mechanism. It has a short coding sequence that could represent a **leader peptide** of 14 amino acids. **Figure 11.26** shows that it contains a ribosome binding site whose AUG codon is followed by a short coding region that contains two successive codons for tryptophan. When the cell runs out of tryptophan, ribosomes initiate translation of the leader peptide, but stop when they reach the Trp codons. The sequence of the mRNA suggests that this **ribosome stalling** influences termination at the attenuator.

The leader sequence can be written in alternative base-paired structures. The ability of the ribosome to proceed through the leader region controls transitions between these structures. The structure determines whether the mRNA can provide the features needed for termination.

**Figure 11.28** draws these structures. In the first, region 1 pairs with region 2; and region 3 pairs with region 4. The pairing of regions 3 and 4 generates the hairpin that precedes the  $U_s$  sequence: this is the essential signal for intrinsic termination. Probably the RNA would take up this structure in lieu of any outside intervention.

**Figure 11.28** The *trp* leader region can exist in alternative base-paired conformations. The center shows the four regions that can base pair. Region 1 is complementary to region 2, which is complementary to region 3, which is complementary to region 4. On the left is the conformation produced when region 1 pairs with region 2, and region 3 pairs with region 4. On the right is the conformation when region 2 pairs with region 3, leaving regions 1 and 4 unpaired.

A different structure is formed if region 1 is prevented from pairing with region 2. In this case, region 2 is free to pair with region 3. Then region 4 has no available pairing partner; so it is compelled to remain single-stranded. So the terminator hairpin cannot be formed.

**Figure 11.29** shows that the position of the ribosome can determine which structure is formed, in such a way that termination is attenuated only in the absence of tryptophan. The crucial feature is the position of the Trp codons in the leader peptide coding sequence.

**Figure 11.29** The alternatives for RNA polymerase at the attenuator depend on the location of the ribosome, which determines whether regions 3 and 4 can pair to form the terminator hairpin.

When tryptophan is present, ribosomes are able to synthesize the leader peptide. They continue along the leader section of the mRNA to the UGA codon, which lies between regions 1 and 2. As shown in the lower part of the figure, by progressing to this point, the ribosomes extend over region 2 and prevent it from base pairing. The result is that region 3 is available to base pair with region 4, generating the terminator hairpin. Under these conditions, therefore, RNA polymerase terminates at the attenuator.

When there is no tryptophan, ribosomes stall at the Trp codons, which are part of region 1, as shown in the upper part of the figure. So region 1 is sequestered within the ribosome and cannot base pair with region 2. This means that regions 2 and 3 become base paired before region 4 has been transcribed. This compels region 4 to remain in a single-stranded form. In the absence of the terminator hairpin, RNA polymerase continues transcription past the attenuator (522; 523; for review see 96).

Control by attenuation requires a precise timing of events. For ribosome movement to determine formation of alternative secondary structures that control termination, *translation of the leader must occur at the same time when RNA polymerase approaches the terminator site*. A critical event in controlling the timing is the presence of a site that causes the RNA polymerase to pause at base 90 along the leader. The RNA polymerase remains paused until a ribosome translates the leader peptide. Then the polymerase is released and moves off toward the attenuation site. By the time it arrives there, secondary structure of the attenuation region has been determined.

**Figure 11.30** summarizes the role of Trp-tRNA in controlling expression of the operon. *By providing a mechanism to sense the inadequacy of the supply of Trp-tRNA, attenuation responds directly to the need of the cell for tryptophan in protein synthesis* (for review see 97).

**Figure 11.30** In the presence of tryptophan tRNA, ribosomes translate the leader peptide and are released. This allows hairpin formation, so that RNA polymerase terminates. In the absence of tryptophan tRNA, the ribosome is blocked, the termination hairpin cannot form, and RNA polymerase continues.

How widespread is the use of attenuation as a control mechanism for bacterial operons? It is used in at least six operons that code for enzymes concerned with the biosynthesis of amino acids. So a feedback from the level of the amino acid available for protein synthesis (as represented by the availability of aminoacyl-tRNA) to the production of the enzymes may be common (for review see 91).

The use of the ribosome to control RNA secondary structure in response to the availability of an aminoacyl-tRNA establishes an inverse relationship between the presence of aminoacyl-tRNA and the transcription of the operon, equivalent to a

situation in which aminoacyl-tRNA functions as a corepressor of transcription. Since the regulatory mechanism is mediated by changes in the formation of duplex regions, attenuation provides a striking example of the importance of secondary structure in the termination event, and of its use in regulation.

*E. coli* and *B. subtilis* therefore use the same types of mechanisms, involving control of mRNA structure in response to the presence or absence of a tRNA, but they have combined the individual interactions in different ways. The end result is the same: to inhibit production of the enzymes when there is an excess supply of the amino acid, and to activate production when a shortage is indicated by the accumulation of uncharged tRNA<sup>Trp</sup>.

## REGULATORY CIRCUITS

### 3.11.18 Antisense RNA can be used to inactivate gene expression

---

#### Key Terms

An **antisense gene** codes for an (antisense) RNA that has a complementary sequence to an RNA that is its target.

#### Key Concepts

- Antisense genes block expression of their targets when introduced into eukaryotic cells.

---

Base pairing offers a powerful means for one RNA to control the activity of another. There are many cases in both prokaryotes and eukaryotes where a (usually rather short) single-stranded RNA base pairs with a complementary region of an mRNA, and as a result prevents expression of the mRNA. One of the early illustrations of this effect was provided by an artificial situation, in which **antisense genes** were introduced into eukaryotic cells.

Antisense genes are constructed by reversing the orientation of a gene with regard to its promoter, so that the "antisense" strand is transcribed, as illustrated in **Figure 11.31**. Synthesis of antisense RNA can inactivate a target RNA in either prokaryotic or eukaryotic cells. An antisense RNA is in effect a synthetic RNA regulator. An antisense thymidine kinase gene inhibits synthesis of thymidine kinase from the endogenous gene. Quantitation of the effect is not entirely reliable, but it seems that an excess (perhaps a considerable excess) of the antisense RNA may be necessary (524).

**Figure 11.31** Antisense RNA can be generated by reversing the orientation of a gene with respect to its promoter, and can anneal with the wild-type transcript to form duplex RNA.

At what level does the antisense RNA inhibit expression? It could in principle prevent transcription of the authentic gene, processing of its RNA product, or translation of the messenger. Results with different systems show that the inhibition depends on formation of RNA-RNA duplex molecules, but this can occur either in the nucleus or in the cytoplasm. In the case of an antisense gene stably carried by a cultured cell, sense-antisense RNA duplexes form in the nucleus, preventing normal processing and/or transport of the sense RNA. In another case, injection of antisense RNA into the cytoplasm inhibits translation by forming duplex RNA in the 5' region of the mRNA.

This technique offers a powerful approach for turning off genes at will; for example, the function of a regulatory gene can be investigated by introducing an antisense version. An extension of this technique is to place the antisense gene under control of a promoter itself subject to regulation. Then the target gene can be turned off and on by regulating the production of antisense RNA. This technique allows investigation of the importance of the timing of expression of the target gene.

## REGULATORY CIRCUITS

### 3.11.19 Small RNA molecules can regulate translation

---

#### Key Concepts

- A regulator RNA functions by forming a duplex region with a target RNA.
  - The duplex may block initiation of translation, cause termination of transcription, or create a target for an endonuclease.
- 

Repressors and activators are *trans*-acting proteins. Yet the formal circuitry of a regulatory network could equally well be constructed by using an RNA as regulator. In fact, the original model for the operon left open the question of whether the regulator might be RNA or protein. Indeed, the construction of synthetic antisense RNAs turns out to mimic a class of RNA regulators that is becoming of increasing importance.

Like a protein regulator, a small regulator RNA is an independently synthesized molecule that diffuses to a target site consisting of a specific nucleotide sequence. The target for a regulator RNA is a single-stranded nucleic acid sequence. The regulator RNA functions by complementarity with its target, at which it can form a double-stranded region.

We can imagine two general mechanisms for the action of a regulator RNA:

- Formation of a duplex region with the target nucleic acid directly prevents its ability to function, by forming or sequestering a specific site. **Figure 11.32** illustrates the situation in which a protein that binds to single-stranded RNA is prevented from acting by formation of a duplex. **Figure 11.33** shows the opposite type of relationship in which the formation of a double-stranded region creates a target site for an endonuclease that destroys the RNA target.
- Formation of a duplex region in one part of the target molecule changes the conformation of another region, thus indirectly affecting its function. **Figure 11.34** shows an example. The mechanism is essentially similar to the use of secondary structure in attenuation (see *Molecular Biology 3.11.14 Alternative secondary structures control attenuation*), except that the interacting regions are on different RNA molecules instead of being part of the same RNA molecule.

**Figure 11.32** A protein that binds to a single-stranded region in a target RNA could be excluded by a regulator RNA that forms a duplex in this region.

**Figure 11.33** By binding to a target RNA to form a duplex region, a regulator RNA may create a site that is attacked by a nuclease.

**Figure 11.34** The secondary structure formed by base pairing between two regions of the target RNA may be prevented from forming by base pairing with a regulator RNA. In this example, the ability of the 3' end of the RNA to pair with the 5' end is prevented by the regulator.

*The feature common to both types of RNA-mediated regulation is that changes in secondary structure of the target control its activity.*

A difference between RNA regulators and the proteins that repress operons is that the RNA does not have allosteric properties; it cannot respond to other small molecules by changing its ability to recognize its target. It can be turned on by controlling transcription of its gene or it could be turned off by an enzyme that degrades the RNA regulator product.

---

## REGULATORY CIRCUITS

### 3.11.20 Bacteria contain regulator RNAs

---

#### Key Terms

An **sRNA** is a small bacterial RNA that functions as a regulator of gene expression.

#### Key Concepts

- Bacterial regulator RNAs are called sRNAs.
- Several of the sRNAs are bound by the protein Hfq, which increases their effectiveness.
- The OxyS sRNA activates or represses expression of >10 loci at the post-transcriptional level.

---

In bacteria, regulator RNAs are short molecules, collectively known as **sRNAs**; *E. coli* contains at least 17 different sRNAs (2945). Some of the sRNAs are general regulators that affect many target genes (for review see 3234). They function by base pairing with target RNAs (typically mRNAs) to control either their stability or function.

An example of stability control is provided by the small antisense regulator RyhB, which regulates 6 mRNAs coding for proteins concerned with iron storage in *E. coli*. It base pairs with each of the target mRNAs to form double-stranded regions that are substrates for RNAase E. An interesting feature of the circuit is that the ribonuclease destroys the regulator RNA as well as the mRNA (4521).

Oxidative stress provides an interesting example of a general control system in which RNA is the regulator. When exposed to reactive oxygen species, bacteria respond by inducing antioxidant defense genes. Hydrogen peroxide activates the transcription activator OxyR, which controls the expression of several inducible genes. One of these genes is *oxyS*, which codes for a small RNA.

**Figure 11.35** shows two salient features of the control of *oxyS* expression. In a wild-type bacterium under normal conditions, it is not expressed. The pair of gels on the left side of the figure shows that it is expressed at high levels in a mutant bacterium with a constitutively active *oxyR* gene. This identifies *oxyS* as a target for activation by *oxyR*. The pair of gels on the right side of the figure show that OxyS RNA is transcribed within 1 minute of exposure to hydrogen peroxide (2944).

**Figure 11.35** The gels on the left show that *oxyS* RNA is induced in an *oxyR* constitutive mutant. The gels on the right show that *oxyS* RNA is induced within 1 minute of adding hydrogen peroxide to a wild-type culture. Photograph kindly provided by Gisela Storz (see 2944).

The OxyS RNA is a short sequence (109 nucleotides) that does not code for protein. It is a *trans*-acting regulator that affects gene expression at post-transcriptional levels. It has >10 target loci; at some of them, it activates expression, at others it represses expression. **Figure 11.36** shows the mechanism of repression of one target, the FlhA mRNA. Three stem-loop structures protrude in the secondary structure of OxyR mRNA, and the loop close to the 3' terminus is complementary to a sequence just preceding the initiation codon of FlhA mRNA. Base pairing between OxyS RNA and FlhA RNA prevents the ribosome from binding to the initiation codon, and therefore represses translation (2943). There is also a second pairing interaction that involves a sequence within the coding region of FlhA.

**Figure 11.36** *oxyS* RNA inhibits translation of *fhhA* mRNA by base pairing with a sequence just upstream of the AUG initiation codon.

Another target for *oxyS* is *rpoS*, the gene coding for an alternative sigma factor (which activates a general stress response). By inhibiting production of the sigma factor, *oxyS* ensures that the specific response to oxidative stress does not trigger the response that is appropriate for other stress conditions. The *rpoS* gene is also regulated by two other sRNAs (DsrA and RprA), which activate it. These three sRNAs appear to be global regulators that coordinate responses to various environmental conditions.

The actions of all three sRNAs are assisted by an RNA-binding protein called Hfq. The Hfq protein was originally identified as a bacterial host factor needed for replication of the RNA bacteriophage Q  $\beta$ . It is related to the Sm proteins of eukaryotes that bind to many of the snRNAs (small nuclear RNAs) that have regulatory roles in gene expression (see *Molecular Biology 5.24.5 snRNAs are required for splicing*) (2941; 2942). Mutations in its gene have many effects, identifying it as a pleiotropic protein. Hfq binds to many of the sRNAs of *E. coli*. It increases the effectiveness of OxyS RNA by enhancing its ability to bind to its target mRNAs. The effect of Hfq is probably mediated by causing a small change in the secondary structure of OxyS RNA that improves the exposure of the single-stranded sequences that pair with the target mRNAs.

## REGULATORY CIRCUITS

### 3.11.21 MicroRNAs are regulators in many eukaryotes

---

#### Key Terms

**MicroRNAs** are very short RNAs that may regulate gene expression.

#### Key Concepts

- Animal and plant genomes code for many short (~22 base) RNA molecules, called microRNAs.
  - MicroRNAs regulate gene expression by base pairing with complementary sequences in target mRNAs.
- 

Very small RNAs are gene regulators in many eukaryotes. The first example was discovered in the nematode *C. elegans* as the result of the interaction between the regulator gene *lin4* and its target gene, *lin14*. **Figure 11.37** illustrates the behavior of this regulatory system. The *lin14* target gene regulates larval development. Expression of *lin14* is controlled by *lin4*, which codes for a small transcript of 22 nucleotides (2195; 2196). The *lin4* transcripts are complementary to a 10 base sequence that is repeated 7 times in the 3' nontranslated region of *lin14*. Expression of *lin4* represses expression of *lin14* post-transcriptionally, most likely because the base pairing reaction between the two RNAs leads to degradation of the mRNA. This system is especially interesting in implicating the 3' end as a site for regulation.

**Figure 11.37** *lin4* RNA regulates expression of *lin14* by binding to the 3' nontranslated region.

The *lin4* RNA is an example of a **microRNA** (miRNA). There are ~80 genes in the *C. elegans* genome coding for microRNAs of 21-24 nucleotide length (2193; 2194). They have varying patterns of expression during development and are likely to be regulators of gene expression. Many of the microRNAs of *C. elegans* are contained in a large (15S) ribonucleoprotein particle (2510).

Many of the *C. elegans* microRNAs have homologues in mammals, so the mechanism may be widespread. They are also found in plants. Of 16 microRNAs in *Arabidopsis*, 8 are completely conserved in rice, suggesting widespread conservation of this regulatory mechanism (3027).

The mechanism of production of the microRNAs is also widely conserved. In the example of *lin4*, the gene is transcribed into a transcript that forms a double-stranded region that becomes a target for a nuclease called Dicer. This has an N-terminal helicase activity, enabling it to unwind the double-stranded region, and two nuclease domains that are related to the bacterial ribonuclease III. Related enzymes are found in flies, worms, and plants (3028; 3029; 3027). Cleavage of the initial transcript generates the active microRNA. Interfering with the enzyme activity blocks the production of microRNAs and causes developmental defects.

## REGULATORY CIRCUITS

### 3.11.22 RNA interference is related to gene silencing

---

#### Key Terms

**RNA interference (RNAi)** describes the technique in which double-strand RNA is introduced into cells to eliminate or reduce the activity of a target gene. It is caused by using sequences complementary to the double-stranded RNA sequences to trigger degradation of the mRNA of the gene.

**RNA silencing** describes the ability of a dsRNA to suppress expression of the corresponding gene systemically in a plant.

**Cosuppression** describes the ability of a transgene (usually in plants) to inhibit expression of the corresponding endogenous gene.

#### Key Concepts

- RNA interference triggers degradation of mRNAs complementary to either strand of a short dsRNA.
- dsRNA may cause silencing of host genes.

---

The regulation of mRNAs by microRNAs is mimicked by the phenomenon of **RNA interference (RNAi)**. This was discovered when it was observed that antisense and sense RNAs can be equally effective in inhibiting gene expression (for review see 2077). The reason is that preparations of either type of (supposedly) single-stranded RNA are actually contaminated by small amounts of double-stranded RNA (1189).

Work with an *in vitro* system shows that the dsRNA is degraded by ATP-dependent cleavage to give oligonucleotides of 21-23 bases. The short RNA is sometimes called siRNA (short interfering RNA). **Figure 11.38** shows that the mechanism of cleavage involves making breaks relative to each 3' end of a long dsRNA to generate siRNA fragments with short (2 base) protruding 3' ends. The same enzyme (Dicer) that generates microRNAs is responsible for the cleavage.

**Figure 11.38** siRNA that mediates RNA interference is generated by cleaving dsRNA into smaller fragments. The cleavage reaction occurs 21-23 nucleotides from a 3' end. The siRNA product has protruding bases on its 3' ends.

RNAi occurs post-transcriptionally when an siRNA induces degradation of a complementary mRNA (1190; 1191). **Figure 11.39** suggests that the siRNA may provide a template that directs a nuclease to degrade mRNAs that are complementary to one or both strands, perhaps by a process in which the mRNA pairs with the fragments (1192). It is likely that a helicase is required to assist the pairing reaction. The siRNA directs cleavage of the mRNA in the middle of the paired segment. These reactions occur within a ribonucleoprotein complex called RISC (RNA-induced silencing complex) (for review see 2511).

**Figure 11.39** RNAi occurs when a dsRNA is cleaved into fragments that direct cleavage of the corresponding mRNA.

RNAi has become a powerful technique for ablating the expression of a specific target gene in invertebrate cells, especially in *C. elegans* and *D. melanogaster*. However, the technique has been limited in mammalian cells, which have a more generalized response to dsRNA of shutting down protein synthesis and degrading mRNA. **Figure 11.40** shows that this happens because of two reactions. The dsRNA activates the enzyme PKR, which inactivates the translation initiation factor eIF2a by phosphorylating it. And it activates 2' 5' oligoadenylate synthetase, whose product activates RNAase L, which degrades all mRNAs. However, it turns out that these reactions require dsRNA that is longer than 26 nucleotides. If shorter dsRNA (21-23 nucleotides) is introduced into mammalian cells, it triggers the specific degradation of complementary RNAs just as with the RNAi technique in worms and flies (1905). With this advance, it seems likely that RNAi will become the universal mechanism of choice for turning off the expression of a specific gene.

**Figure 11.40** dsRNA inhibits protein synthesis and triggers degradation of all mRNA in mammalian cells as well as having sequence-specific effects.

As an example of the progress being made with the technique, it has been possible to use RNAi for a systematic analysis of gene expression in *C. elegans*. Loss of function phenotypes can be generated by feeding worms with bacteria expressing a dsRNA that is homologous to a target gene. By making a library of bacteria in which each bacterium expresses a dsRNA corresponding to a different gene, worms have been screened for the effects of knocking out most (86%) of the genes (3323).

RNA interference is related to natural processes in which gene expression is silenced. Plants and fungi show **RNA silencing** (sometimes called post-transcriptional gene silencing) in which dsRNA inhibits expression of a gene (for review see 3242). The most common source of the RNA is a replicating virus. This mechanism may have evolved as a defense against viral infection. When a virus infects a plant cell, the formation of dsRNA triggers the suppression of expression from the plant genome (1396). RNA silencing has the further remarkable feature that it is not limited to the

cell in which the viral infection occurs: it can spread throughout the plant systemically (1397). Presumably the propagation of the signal involves passage of RNA or fragments of RNA. It may require some of the same features that are involved in movement of the virus itself. It is possible that RNA silencing involves an amplification of the signal by an RNA-dependent RNA synthesis process in which a novel polymerase uses the siRNA as a primer to synthesize more RNA on a template of complementary RNA (for review see 2490).

A related process is the phenomenon of **cosuppression** in which introduction of a transgene causes the corresponding endogenous gene to be silenced. This has been largely characterized in plants (1193). The implication is that the transgene must make both antisense and sense RNA copies, and this inhibits expression of the endogenous gene.

Silencing takes place by RNA-RNA interactions. It is also possible that dsRNA may inhibit gene expression by interacting with the DNA. If a DNA copy of a viroid RNA sequence is inserted into a plant genome, it becomes methylated when the viroid RNA replicates (2149). This suggests that the RNA sequence could be inducing methylation of the DNA sequence. Similar targeting of methylation of DNA corresponding to sequences represented in dsRNA has been detected in plant cells (2150). Methylation of DNA is associated with repression of transcription, so this could be another means of silencing genes represented in dsRNA (see *Molecular Biology 5.21.18 Gene expression is associated with demethylation*). Nothing is known about the mechanism (for review see 2077; 2078).

## REGULATORY CIRCUITS

### 3.11.23 Summary

---

Gene expression can be regulated positively by factors that activate a gene or negatively by factors that repress a gene. The first and most common level of control is at the initiation of transcription, but termination of transcription may be also be controlled. Translation may be controlled by regulators that interact with mRNA. The regulatory products may be proteins, which often are controlled by allosteric interactions in response to the environment, or RNAs, which function by base pairing with the target RNA to change its secondary structure. Regulatory networks can be created by linking regulators so that the production or activity of one regulator is controlled by another.

Bacteria respond to the supply of glucose by repressing the production of the enzyme systems that catabolize alternative carbon sources. Inducer exclusion is a major component of the response, and works by inhibiting the uptake of the other sugars into the bacterium, with the result that the operons coding for their enzyme systems fail to be turned on. Increase in glucose levels also may lead to a reduction in the level of the small nucleotide cyclic AMP, although this is now controversial.

Some promoters cannot be recognized by RNA polymerase (or are recognized only poorly) unless a specific activator protein is present. Activator proteins also may be regulated by small molecules. The CRP activator becomes able to bind to target sequences in the presence of cyclic AMP. All promoters that respond to CRP have at least one copy of the target sequence. Binding of CRP to its target involves bending DNA. Direct contact between one subunit of CRP and RNA polymerase is required to activate transcription.

A common means for controlling translation is for a regulator protein to bind to a site on the mRNA that overlaps the ribosome binding site at the initiation codon. This prevents ribosomes from initiating translation. RegA of T4 is a general regulator that functions on several target mRNAs at the level of translation. Most proteins that repress translation possess this capacity in addition to other functional roles; in particular, translation is controlled in some cases of autogenous regulation, when a gene product regulates expression of the operon containing its own gene.

The level of protein synthesis itself provides an important coordinating signal. Deficiency in aminoacyl-tRNA causes an idling reaction on the ribosome, which leads to the synthesis of the unusual nucleotide ppGpp. This is an effector that inhibits initiation of transcription at certain promoters; it also has a general effect in inhibiting elongation on all templates.

Attenuation is a mechanism that relies on regulation of termination to control transcription through bacterial operons. It is commonly used in operons that code for enzymes involved in biosynthesis of an amino acid. The polycistronic mRNA of the operon starts with a sequence that can form alternative secondary structures. One of the structures has a hairpin loop that provides an intrinsic terminator upstream of the structural genes; the alternative structure lacks the hairpin. Various types of interaction can be used to determine whether the hairpin forms. One is for a protein

to bind to the mRNA to prevent formation of the alternative structure. In the *trp* operon of *B. subtilis*, the TRAP protein has this function; it is controlled by the anti-TRAP protein, whose production in turn is controlled by the level of uncharged aminoacyl-tRNA<sup>Trp</sup>. In the *trp* operon of *E. coli*, the choice of which structure forms is controlled by the progress of translation through a short leader sequence that includes codons for the amino acid(s) that are the product of the system. In the presence of aminoacyl-tRNA bearing such amino acid(s), ribosomes translate the leader peptide, allowing a secondary structure to form that supports termination. In the absence of this aminoacyl-tRNA, the ribosome stalls, resulting in a new secondary structure in which the hairpin needed for termination cannot form. The supply of aminoacyl-tRNA therefore (inversely) controls amino acid biosynthesis.

Small regulator RNAs are found in both bacteria and eukaryotes. *E. coli* has ~17 sRNA species. The *oxyS* sRNA controls about 10 target loci at the post-transcriptional level; some of them are repressed, and others are activated. Repression is caused when the sRNA binds to a target mRNA to form a duplex region that includes the ribosome-binding site. MicroRNAs are ~22 bases long and are produced in many eukaryotes by cleavage of a longer transcript. They function by base pairing with target mRNAs to form duplex regions that are susceptible to cleavage by endonucleases. The degradation of the mRNA prevents its expression. The technique of RNA interference is becoming the method of choice for inactivating eukaryotic genes. It uses the introduction of short dsRNA sequences with one strand complementary to the target RNA, and it works by inducing degradation of the targets. This may be related to a natural defense system in plants called RNA silencing.

## PHAGE STRATEGIES

### 3.12.1 Introduction

---

#### Key Terms

**Lytic infection** of a bacterium by a phage ends in the destruction of the bacterium with release of progeny phage.

**Lysis** describes the death of bacteria at the end of a phage infective cycle when they burst open to release the progeny of an infecting phage (because phage enzymes disrupt the bacterium's cytoplasmic membrane or cell wall). The same term also applies to eukaryotic cells; for example, when infected cells are attacked by the immune system.

**Prophage** is a phage genome covalently integrated as a linear part of the bacterial chromosome.

**Lysogeny** describes the ability of a phage to survive in a bacterium as a stable prophage component of the bacterial genome.

**Integration** of viral or another DNA sequence describes its insertion into a host genome as a region covalently linked on either side to the host sequences.

**Induction of prophage** describes its entry into the lytic (infective) cycle as a result of destruction of the lysogenic repressor, which leads to excision of free phage DNA from the bacterial chromosome.

The **excision** of phage or episome or other sequence describes its release from the host chromosome as an autonomous DNA molecule.

A **plasmid** is a circular, extrachromosomal DNA. It is autonomous and can replicate itself.

An **extrachromosomal genome** in a bacterium is a self-replicating set of genes that is not part of the bacterial chromosome. In many cases, the genes are necessary for bacterial growth under certain environmental conditions.

An **episome** is a plasmid able to integrate into bacterial DNA.

**Immunity** in phages refers to the ability of a prophage to prevent another phage of the same type from infecting a cell. It results from the synthesis of phage repressor by the prophage genome.

**Immunity** in plasmids describes the ability of a plasmid to prevent another of the same type from becoming established in a cell. It results usually from interference with the ability to replicate.

---

Some phages have only a single strategy for survival. On infecting a susceptible host, they subvert its functions to the purpose of producing a large number of progeny phage particles. As the result of this **lytic infection**, the host bacterium dies. In the typical lytic cycle, the phage DNA (or RNA) enters the host bacterium, its genes are transcribed in a set order, the phage genetic material is replicated, and the protein components of the phage particle are produced. Finally, the host bacterium is broken open (*lysed*) to release the assembled progeny particles by the process of **lysis**.

---

Other phages have a dual existence. They are able to perpetuate themselves via the same sort of lytic cycle in what amounts to an open strategy for producing as many copies of the phage as rapidly as possible. But they also have an alternative form of existence, in which the phage genome is present in the bacterium in a latent form known as **prophage**. This form of propagation is called **lysogeny**.

In a lysogenic bacterium, the prophage is inserted into the bacterial genome, and is inherited in the same way as bacterial genes. The process by which it is converted from an independent phage genome into a prophage that is a linear part of the bacterial genome is described as **integration**. By virtue of its possession of a prophage, a lysogenic bacterium has **immunity** against infection by further phage particles of the same type. Immunity is established by a single integrated prophage, so usually a bacterial genome contains only one copy of a prophage of any particular type.

Transitions occur between the lysogenic and lytic modes of existence. **Figure 12.1** shows that when a phage produced by a lytic cycle enters a new bacterial host cell, it either repeats the lytic cycle or enters the lysogenic state. The outcome depends on the conditions of infection and the genotypes of phage and bacterium.

**Figure 12.1** Lytic development involves the reproduction of phage particles with destruction of the host bacterium, but lysogenic existence allows the phage genome to be carried as part of the bacterial genetic information.

A prophage is freed from the restrictions of lysogeny by the process called **induction**. First the phage DNA is released from the bacterial chromosome by **excision**; then the free DNA proceeds through the lytic pathway.

The alternative forms in which these phages are propagated are determined by the regulation of transcription. Lysogeny is maintained by the interaction of a phage repressor with an operator. The lytic cycle requires a cascade of transcriptional controls. And the transition between the two life-styles is accomplished by the establishment of repression (lytic cycle to lysogeny) or by the relief of repression (induction of lysogen to lytic phage).

Another type of existence within bacteria is represented by **plasmids**. These are autonomous units that exist in the cell as **extrachromosomal genomes**. Plasmids are self-replicating circular molecules of DNA that are maintained in the cell in a stable

and characteristic number of copies; that is, the number remains constant from generation to generation.

Some plasmids also have alternative life-styles. They can exist either in the autonomous extrachromosomal state; or they can be inserted into the bacterial chromosome, and then are carried as part of it like any other sequence. Such units are properly called **episomes** (but the terms "plasmid" and "episome" are sometimes used loosely as though interchangeable).

Like lysogenic phages, plasmids and episomes maintain a selfish possession of their bacterium and often make it impossible for another element of the same type to become established. This effect also is called **immunity**, although the basis for plasmid immunity is different from lysogenic immunity. (We discuss the control of plasmid perpetuation in *Molecular Biology 4.13 The replicon*.)

**Figure 12.2** summarizes the types of genetic units that can be propagated in bacteria as independent genomes. Lytic phages may have genomes of any type of nucleic acid; they transfer between cells by release of infective particles. Lysogenic phages have double-stranded DNA genomes, as do plasmids and episomes. Some plasmids and episomes transfer between cells by a conjugative process (involving direct contact between donor and recipient cells). A feature of the transfer process in both cases is that on occasion some bacterial host genes are transferred with the phage or plasmid DNA, so these events play a role in allowing exchange of genetic information between bacteria.

Phages and plasmids live in bacteria			
Type of Unit	Genome Structure	Mode of Propagation	Consequences
Lytic phage	ds- or ss-DNA or RNA linear or circular	Infects susceptible host	Usually kills host
Lysogenic phage	ds-DNA	Linear sequence in host chromosome	Immunity to infection
Plasmid	ds-DNA circle	Replicates at defined copy number May be transmissible	Immunity to plasmids in same group
Episome	ds-DNA circle	Free circle or linear integrated	May transfer host DNA

## PHAGE STRATEGIES

### 3.12.2 Lytic development is divided into two periods

---

#### Key Terms

**Early infection** is the part of the phage lytic cycle between entry and replication of the phage DNA. During this time, the phage synthesizes the enzymes needed to replicate its DNA.

**Late infection** is the part of the phage lytic cycle from DNA replication to lysis of the cell. During this time, the DNA is replicated and structural components of the phage particle are synthesized.

#### Key Concepts

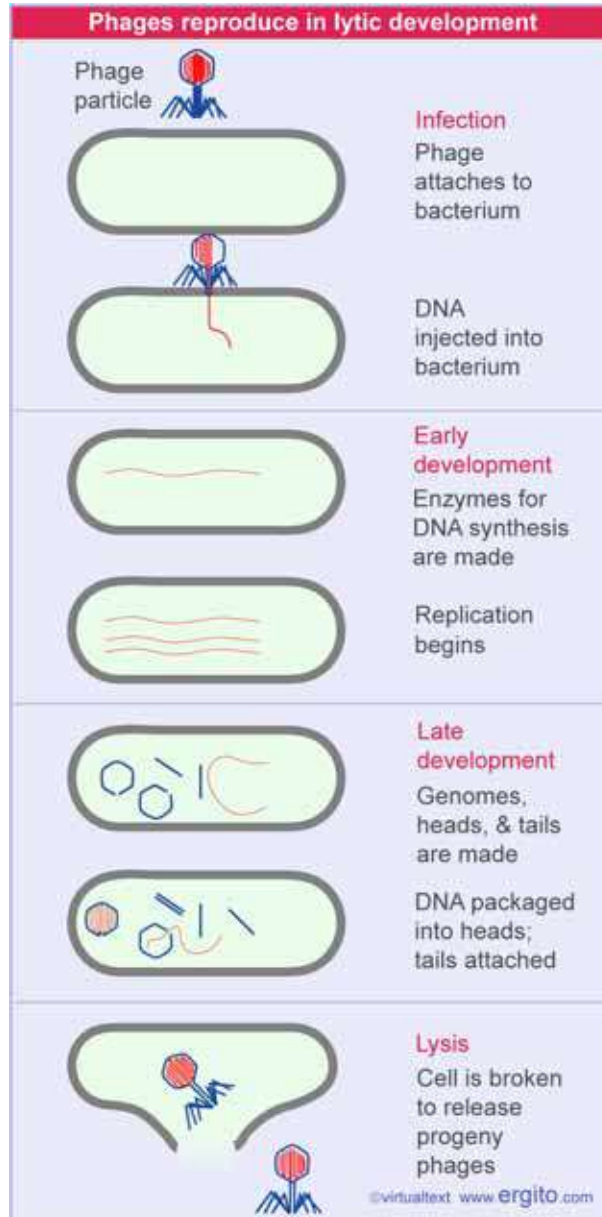

- A phage infective cycle is divided into the early period (before replication) and the late period (after the onset of replication).
- A phage infection generates a pool of progeny phage genomes that replicate and recombine.

---

Phage genomes of necessity are small. As with all viruses, they are restricted by the need to package the nucleic acid within the protein coat. This limitation dictates many of the viral strategies for reproduction. Typically a virus takes over the apparatus of the host cell, which then replicates and expresses phage genes instead of the bacterial genes.

Usually the phage includes genes whose function is to ensure preferential replication of phage DNA. These genes are concerned with the initiation of replication and may even include a new DNA polymerase. Changes are introduced in the capacity of the host cell to engage in transcription. They involve replacing the RNA polymerase or modifying its capacity for initiation or termination. The result is always the same: phage mRNAs are preferentially transcribed. So far as protein synthesis is concerned, usually the phage is content to use the host apparatus, redirecting its activities principally by replacing bacterial mRNA with phage mRNA.

Lytic development is accomplished by a pathway in which the phage genes are expressed in a particular order. This ensures that the right amount of each component is present at the appropriate time. The cycle can be divided into the two general parts illustrated in **Figure 12.3**:

**Figure 12.3** Lytic development takes place by producing phage genomes and protein particles that are assembled into progeny phages.

- **Early infection** describes the period from entry of the DNA to the start of its replication.
- **Late infection** defines the period from the start of replication to the final step of lysing the bacterial cell to release progeny phage particles.

The early phase is devoted to the production of enzymes involved in the reproduction of DNA. These include the enzymes concerned with DNA synthesis, recombination, and sometimes modification. Their activities cause a *pool* of phage genomes to

accumulate. In this pool, genomes are continually replicating and recombining, so that *the events of a single lytic cycle concern a population of phage genomes*.

During the late phase, the protein components of the phage particle are synthesized. Often many different proteins are needed to make up head and tail structures, so the largest part of the phage genome consists of late functions. In addition to the structural proteins, "assembly proteins" are needed to help construct the particle, although they are not themselves incorporated into it. By the time the structural components are assembling into heads and tails, replication of DNA has reached its maximum rate. The genomes then are inserted into the empty protein heads, tails are added, and the host cell is lysed to allow release of new viral particles.

---

## PHAGE STRATEGIES

### 3.12.3 Lytic development is controlled by a cascade

---

#### Key Terms

A **cascade** is a sequence of events, each of which is stimulated by the previous one.

In transcriptional regulation, as seen in sporulation and phage lytic development, it means that regulation is divided into stages, and at each stage, one of the genes that are expressed codes for a regulator needed to express the genes of the next stage.

**Early genes** are transcribed before the replication of phage DNA. They code for regulators and other proteins needed for later stages of infection.

**Immediate early** phage genes in phage lambda are equivalent to the early class of other phages. They are transcribed immediately upon infection by the host RNA polymerase.

**Delayed early** genes in phage lambda are equivalent to the middle genes of other phages. They cannot be transcribed until regulator protein(s) coded by the immediate early genes have been synthesized.

**Middle genes** are phage genes that are regulated by the proteins coded by early genes. Some proteins coded by middle genes catalyze replication of the phage DNA; others regulate the expression of a later set of genes.

**Late genes** are transcribed when phage DNA is being replicated. They code for components of the phage particle.

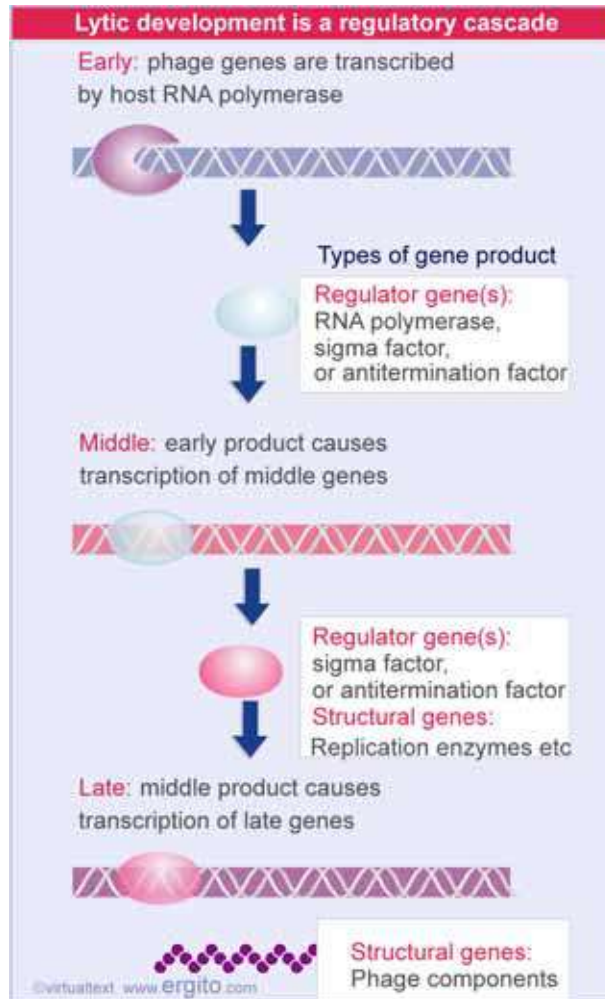

#### Key Concepts

- The early genes transcribed by host RNA polymerase following infection include or comprise regulators required for expression of the middle set of phage genes.
- The middle group of genes include regulators to transcribe the late genes.
- This results in the ordered expression of groups of genes during phage infection.

---

The organization of the phage genetic map often reflects the sequence of lytic development. The concept of the operon is taken to somewhat of an extreme, in which the genes coding for proteins with related functions are clustered to allow their control with the maximum economy. This allows the pathway of lytic development to be controlled with a small number of regulatory switches.

The lytic cycle is under positive control, so that each group of phage genes can be expressed only when an appropriate signal is given. **Figure 12.4** shows that the regulatory genes function in a **cascade**, in which a gene expressed at one stage is necessary for synthesis of the genes that are expressed at the next stage.

**Figure 12.4** Phage lytic development proceeds by a regulatory cascade, in which a gene product at each stage is needed for expression of the genes at the next stage.

The first stage of gene expression necessarily relies on the transcription apparatus of the host cell. Usually only a few genes are expressed at this stage. Their promoters are indistinguishable from those of host genes. The name of this class of genes depends on the phage. In most cases, they are known as the **early genes**. In phage lambda, they are given the evocative description of **immediate early**. Irrespective of the name, they constitute only a preliminary, representing just the initial part of the early period. Sometimes they are exclusively occupied with the transition to the next period. At all events, *one of these genes always codes for a protein that is necessary for transcription of the next class of genes.*

This second class of genes is known variously as the **delayed early** or **middle gene** group. Its expression typically starts as soon as the regulator protein coded by the early gene(s) is available. Depending on the nature of the control circuit, the initial set of early genes may or may not continue to be expressed at this stage. If control is at initiation, the two events are independent (see **Figure 12.5**), and early genes can be switched off when middle genes are transcribed. If control is at termination, the early genes must continue to be expressed (see **Figure 12.6**). Often the expression of

host genes is reduced. Together the two sets of early genes account for all necessary phage functions except those needed to assemble the particle coat itself and to lyse the cell.

When the replication of phage DNA begins, it is time for the **late genes** to be expressed. Their transcription at this stage usually is arranged by embedding a further regulator gene within the previous (delayed early or middle) set of genes. This regulator may be another antitermination factor (as in lambda) or it may be another sigma factor (as in SPO1).

A lytic infection often falls into three stages, as shown in **Figure 12.4**. The first stage consists of early genes transcribed by host RNA polymerase (sometimes the regulators are the only products at this stage). The second stage consists of genes transcribed under direction of the regulator produced in the first stage (most of these genes code for enzymes needed for replication of phage DNA). The final stage consists of genes for phage components, transcribed under direction of a regulator synthesized in the second stage.

*The use of these successive controls, in which each set of genes contains a regulator that is necessary for expression of the next set, creates a cascade in which groups of genes are turned on (and sometimes off) at particular times.* The means used to construct each phage cascade are different, but the results are similar, as the following sections show.

*This content is available online at <http://www.ergito.com/main.jsp?bcs=MBIO.3.12.3>*

---

## PHAGE STRATEGIES

### 3.12.4 Two types of regulatory event control the lytic cascade

---

#### Key Concepts

- Regulator proteins used in phage cascades may sponsor initiation at new (phage) promoters or cause the host polymerase to read through transcription terminators.
- 

At every stage of phage expression, one or more of the active genes is a regulator that is needed for the subsequent stage. The regulator may take the form of a new RNA polymerase, a sigma factor that redirects the specificity of the host RNA polymerase (see *Molecular Biology 3.9.18 Sigma factors may be organized into cascades*), or an antitermination factor that allows it to read a new group of genes (see *Molecular Biology 3.9.23 Antitermination is a regulatory event*). The next two figures compare the use of switching at initiation or termination to control gene expression.

One mechanism for recognizing new phage promoters is to replace the sigma factor of the host enzyme with another factor that redirects its specificity in initiation (see **Figure 9.31**). An alternative mechanism is to synthesize a new phage RNA polymerase. In either case, the critical feature that distinguishes the new set of genes is their possession of *different promoters from those originally recognized by host RNA polymerase*. **Figure 12.5** shows that the two sets of transcripts are independent; as a consequence, early gene expression can cease after the new sigma factor or polymerase has been produced.

**Figure 12.5** Control at initiation utilizes independent transcription units, each with its own promoter and terminator, which produce independent mRNAs. The transcription units need not be located near one another.

Antitermination provides an alternative mechanism for phages to control the switch from early genes to the next stage of expression. The use of antitermination depends on a particular arrangement of genes. **Figure 12.6** shows that the early genes lie adjacent to the genes that are to be expressed next, but are separated from them by terminator sites. *If termination is prevented at these sites, the polymerase reads through into the genes on the other side.* So in antitermination, the *same promoters* continue to be recognized by RNA polymerase. So the new genes are expressed only by extending the RNA chain to form molecules that contain the early gene sequences at the 5' end and the new gene sequences at the 3' end. Since the two types of sequence remain linked, early gene expression inevitably continues (for review see 102).

**Figure 12.6** Control at termination requires adjacent units, so that transcription can read from the first gene into the next gene. This produces a single mRNA that contains both sets of genes.

The regulator gene that controls the switch from immediate early to delayed early expression in phage lambda is identified by mutations in gene *N* that can transcribe *only* the immediate early genes; they proceed no further into the infective cycle (see **Figure 9.53**). The same effect is seen when gene 28 of phage SPO1 is mutated to prevent the production of  $\sigma^{gp28}$  (see **Figure 9.40**). From the genetic point of view, the mechanisms of new initiation and antitermination are similar. *Both are positive controls in which an early gene product must be made by the phage in order to express the next set of genes.* By employing either sigma factors or antitermination proteins with different specificities, a cascade for gene expression can be constructed

**PHAGE STRATEGIES****3.12.5 The T7 and T4 genomes show functional clustering****Key Concepts**

- Genes concerned with related functions are often clustered.
- Phages T7 and T4 are examples of regulatory cascades in which phage infection is divided into three periods.

The genome of phage T7 has three classes of genes, each constituting a group of adjacent loci. As **Figure 12.7** shows, the class I genes are the immediate early type, expressed by host RNA polymerase as soon as the phage DNA enters the cell. Among the products of these genes are a phage RNA polymerase and enzymes that interfere with host gene expression. The phage RNA polymerase is responsible for expressing the class II genes (concerned principally with DNA synthesis functions) and the class III genes (concerned with assembling the mature phage particle).

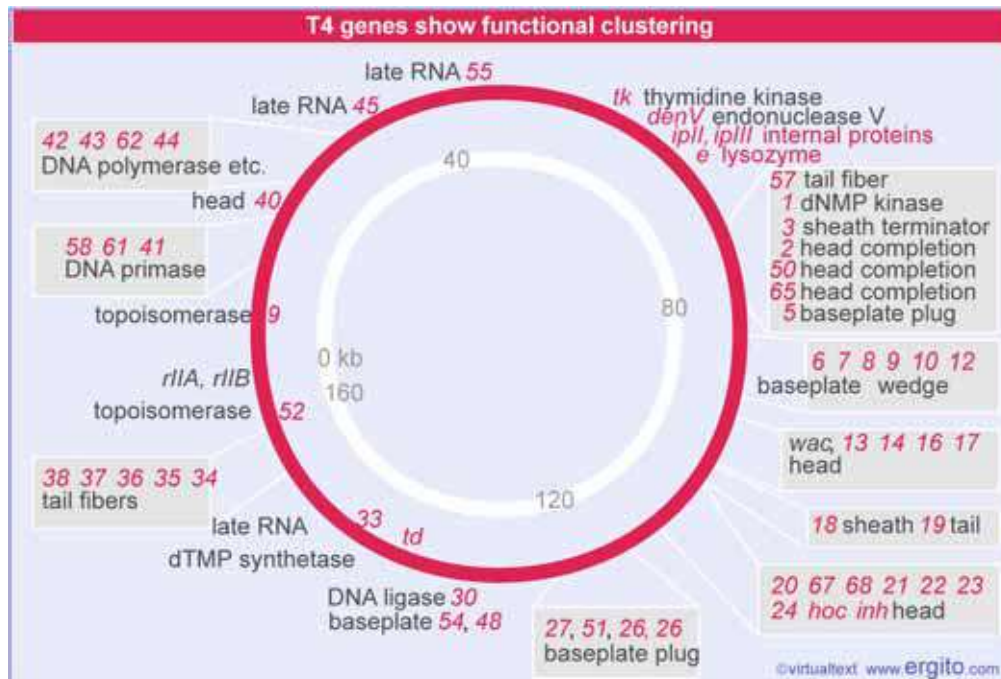

**Figure 12.7** Phage T7 contains three classes of genes that are expressed sequentially. The genome is ~38 kb.

T4 has one of the larger phage genomes (165 kb), organized with extensive functional grouping of genes. **Figure 12.8** presents the genetic map. *Essential genes* are numbered: a mutation in any one of these loci prevents successful completion of the lytic cycle. *Nonessential genes* are indicated by three-letter abbreviations. (They are defined as nonessential under the usual conditions of infection. We do not really understand the inclusion of many nonessential genes, but presumably they confer a selective advantage in some of T4's habitats. In smaller phage genomes, most or all

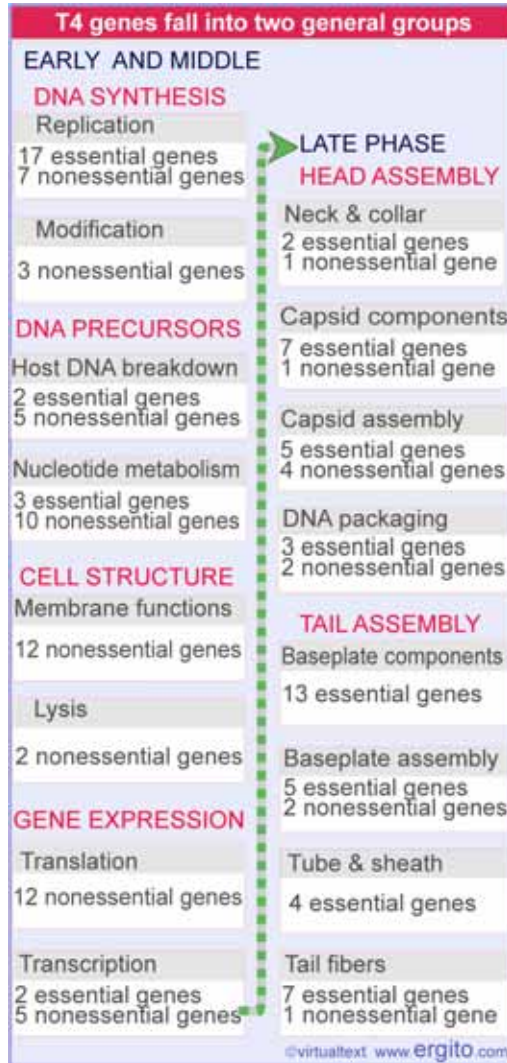

of the genes are essential.)

**Figure 12.8** The map of T4 is circular. There is extensive clustering of genes coding for components of the phage and processes such as DNA replication, but there is also dispersion of genes coding for a variety of enzymatic and other functions. Essential genes are indicated by numbers. Nonessential genes are identified by letters. Only some representative T4 genes are shown on the map.

There are three phases of gene expression. A summary of the functions of the genes expressed at each stage is given in **Figure 12.9**. The early genes are transcribed by host RNA polymerase. The middle genes are also transcribed by host RNA polymerase, but two phage-encoded products, MotA and AsiA, are also required. The middle promoters lack a consensus  $-30$  sequence, and instead have a binding sequence for MotA. The phage protein is an activator that compensates for the deficiency in the promoter by assisting host RNA polymerase to bind. (This is similar to a mechanism employed by phage lambda, which is illustrated later in **Figure 12.28**.) The early and middle genes account for virtually all of the phage functions concerned with the synthesis of DNA, modifying cell structure, and transcribing and translating phage genes.

**Figure 12.9** The phage T4 lytic cascade falls into two parts: early functions are concerned with DNA synthesis and gene expression; late functions are concerned with particle assembly.

The two essential genes in the "transcription" category fulfill a regulatory function: their products are necessary for late gene expression. Phage T4 infection depends on a mechanical link between replication and late gene expression. Only actively replicating DNA can be used as template for late gene transcription. The connection is generated by introducing a new sigma factor and also by making other modifications in the host RNA polymerase so that it is active only with a template of replicating DNA. This link establishes a correlation between the synthesis of phage protein components and the number of genomes available for packaging.

## PHAGE STRATEGIES

### 3.12.6 Lambda immediate early and delayed early genes are needed for both lysogeny and the lytic cycle

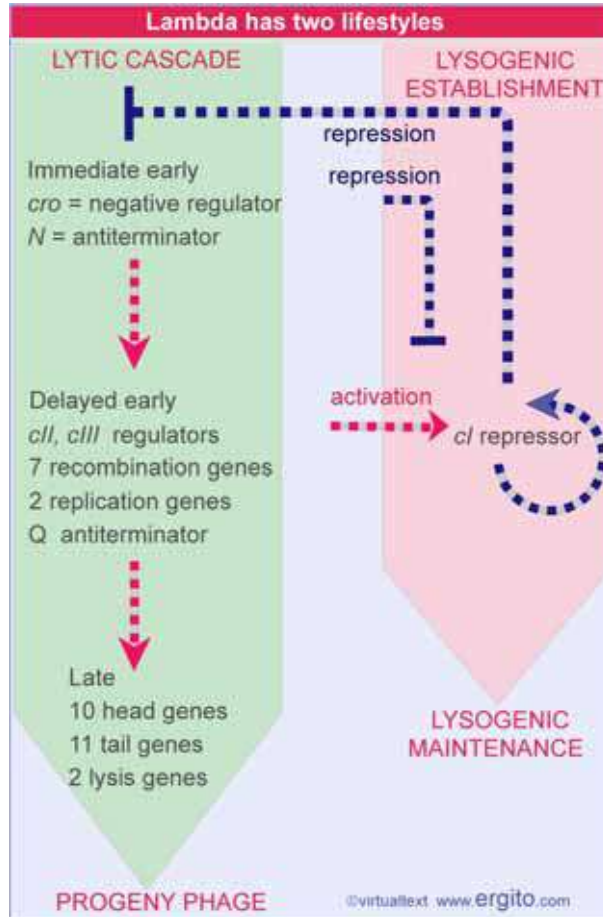

---

#### Key Concepts

- Lambda has two immediate early genes, *N* and *cro*, which are transcribed by host RNA polymerase.
- *N* is required to express the delayed early genes.
- Three of the delayed early genes are regulators.
- Lysogeny requires the delayed early genes *cII-cIII*.
- The lytic cycle requires the immediate early gene *cro* and the delayed early gene *Q*.

---

One of the most intricate cascade circuits is provided by phage lambda. Actually, the cascade for lytic development itself is straightforward, with two regulators controlling the successive stages of development. But the circuit for the lytic cycle is interlocked with the circuit for establishing lysogeny, as summarized in **Figure 12.10** (for review see 100).

**Figure 12.10** The lambda lytic cascade is interlocked with the circuitry for lysogeny.

When lambda DNA enters a new host cell, the lytic and lysogenic pathways start off the same way. Both require expression of the immediate early and delayed early genes. But then they diverge: lytic development follows if the late genes are expressed; lysogeny ensues if synthesis of the repressor is established.

Lambda has only two immediate early genes, transcribed independently by host RNA polymerase:

- *N* codes for an antitermination factor whose action at the *nut* sites allows transcription to proceed into the delayed early genes (see *Molecular Biology 3.9.24 Antitermination requires sites that are independent of the terminators*).
- *cro* has dual functions: it prevents synthesis of the repressor (a necessary action if the lytic cycle is to proceed); and it turns off expression of the immediate early genes (which are not needed later in the lytic cycle).

The delayed early genes include two replication genes (needed for lytic infection), seven recombination genes (some involved in recombination during lytic infection,

two necessary to integrate lambda DNA into the bacterial chromosome for lysogeny), and three regulators. The regulators have opposing functions:

- The *cII-cIII* pair of regulators is needed to establish the synthesis of repressor.
- The *Q* regulator is an antitermination factor that allows host RNA polymerase to transcribe the late genes.

So the delayed early genes serve two masters: some are needed for the phage to enter lysogeny, the others are concerned with controlling the order of the lytic cycle.

This content is available online at <http://www.ergito.com/main.jsp?bcs=MBIO.3.12.6>

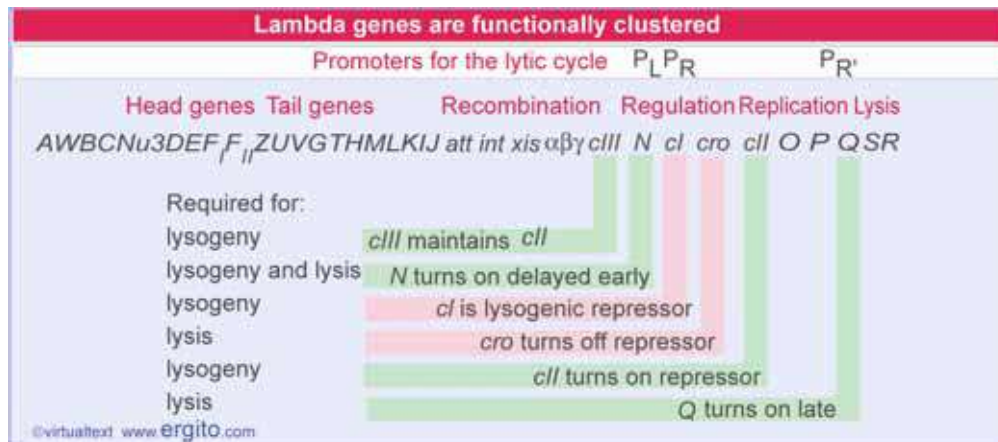

## PHAGE STRATEGIES

### 3.12.7 The lytic cycle depends on antitermination

#### Key Concepts

- pN is an antitermination factor that allows RNA polymerase to continue transcription past the ends of the two immediate early genes.
- pQ is the product of a delayed early gene and is an antiterminator that allows RNA polymerase to transcribe the late genes.
- Because lambda DNA circularizes after infection, the late genes form a single transcription unit.

To disentangle the two pathways, let's first consider just the lytic cycle. **Figure 12.11** gives the map of lambda phage DNA. A group of genes concerned with regulation is surrounded by genes needed for recombination and replication. The genes coding for structural components of the phage are clustered. All of the genes necessary for the lytic cycle are expressed in polycistronic transcripts from three promoters.

**Figure 12.11** The lambda map shows clustering of related functions. The genome is 48,514 bp.

**Figure 12.12** shows that the two immediate early genes, *N* and *cro*, are transcribed by host RNA polymerase. *N* is transcribed toward the left, and *cro* toward the right. Each transcript is terminated at the end of the gene. pN is the regulator that allows transcription to continue into the delayed early genes. It is an antitermination factor that suppresses use of the terminators  $t_L$  and  $t_R$  (see *Molecular Biology 3.9.25 Termination and anti-termination factors interact with RNA polymerase*). In the presence of pN, transcription continues to the left of *N* into the recombination genes, and to the right of *cro* into the replication genes.

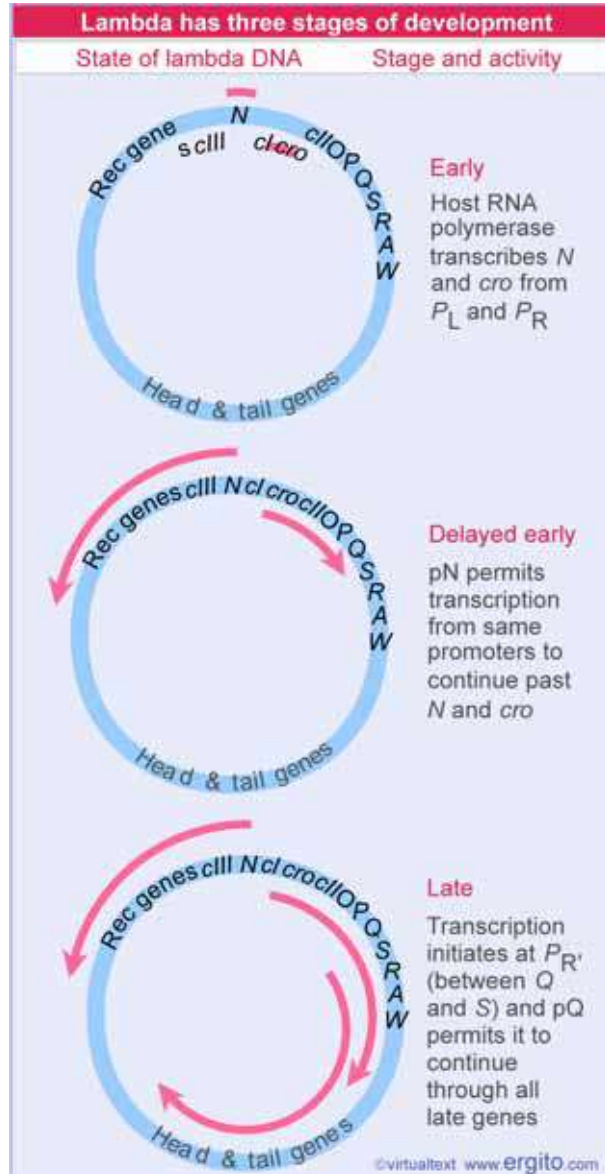

**Figure 12.12** Phage lambda has two early transcription units; in the "leftward" unit, the "upper" strand is transcribed toward the left; in the "rightward" unit, the "lower" strand is transcribed toward the right. . Genes *N* and *cro* are the immediate early functions, and are separated from the delayed early genes by the terminators. Synthesis of N protein allows RNA polymerase to pass the terminators  $t_{L1}$  to the left and  $t_{R1}$  to the right.

The map in **Figure 12.11** gives the organization of the lambda DNA as it exists in the phage particle. But shortly after infection, the ends of the DNA join to form a circle. **Figure 12.13** shows the true state of lambda DNA during infection. The late genes are welded into a single group, containing the lysis genes *S-R* from the right end of the linear DNA, and the head and tail genes *A-J* from the left end.

**Figure 12.13** Lambda DNA circularizes during infection, so that the late gene cluster is intact in one transcription unit.

The late genes are expressed as a single transcription unit, starting from a promoter  $P_R$ , that lies between *Q* and *S*. The late promoter is used constitutively. However, in the absence of the product of gene *Q* (which is the last gene in the rightward delayed early unit), late transcription terminates at a site  $t_{R3}$ . The transcript resulting from this termination event is 194 bases long; it is known as 6S RNA. When  $p_Q$  becomes available, it suppresses termination at  $t_{R3}$  and the 6S RNA is extended, with the result that the late genes are expressed.

Late gene transcription does not seem to terminate at any specific point, but continues through all the late genes into the region beyond. A similar event happens with the leftward delayed early transcription, which continues past the recombination functions. Transcription in each direction is probably terminated before the

polymerases could crash into each other.

*This content is available online at <http://www.ergito.com/main.jsp?bcs=MBIO.3.12.7>*

## PHAGE STRATEGIES

### 3.12.8 Lysogeny is maintained by repressor protein

#### Key Terms

A **plaque** is an area of clearing in a bacterial lawn. It is created by a single phage particle that has undergone multiple rounds of lytic growth.

A **clear plaque** is a type of plaque that contains only lysed bacterial cells.

#### Key Concepts

- Mutants in the *cI* gene cannot maintain lysogeny.
- *cI* codes for a repressor protein that acts at the  $O_L$  and  $O_R$  operators to block transcription of the immediate early genes.
- Because the immediate early genes trigger a regulatory cascade, their repression prevents the lytic cycle from proceeding.

Looking at the lambda lytic cascade, we see that the entire program is set in train by initiating transcription at the two promoters  $P_L$  and  $P_R$  for the immediate early genes *N* and *cro*. Because lambda uses antitermination to proceed to the next stage of (delayed early) expression, the same two promoters continue to be used throughout the early period.

The expanded map of the regulatory region drawn in **Figure 12.14** shows that the promoters  $P_L$  and  $P_R$  lie on either side of the *cI* gene. Associated with each promoter is an operator ( $O_L$ ,  $O_R$ ) at which repressor protein binds to prevent RNA polymerase from initiating transcription. The sequence of each operator overlaps with the promoter that it controls; so often these are described as the  $P_L/O_L$  and  $P_R/O_R$  control regions.

**Figure 12.14** The lambda regulatory region contains a cluster of *trans*-acting functions and *cis*-acting elements.

Because of the sequential nature of the lytic cascade, the control regions provide a pressure point at which entry to the entire cycle can be controlled. *By denying RNA*

*polymerase access to these promoters, a repressor protein prevents the phage genome from entering the lytic cycle. The repressor functions in the same way as repressors of bacterial operons: it binds to specific operators (525; 526; 527).*

The repressor protein is coded by the *cI* gene. Mutants in this gene cannot maintain lysogeny, but always enter the lytic cycle. Since the original isolation of the repressor protein (525; see *Great Experiments 2.1 Isolation of repressor*), its characterization has shown how it both maintains the lysogenic state and provides immunity for a lysogen against superinfection by new phage lambda genomes.

When a bacterial culture is infected with a phage, the cells are lysed to generate regions that can be seen on a culture plate as small areas of clearing called **plaques**. With wild-type phages, the plaques are turbid or cloudy, because they contain some cells that have established lysogeny instead of being lysed. The effect of a *cI* mutation is to prevent lysogeny, so that the plaques contain only lysed cells. As a result, such an infection generates only **clear plaques**, and three genes (*cI*, *cII*, *cIII*) were named for their involvement in this phenotype. **Figure 12.15** compares wild-type and mutant plaques.

**Figure 12.15** Wild-type and virulent lambda mutants can be distinguished by their plaque types. Photograph kindly provided by Dale Kaiser.

The *cI* gene is transcribed from a promoter  $P_{RM}$  that lies at its right end. (The subscript "RM" stands for repressor maintenance.) Transcription is terminated at the left end of the gene. The mRNA starts with the AUG initiation codon; because of the absence of the usual ribosome binding site, the mRNA is translated somewhat inefficiently, producing only a low level of repressor protein.

---

**PHAGE STRATEGIES****3.12.9 Repressor maintains an autogenous circuit**

---

**Key Concepts**

- Repressor binding at  $O_L$  blocks transcription of gene  $N$  from  $P_L$ .
- Repressor binding at  $O_R$  blocks transcription of  $cro$  but also is required for transcription of  $cI$ .
- Repressor binding to the operators therefore simultaneously blocks entry to the lytic cycle and promotes its own synthesis.

---

The repressor binds independently to the two operators. It has a single function at  $O_L$ , but has dual functions at  $O_R$ . These are illustrated in the upper part of **Figure 12.16**.

**Figure 12.16** Lysogeny is maintained by an autogenous circuit (upper). If this circuit is interrupted, the lytic cycle starts (lower).

At  $O_L$  the repressor has the same sort of effect that we have already discussed for several other systems: it prevents RNA polymerase from initiating transcription at  $P_L$ . This stops the expression of gene  $N$ . Since  $P_L$  is used for all leftward early gene transcription, this action prevents expression of the entire leftward early transcription unit. *So the lytic cycle is blocked before it can proceed beyond the early stages.*

At  $O_R$ , repressor binding prevents the use of  $P_R$ . So  $cro$  and the other rightward early genes cannot be expressed. (We see later why it is important to prevent the expression of  $cro$  when lysogeny is being maintained.)

But the presence of repressor at  $O_R$  also has another effect. The promoter for repressor synthesis,  $P_{RM}$ , is adjacent to the rightward operator  $O_R$ . It turns out that *RNA polymerase can initiate efficiently at  $P_{RM}$  only when repressor is bound at  $O_R$* . The repressor behaves as a positive regulator protein that is necessary for transcription of the  $cI$  gene (see *Molecular Biology 3.12.15 Repressor at  $O_R$*

*interacts with RNA polymerase at  $P_{RM}$ ). Since the repressor is the product of  $cI$ , this interaction creates a positive autogenous circuit, in which the presence of repressor is necessary to support its own continued synthesis.*

The nature of this control circuit explains the biological features of lysogenic existence. Lysogeny is stable because the control circuit ensures that, so long as the level of repressor is adequate, there is continued expression of the  $cI$  gene. The result is that  $O_L$  and  $O_R$  remain occupied indefinitely. By repressing the entire lytic cascade, this action maintains the prophage in its inert form.

## PHAGE STRATEGIES

### 3.12.10 The repressor and its operators define the immunity region

---

#### Key Terms

**Immunity** in phages refers to the ability of a prophage to prevent another phage of the same type from infecting a cell. It results from the synthesis of phage repressor by the prophage genome.

**Virulent** phage mutants are unable to establish lysogeny.

The **immunity region** is a segment of the phage genome that enables a prophage to inhibit additional phage of the same type from infecting the bacterium. This region has a gene that encodes for the repressor, as well as the sites to which the repressor binds.

#### Key Concepts

- Several lambdoid phages have different immunity regions.
- A lysogenic phage confers immunity to further infection by any other phage with the same immunity region.

---

The presence of repressor explains the phenomenon of **immunity**. If a second lambda phage DNA enters a lysogenic cell, repressor protein synthesized from the resident prophage genome will immediately bind to  $O_L$  and  $O_R$  in the new genome. This prevents the second phage from entering the lytic cycle.

The operators were originally identified as the targets for repressor action by **virulent** mutations ( $\lambda vir$ ). These mutations prevent the repressor from binding at  $O_L$  or  $O_R$ , with the result that the phage inevitably proceeds into the lytic pathway when it infects a new host bacterium. And  $\lambda vir$  mutants can grow on lysogens because the virulent mutations in  $O_L$  and  $O_R$  allow the incoming phage to ignore the resident repressor and thus to enter the lytic cycle. Virulent mutations in phages are the equivalent of operator-constitutive mutations in bacterial operons.

Prophage is induced to enter the lytic cycle when the lysogenic circuit is broken. This happens when the repressor is inactivated (see next section). The absence of repressor allows RNA polymerase to bind at  $P_L$  and  $P_R$ , starting the lytic cycle as shown in the lower part of **Figure 12.16** (for review see 104).

The autogenous nature of the repressor-maintenance circuit creates a sensitive response. Because the presence of repressor is necessary for its own synthesis, expression of the *cI* gene stops as soon as the existing repressor is destroyed. So no repressor is synthesized to replace the molecules that have been damaged. This enables the lytic cycle to start without interference from the circuit that maintains lysogeny.

The region including the left and right operators, the *cI* gene, and the *cro* gene determines the immunity of the phage. Any phage that possesses this region has the same type of immunity, because *it specifies both the repressor protein and the sites on which the repressor acts*. Accordingly, this is called the **immunity region** (as marked in **Figure 12.14**). Each of the four lambdoid phages  $\phi 80$ , *21*, *434*, and  $\lambda$  has a unique immunity region. When we say that a lysogenic phage confers immunity to any other phage of the same type, we mean more precisely that the immunity is to any other phage that has the same immunity region (irrespective of differences in other regions).

**PHAGE STRATEGIES****3.12.11 The DNA-binding form of repressor is a dimer****Key Concepts**

- A repressor monomer has two distinct domains.
- The N-terminal domain contains the DNA-binding site.
- The C-terminal domain dimerizes.
- Binding to the operator requires the dimeric form so that two DNA-binding domains can contact the operator simultaneously.
- Cleavage of the repressor between the two domains reduces the affinity for the operator and induces a lytic cycle.

The repressor subunit is a polypeptide of 27 kD with the two distinct domains summarized in **Figure 12.17**.

**Figure 12.17** The N-terminal and C-terminal regions of repressor form separate domains. The C-terminal domains associate to form dimers; the N-terminal domains bind DNA.

- The N-terminal domain, residues 1-92, provides the operator-binding site.
- The C-terminal domain, residues 132-236, is responsible for dimerization.

The two domains are joined by a connector of 40 residues. When repressor is digested by a protease, each domain is released as a separate fragment.

Each domain can exercise its function independently of the other. The C-terminal fragment can form oligomers. The N-terminal fragment can bind the operators, although with a lower affinity than the intact repressor. So the information for

specifically contacting DNA is contained within the N-terminal domain, but the efficiency of the process is enhanced by the attachment of the C-terminal domain (529).

*The dimeric structure of the repressor is crucial in maintaining lysogeny.* The induction of a lysogenic prophage to enter the lytic cycle is caused by cleavage of the repressor subunit in the connector region, between residues 111 and 113. (This is a counterpart to the allosteric change in conformation that results when a small-molecule inducer inactivates the repressor of a bacterial operon, a capacity that the lysogenic repressor does not have.) Induction occurs under certain adverse conditions, such as exposure of lysogenic bacteria to UV irradiation, which leads to proteolytic inactivation of the repressor.

In the intact state, dimerization of the C-terminal domains ensures that when the repressor binds to DNA its two N-terminal domains each contact DNA simultaneously. But cleavage releases the C-terminal domains from the N-terminal domains. As illustrated in **Figure 12.18** this means that the N-terminal domains can no longer dimerize; this upsets the equilibrium between monomers and dimers, so that repressor dissociates from DNA, allowing lytic infection to start. (Another relevant parameter is the loss of cooperative effects between adjacent dimers.)

**Figure 12.18** Repressor dimers bind to the operator. The affinity of the N-terminal domains for DNA is controlled by the dimerization of the C-terminal domains.

The balance between lysogeny and the lytic cycle depends on the concentration of repressor. Intact repressor is present in a lysogenic cell at a concentration sufficient to ensure that the operators are occupied. But if the repressor is cleaved, this concentration is inadequate, because of the lower affinity of the separate N-terminal domain for the operator. Too high a concentration of repressor would make it impossible to induce the lytic cycle in this way; too low a level, of course, would make it impossible to maintain lysogeny.

## PHAGE STRATEGIES

### 3.12.12 Repressor uses a helix-turn-helix motif to bind DNA

#### Key Terms

The **helix-turn-helix** motif describes an arrangement of two  $\alpha$  helices that form a site that binds to DNA, one fitting into the major groove of DNA and other lying across it.

#### Key Concepts

- Each DNA-binding region in the repressor contacts a half-site in the DNA.
- The DNA-binding site of repressor includes two short  $\alpha$ -helical regions which fit into the successive turns of the major groove of DNA.
- A DNA-binding site is a (partially) palindromic sequence of 17 bp.

A repressor dimer is the unit that binds to DNA. It recognizes a sequence of 17 bp displaying partial symmetry about an axis through the central base pair. **Figure 12.19** shows an example of a binding site. The sequence on each side of the central base pair is sometimes called a "half-site". Each individual N-terminal region contacts a half-site. Several DNA-binding proteins that regulate bacterial transcription share a similar mode of holding DNA, in which the active domain contains two short regions of  $\alpha$ -helix that contact DNA. (Some transcription factors in eukaryotic cells use a similar motif; see *Molecular Biology 5.22.14 Homeodomains bind related targets in DNA.*)

**Figure 12.19** The operator is a 17 bp sequence with an axis of symmetry through the central base pair. Each half site is marked in green. Base pairs that are identical in each operator half are in red.

The N-terminal domain of lambda repressor contains several stretches of  $\alpha$ -helix, arranged as illustrated diagrammatically in **Figure 12.20**. Two of the helical regions are responsible for binding DNA. The **helix-turn-helix** model for contact is illustrated in **Figure 12.21**. Looking at a single monomer,  $\alpha$ -helix-3 consists of 9 amino acids, lying at an angle to the preceding region of 7 amino acids that forms  $\alpha$ -helix-2. In the dimer, the two apposed helix-3 regions lie 34 Å apart, enabling them to fit into successive major grooves of DNA. The helix-2 regions lie at an angle that would place them across the groove (530). The symmetrical binding of dimer to the site means that each N-terminal domain of the dimer contacts a similar set of

bases in its half-site.

**Figure 12.20** Lambda repressor's N-terminal domain contains five stretches of  $\alpha$ -helix; helices 2 and 3 are involved in binding DNA.

**Figure 12.21** In the two-helix model for DNA binding, helix-3 of each monomer lies in the wide groove on the same face of DNA, and helix-2 lies across the groove.

## PHAGE STRATEGIES

### 3.12.13 The recognition helix determines specificity for DNA

---

#### Key Terms

The **recognition helix** is the one of the two helices of the helix-turn-helix motif that makes contacts with DNA that are specific for particular bases. This determines the specificity of the DNA sequence that is bound.

#### Key Concepts

- The amino acid sequence of the recognition helix makes contacts with particular bases in the operator sequence that it recognizes.

---

Related forms of the  $\alpha$ -helical motifs employed in the helix-loop-helix of the lambda repressor are found in several DNA-binding proteins, including CRP, the *lac* repressor, and several other phage repressors. By comparing the abilities of these proteins to bind DNA, we can define the roles of each helix:

- Contacts between helix-3 and DNA rely on hydrogen bonds between the amino acid side chains and the exposed positions of the base pairs. This helix is responsible for recognizing the specific target DNA sequence, and is therefore also known as the **recognition helix**.
- Contacts from helix-2 to the DNA take the form of hydrogen bonds connecting with the phosphate backbone. These interactions are necessary for binding, but do not control the specificity of target recognition. In addition to these contacts, a large part of the overall energy of interaction with DNA is provided by ionic interactions with the phosphate backbone.

What happens if we manipulate the coding sequence to construct a new protein by substituting the recognition helix in one repressor with the corresponding sequence from a closely related repressor? The specificity of the hybrid protein is that of its new recognition helix. *The amino acid sequence of this short region determines the sequence specificities of the individual proteins, and is able to act in conjunction with the rest of the polypeptide chain (531).*

**Figure 12.22** shows the details of the binding to DNA of two proteins that bind similar DNA sequences. Both lambda repressor and Cro protein have a similar organization of the helix-turn-helix motif, although their individual specificities for DNA are not identical:

**Figure 12.22** Two proteins that use the two-helix arrangement to contact DNA recognize lambda operators with affinities determined by the amino acid sequence of helix-3.

- Each protein uses similar interactions between hydrophobic amino acids to maintain the relationship between helix-2 and helix-3: repressor has an Ala-Val connection, while Cro has an Ala-Ile association.
- Amino acids in helix-3 of the repressor make contacts with specific bases in the operator. Three amino acids in repressor recognize three bases in DNA; the amino acids at these positions and also at additional positions in Cro recognize five (or possibly six) bases in DNA.

Two of the amino acids involved in specific recognition are identical in repressor and Cro (Gln and Ser at the N-terminal end of the helix), while the other contacts are different (Ala in repressor versus Lys and the additional Asn in Cro). Also, a Thr in helix-2 of Cro directly contacts DNA.

The interactions shown in the figure represent binding to the DNA sequence that each protein recognizes most tightly. The sequences shown at the bottom of the figure with the contact points in color differ at 3 of the 9 base pairs. The use of overlapping, but not identical contacts between amino acids and bases shows how related recognition helices confer recognition of related DNA sequences. This enables repressor and Cro to recognize the same set of sequences, but with different relative affinities for particular members of the group.

The bases contacted by helix-3 of repressor or Cro lie on one face of DNA, as can be seen from the positions indicated on the helical diagram in **Figure 12.22**. However, repressor makes an additional contact with the other face of DNA. Removing the last six N-terminal amino acids (which protrude from helix-1) eliminates some of the contacts. This observation provides the basis for the idea that the bulk of the N-terminal domain contacts one face of DNA, while the last six N-terminal amino

acids form an "arm" extending around the back. **Figure 12.23** shows the view from the back. Lysine residues in the arm make contacts with G residues in the major groove, and also with the phosphate backbone. The interaction between the arm and DNA contributes heavily to DNA binding; the affinity of the armless repressor for DNA is reduced by ~1000-fold (532).

**Figure 12.23** A view from the back shows that the bulk of the repressor contacts one face of DNA, but its N-terminal arms reach around to the other face.

Bases that are not contacted directly by repressor protein may have an important effect on binding. The related phage *434* repressor binds DNA via a helix-turn-helix motif, and the crystal structure shows that helix-3 is positioned at each half-site so that it contacts the 5 outermost base pairs but not the inner 2. However, operators with A·T base pairs at the inner positions bind *434* repressor more strongly than operators with G·C base pairs. The reason is that *434* repressor binding slightly twists DNA at the center of the operator, widening the angle between the two half-sites of DNA by  $\sim 3^\circ$ . This is probably needed to allow each monomer of the repressor dimer to make optimal contacts with DNA. A·T base pairs allow this twist more readily than G·C pairs, thus affecting the affinity of the operator for repressor.

## PHAGE STRATEGIES

### 3.12.14 Repressor dimers bind cooperatively to the operator

#### Key Concepts

- Repressor binding to one operator increases the affinity for binding a second repressor dimer to the adjacent operator.
- The affinity is 10× greater for  $O_L 1$  and  $O_R 1$  than other operators, so they are bound first.
- Cooperativity allows repressor to bind the  $O1/O2$  sites at lower concentrations.

Each operator contains three repressor-binding sites. As can be seen from **Figure 12.24**, no two of the six individual repressor-binding sites are identical, but they all conform with a consensus sequence. The binding sites within each operator are separated by spacers of 3-7 bp that are rich in A·T base pairs. The sites at each operator are numbered so that  $O_R$  consists of the series of binding sites  $O_R 1-O_R 2-O_R 3$ , while  $O_L$  consists of the series  $O_L 1-O_L 2-O_L 3$ . In each case, site 1 lies closest to the startpoint for transcription in the promoter, and sites 2 and 3 lie farther upstream.

**Figure 12.24** Each operator contains three repressor-binding sites, and overlaps with the promoter at which RNA polymerase binds. The orientation of  $O_L$  has been reversed from usual to facilitate comparison with  $O_R$ .

Faced with the triplication of binding sites at each operator, how does repressor

decide where to start binding? At each operator, site 1 has a greater affinity (roughly tenfold) than the other sites for the repressor. So the repressor always binds first to  $O_{L1}$  and  $O_{R1}$ .

*Lambda repressor binds to subsequent sites within each operator in a cooperative manner.* The presence of a dimer at site 1 greatly increases the affinity with which a second dimer can bind to site 2. When both sites 1 and 2 are occupied, this interaction does *not* extend farther, to site 3. At the concentrations of repressor usually found in a lysogen, both sites 1 and 2 are filled at each operator, but site 3 is not occupied (528).

If site 1 is inactive (because of mutation), then repressor binds cooperatively to sites 2 and 3. That is, binding at site 2 assists another dimer to bind at site 3. This interaction occurs directly between repressor dimers and not via conformational change in DNA. The C-terminal domain is responsible for the cooperative interaction between dimers as well as for the dimer formation between subunits. **Figure 12.25** shows that it involves both subunits of each dimer, that is, each subunit contacts its counterpart in the other dimer, forming a tetrameric structure (1199).

**Figure 12.25** When two lambda repressor dimers bind cooperatively, each of the subunits of one dimer contacts a subunit in the other dimer.

A result of cooperative binding is to increase the effective affinity of repressor for the operator at physiological concentrations. This enables a lower concentration of repressor to achieve occupancy of the operator. This is an important consideration in a system in which release of repression has irreversible consequences. In an operon coding for metabolic enzymes, after all, failure of repression will merely allow unnecessary synthesis of enzymes. But failure to repress lambda prophage will lead to induction of phage and lysis of the cell.

From the sequences shown in **Figure 12.24**, we see that  $O_{L1}$  and  $O_{R1}$  lie more or less in the center of the RNA polymerase binding sites of  $P_{L1}$  and  $P_{R1}$ , respectively. Occupancy of  $O_{L1}$ - $O_{L2}$  and  $O_{R1}$ - $O_{R2}$  thus physically blocks access of RNA polymerase to the corresponding promoters.

---

**PHAGE STRATEGIES****3.12.15 Repressor at  $O_R2$  interacts with RNA polymerase at  $P_{RM}$** 

---

**Key Concepts**

- The DNA-binding region of repressor at  $O_R2$  contacts RNA polymerase and stabilizes its binding to  $P_{RM}$ .
  - This is the basis for the autogenous control of repressor maintenance.
- 

A different relationship is shown between  $O_R$  and the promoter  $P_{RM}$  for transcription of *cI*. The RNA polymerase binding site is adjacent to  $O_R2$ . This explains how repressor autogenously regulates its own synthesis. When two dimers are bound at  $O_{R1}-O_R2$ , the dimer at  $O_R2$  interacts with RNA polymerase (see **Figure 12.16** in *Molecular Biology 3.12.9 Repressor maintains an autogenous circuit*). This effect resides in the amino terminal domain of repressor.

Mutations that abolish positive control map in the *cI* gene. One interesting class of mutants remain able to bind the operator to repress transcription, but cannot stimulate RNA polymerase to transcribe from  $P_{RM}$ . They map within a small group of amino acids, located on the outside of helix-2 or in the turn between helix-2 and helix-3. The mutations reduce the negative charge of the region; conversely, mutations that increase the negative charge enhance the activation of RNA polymerase. This suggests that the group of amino acids constitutes an "acidic patch" that functions by an electrostatic interaction with a basic region on RNA polymerase.

The location of these "positive control mutations" in the repressor is indicated on **Figure 12.26**. They lie at a site on repressor that is close to a phosphate group on DNA that is also close to RNA polymerase. So the group of amino acids on repressor that is involved in positive control is in a position to contact the polymerase. The interaction between repressor and polymerase is needed for the polymerase to make the transition from a closed complex to an open complex (see also **Figure 12.29**). The important principle is that *protein-protein interactions can release energy that is used to help to initiate transcription*.

**Figure 12.26** Positive control mutations identify a small region at helix-2 that interacts directly with RNA polymerase.

What happens if a repressor dimer binds to  $O_R3$ ? This site overlaps with the RNA polymerase binding site at  $P_{RM}$ . So if the repressor concentration becomes great enough to cause occupancy of  $O_R3$ , the transcription of *cI* is prevented. This leads in due course to a reduction in repressor concentration;  $O_R3$  then becomes empty, and the autogenous loop can start up again because  $O_R2$  remains occupied.

This mechanism could prevent the concentration of repressor from becoming too great, although it would require repressor concentration in lysogens to reach unusually high levels. In the formal sense, the repressor is an autogenous regulator of its own expression that functions positively at low concentrations and negatively at high concentrations.

Virulent mutations occur in sites 1 and 2 of both  $O_L$  and  $O_R$ . The mutations vary in their degree of virulence, according to the extent to which they reduce the affinity of the binding site for repressor, and also depending on the relationship of the affected site to the promoter. Consistent with the conclusion that  $O_R3$  and  $O_L3$  usually are not occupied, virulent mutations are not found in these sites.

---

**PHAGE STRATEGIES****3.12.16 The *cII* and *cIII* genes are needed to establish lysogeny**

---

**Key Concepts**

- The delayed early gene products *cII* and *cIII* are necessary for RNA polymerase to initiate transcription at the promoter  $P_{RE}$ .
  - *cII* acts directly at the promoter and *cIII* protects *cII* from degradation.
  - Transcription from  $P_{RE}$  leads to synthesis of repressor and also blocks the transcription of *cro*.
- 

The control circuit for maintaining lysogeny presents a paradox. *The presence of repressor protein is necessary for its own synthesis.* This explains how the lysogenic condition is perpetuated. But how is the synthesis of repressor established in the first place?

When a lambda DNA enters a new host cell, RNA polymerase cannot transcribe *cI*, because there is no repressor present to aid its binding at  $P_{RM}$ . But this same absence of repressor means that  $P_R$  and  $P_L$  are available. So the first event when lambda DNA infects a bacterium is for genes *N* and *cro* to be transcribed. Then pN allows transcription to be extended farther. This allows *cIII* (and other genes) to be transcribed on the left, while *cII* (and other genes) are transcribed on the right (see **Figure 12.14**).

The *cII* and *cIII* genes share with *cI* the property that mutations in them cause clear plaques. But there is a difference. The *cI* mutants can neither establish nor maintain lysogeny. The *cII* or *cIII* mutants have some difficulty in establishing lysogeny, but once established, they are able to maintain it by the *cI* autogenous circuit.

This implicates the *cII* and *cIII* genes as positive regulators whose products are needed for an alternative system for repressor synthesis. The system is needed only to *initiate* the expression of *cI* in order to circumvent the inability of the autogenous circuit to engage in *de novo* synthesis. They are not needed for continued expression.

The *cII* protein acts directly on gene expression. Between the *cro* and *cII* genes is another promoter, called  $P_{RE}$ . (The subscript "RE" stands for repressor establishment.) This promoter can be recognized by RNA polymerase only in the presence of *cII*, whose action is illustrated in **Figure 12.27**.

**Figure 12.27** Repressor synthesis is established by the action of cII and RNA polymerase at  $P_{RE}$  to initiate transcription that extends from the antisense strand of *cro* through the *cl* gene.

The cII protein is extremely unstable *in vivo*, because it is degraded as the result of the activity of a host protein called HflA. The role of cIII is to protect cII against this degradation.

Transcription from  $P_{RE}$  promotes lysogeny in two ways. Its direct effect is that *cl* is translated into repressor protein. An indirect effect is that transcription proceeds through the *cro* gene in the "wrong" direction. So the 5' part of the RNA corresponds to an antisense transcript of *cro*; in fact, it hybridizes to authentic *cro* mRNA, inhibiting its translation. This is important because *cro* expression is needed to enter the lytic cycle (see *Molecular Biology 3.12.19 The cro repressor is needed for lytic infection*).

The *cl* coding region on the  $P_{RE}$  transcript is very efficiently translated, in contrast with the weak translation of the  $P_{RM}$  transcript. In fact, repressor is synthesized ~7-8 times more effectively via expression from  $P_{RE}$  than from  $P_{RM}$ . This reflects the fact that the  $P_{RE}$  transcript has an efficient ribosome-binding site, whereas the  $P_{RM}$  transcript has no ribosome-binding site and actually starts with the AUG initiation codon.

This content is available online at <http://www.ergito.com/main.jsp?bcs=MBIO.3.12.16>

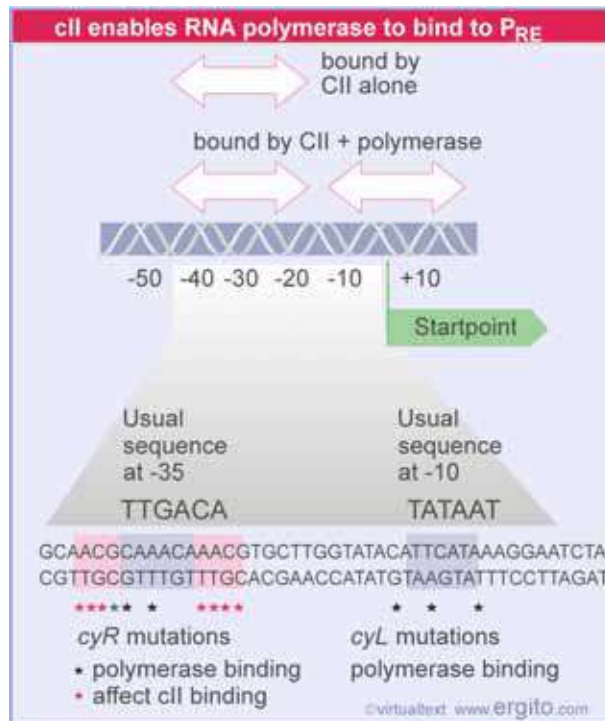

## PHAGE STRATEGIES

### 3.12.17 A poor promoter requires cII protein

#### Key Concepts

- $P_{RE}$  has atypical sequences at  $-10$  and  $-35$ .
- RNA polymerase binds the promoter only in the presence of cII.
- cII binds to sequences close to the  $-35$  region.

The  $P_{RE}$  promoter has a poor fit with the consensus at  $-10$  and lacks a consensus sequence at  $-35$ . This deficiency explains its dependence on cII. The promoter cannot be transcribed by RNA polymerase alone *in vitro*, but can be transcribed when cII is added. The regulator binds to a region extending from about  $-25$  to  $-45$ . When RNA polymerase is added, an additional region is protected, extending from  $-12$  to  $+13$ . As summarized in **Figure 12.28**, the two proteins bind to overlapping sites.

**Figure 12.28** RNA polymerase binds to  $P_{RE}$  only in the presence of cII, which contacts the region around  $-35$ .

The importance of the  $-35$  and  $-10$  regions for promoter function, in spite of their lack of resemblance with the consensus, is indicated by the existence of *cy* mutations. These have effects similar to those of *cII* and *cIII* mutations in preventing the establishment of lysogeny; but they are *cis*-acting instead of *trans*-acting. They fall

into two groups, *cyL* and *cyR*, localized at the consensus operator positions of  $-10$  and  $-35$ .

The *cyL* mutations are located around  $-10$ , and probably prevent RNA polymerase from recognizing the promoter.

The *cyR* mutations are located around  $-35$ , and fall into two types, affecting either RNA polymerase or cII binding. Mutations in the center of the region do not affect cII binding; presumably they prevent RNA polymerase binding. On either side of this region, mutations in short tetrameric repeats, TTGC, prevent cII from binding. Each base in the tetramer is 10 bp (one helical turn) separated from its homologue in the other tetramer, so that when cII recognizes the two tetramers, it lies on one face of the double helix.

Positive control of a promoter implies that an accessory protein has increased the efficiency with which RNA polymerase initiates transcription. **Figure 12.29** reports that either or both stages of the interaction between promoter and polymerase can be the target for regulation. Initial binding to form a closed complex or its conversion into an open complex can be enhanced.

Positive regulation influences initiation			
Promoter	Regulator	Polymerase Binding (equilibrium constant, $K_B$ )	Closed-Open Conversion (rate constant, $k_2$ )
$P_{RM}$	repressor	no effect	11X
$P_{RE}$	CII	100X	100X

©virtualtext www.ergito.com

**Figure 12.29** Positive regulation can influence RNA polymerase at either stage of initiating transcription.

This content is available online at <http://www.ergito.com/main.jsp?bcs=MBIO.3.12.17>

---

**PHAGE STRATEGIES****3.12.18 Lysogeny requires several events**

---

**Key Concepts**

- *cII/cIII* cause repressor synthesis to be established and also trigger inhibition of late gene transcription.
  - Establishment of repressor turns off immediate and delayed early gene expression.
  - Repressor turns on the maintenance circuit for its own synthesis.
  - Lambda DNA is integrated into the bacterial genome at the final stage in establishing lysogeny.
- 

Now we can see how lysogeny is established during an infection. **Figure 12.30** recapitulates the early stages and shows what happens as the result of expression of *cIII* and *cII*. The presence of *cII* allows  $P_{RE}$  to be used for transcription extending through *cI*. Repressor protein is synthesized in high amounts from this transcript. Immediately it binds to  $O_L$  and  $O_R$ .

**Figure 12.30** A cascade is needed to establish lysogeny, but then this circuit is switched off and replaced by the autogenous repressor-maintenance circuit.

By directly inhibiting any further transcription from  $P_L$  and  $P_R$ , repressor binding turns off the expression of all phage genes. This halts the synthesis of *cII* and *cIII*, which are unstable; they decay rapidly, with the result that  $P_{RE}$  can no longer be used. So the synthesis of repressor via the establishment circuit is brought to a halt.

But repressor now is present at  $O_R$ . It switches on the maintenance circuit for

expression from  $P_{RM}$ . Repressor continues to be synthesized, although at the lower level typical of  $P_{RM}$  function. So the establishment circuit starts off repressor synthesis at a high level; then repressor turns off all other functions, while at the same time turning on the maintenance circuit, which functions at the low level adequate to sustain lysogeny.

We shall not now deal in detail with the other functions needed to establish lysogeny, but we can just briefly remark that the infecting lambda DNA must be inserted into the bacterial genome (see *Molecular Biology 4.15.16 Specialized recombination involves specific sites*). The insertion requires the product of gene *int*, which is expressed from its own promoter  $P_I$ , at which cII also is necessary. The sequence of  $P_I$  shows homology with  $P_{RE}$  in the cII binding site (although not in the  $-10$  region). The functions necessary for establishing the lysogenic control circuit are therefore under the same control as the function needed to integrate the phage DNA into the bacterial genome. So the establishment of lysogeny is under a control that ensures all the necessary events occur with the same timing.

Emphasizing the tricky quality of lambda's intricate cascade, we now know that cII promotes lysogeny in another, indirect manner. It sponsors transcription from a promoter called  $P_{anti-Q}$ , which is located within the *Q* gene. This transcript is an antisense version of the *Q* region, and it hybridizes with *Q* mRNA to prevent translation of Q protein, whose synthesis is essential for lytic development. So the same mechanisms that directly promote lysogeny by causing transcription of the *cI* repressor gene also indirectly help lysogeny by inhibiting the expression of *cro* (see above) and *Q*, the regulator genes needed for the antagonistic lytic pathway.

---

**PHAGE STRATEGIES****3.12.19 The cro repressor is needed for lytic infection**

---

**Key Concepts**

- Cro binds to the same operators as repressor but with different affinities.
  - When Cro binds to  $O_3$ , it prevents RNA polymerase from binding to  $P_{RM}$ , and blocks maintenance of repressor.
  - When Cro binds to other operators at  $O_R$  or  $O_L$ , it prevents RNA polymerase from expressing immediate early genes, which (indirectly) blocks repressor establishment.
- 

Lambda has the alternatives of entering lysogeny or starting a lytic infection. Lysogeny is initiated by establishing an autogenous maintenance circuit that inhibits the entire lytic cascade through applying pressure at two points. The program for establishing lysogeny proceeds through some of the same events that are required for the lytic cascade (expression of delayed early genes via expression of  $N$  is needed). We now face a problem. How does the phage enter the lytic cycle?

The key influence on the lytic cycle is the role of gene *cro*, which codes for another repressor. *Cro is responsible for preventing the synthesis of the repressor protein*; this action shuts off the possibility of establishing lysogeny. *cro* mutants usually establish lysogeny rather than entering the lytic pathway, because they lack the ability to switch events away from the expression of repressor.

Cro forms a small dimer (the subunit is 9 kD) that acts within the immunity region. It has two effects:

- It prevents the synthesis of repressor via the maintenance circuit; that is, it prevents transcription via  $P_{RM}$ .
- It also inhibits the expression of early genes from both  $P_L$  and  $P_R$ .

This means that, when a phage enters the lytic pathway, Cro has responsibility both for preventing the synthesis of repressor and (subsequently) for turning down the expression of the early genes.

Cro achieves its function by binding to the same operators as (*cI*) repressor protein. Cro includes a region with the same general structure as the repressor; a helix-2 is offset at an angle from recognition helix-3. (The remainder of the structure is different, demonstrating that the helix-turn-helix motif can operate within various contexts.) Like repressor, Cro binds symmetrically at the operators.

The sequences of Cro and repressor in the helix-turn-helix region are related, explaining their ability to contact the same DNA sequences (see **Figure 12.22**). Cro makes similar contacts to those made by repressor, but binds to only one face of DNA; it lacks the N-terminal arms by which repressor reaches around to the other side.

How can two proteins have the same sites of action, yet have such opposite effects? The answer lies in the different affinities that each protein has for the individual binding sites within the operators. Let us just consider  $O_R$ , where more is known, and where Cro exerts both its effects. The series of events is illustrated in **Figure 12.31**. (Note that the first two stages are identical to those of the lysogenic circuit shown in **Figure 12.30**.)

**Figure 12.31** The lytic cascade requires Cro protein, which directly prevents repressor maintenance via  $P_{RM}$  as well as turning off delayed early gene expression, indirectly preventing repressor establishment.

The affinity of Cro for  $O_3$  is greater than its affinity for  $O_2$  or  $O_1$ . So it binds first to  $O_3$ . This inhibits RNA polymerase from binding to  $P_{RM}$ . So Cro's first action is to prevent the maintenance circuit for lysogeny from coming into play.

Then Cro binds to  $O_2$  or  $O_1$ . Its affinity for these sites is similar, and there is no cooperative effect. Its presence at either site is sufficient to prevent RNA polymerase

from using  $P_R$ . This in turn stops the production of the early functions (including Cro itself). Because cII is unstable, any use of  $P_{RE}$  is brought to a halt. So the two actions of Cro together block *all* production of repressor.

So far as the lytic cycle is concerned, Cro turns down (although it does not completely eliminate) the expression of the early genes. Its incomplete effect is explained by its affinity for  $O_1$  and  $O_2$ , which is about eight times lower than that of repressor. This effect of Cro does not occur until the early genes have become more or less superfluous, because pQ is present; by this time, the phage has started late gene expression, and is concentrating on the production of progeny phage particles.

## PHAGE STRATEGIES

### 3.12.20 What determines the balance between lysogeny and the lytic cycle?

---

#### Key Concepts

- The delayed early stage when both Cro and repressor are being expressed is common to lysogeny and the lytic cycle.
  - The critical event is whether cII causes sufficient synthesis of repressor to overcome the action of Cro.
- 

The programs for the lysogenic and lytic pathways are so intimately related that it is impossible to predict the fate of an individual phage genome when it enters a new host bacterium. Will the antagonism between repressor and Cro be resolved by establishing the autogenous maintenance circuit shown in **Figure 12.30**, or by turning off repressor synthesis and entering the late stage of development shown in **Figure 12.31**?

The same pathway is followed in both cases right up to the brink of decision. Both involve the expression of the immediate early genes and extension into the delayed early genes. The difference between them comes down to the question of whether repressor or Cro will obtain occupancy of the two operators.

The early phase during which the decision is taken is limited in duration in either case. No matter which pathway the phage follows, expression of all early genes will be prevented as  $P_L$  and  $P_R$  are repressed; and, as a consequence of the disappearance of cII and cIII, production of repressor via  $P_{RE}$  will cease.

The critical question comes down to whether the cessation of transcription from  $P_{RE}$  is followed by activation of  $P_{RM}$  and the establishment of lysogeny, or whether  $P_{RM}$  fails to become active and the pQ regulator commits the phage to lytic development. **Figure 12.32** shows the critical stage, at which both repressor and Cro are being synthesized.

**Figure 12.32** The critical stage in deciding between lysogeny and lysis is when delayed early genes are being expressed. If  $cII$  causes sufficient synthesis of repressor, lysogeny will result because repressor occupies the operators. Otherwise Cro occupies the operators, resulting in a lytic cycle.

The initial event in establishing lysogeny is the binding of repressor at  $O_L1$  and  $O_R1$ . Binding at the first sites is rapidly succeeded by cooperative binding of further repressor dimers at  $O_L2$  and  $O_R2$ . This shuts off the synthesis of Cro and starts up the synthesis of repressor via  $P_{RM}$ .

The initial event in entering the lytic cycle is the binding of Cro at  $O_R3$ . This stops the lysogenic-maintenance circuit from starting up at  $P_{RM}$ . Then Cro must bind to  $O_R1$  or  $O_R2$ , and to  $O_L1$  or  $O_L2$ , to turn down early gene expression. By halting production of  $cII$  and  $cIII$ , this action leads to the cessation of repressor synthesis via

$P_{RE}$ . The shutoff of repressor establishment occurs when the unstable cII and cIII proteins decay.

The critical influence over the switch between lysogeny and lysis is cII. If cII is active, synthesis of repressor via the establishment promoter is effective; and, as a result, repressor gains occupancy of the operators. If cII is not active, repressor establishment fails, and Cro binds to the operators.

The level of cII protein under any particular set of circumstances determines the outcome of an infection. Mutations that increase the stability of cII increase the frequency of lysogenization. Such mutations occur in *cII* itself or in other genes. The cause of cII's instability is its susceptibility to degradation by host proteases. Its level in the cell is influenced by *cIII* as well as by host functions.

The effect of the lambda protein cIII is secondary: it helps to protect cII against degradation. Although the presence of cIII does not guarantee the survival of cII, in the absence of cIII, cII is virtually always inactivated.

Host gene products act on this pathway. Mutations in the host genes *hflA* and *hflB* increase lysogeny – *hfl* stands for *high frequency lysogenization*. The mutations stabilize cII because they inactivate host protease(s) that degrade it.

The influence of the host cell on the level of cII provides a route for the bacterium to interfere with the decision-taking process. For example, host proteases that degrade cII are activated by growth on rich medium, so lambda tends to lyse cells that are growing well, but is more likely to enter lysogeny on cells that are starving (and which lack components necessary for efficient lytic growth).

## PHAGE STRATEGIES

### 3.12.21 Summary

Phages have a lytic life cycle, in which infection of a host bacterium is followed by production of a large number of phage particles, lysis of the cell, and release of the viruses. Some phages also can exist in lysogenic form, in which the phage genome is integrated into the bacterial chromosome and is inherited in this inert, latent form like any other bacterial gene.

Lytic infection falls typically into three phases. In the first phase a small number of phage genes are transcribed by the host RNA polymerase. One or more of these genes is a regulator that controls expression of the group of genes expressed in the second phase. The pattern is repeated in the second phase, when one or more genes is a regulator needed for expression of the genes of the third phase. Genes of the first two phases code for enzymes needed to reproduce phage DNA; genes of the final phase code for structural components of the phage particle. It is common for the very early genes to be turned off during the later phases.

In phage lambda, the genes are organized into groups whose expression is controlled by individual regulatory events. The immediate early gene  $N$  codes for an antiterminator that allows transcription of the leftward and rightward groups of delayed early genes from the early promoters  $P_R$  and  $P_L$ . The delayed early gene  $Q$  has a similar antitermination function that allows transcription of all late genes from the promoter  $P_{R'}$ . The lytic cycle is repressed, and the lysogenic state maintained, by expression of the  $cI$  gene, whose product is a repressor protein that acts at the operators  $O_R$  and  $O_L$  to prevent use of the promoters  $P_R$  and  $P_L$ , respectively. A lysogenic phage genome expresses only the  $cI$  gene, from its promoter  $P_{RM}$ . Transcription from this promoter involves positive autogenous regulation, in which repressor bound at  $O_R$  activates RNA polymerase at  $P_{RM}$ .

Each operator consists of three binding sites for repressor. Each site is palindromic, consisting of symmetrical half-sites. Repressor functions as a dimer. Each half binding site is contacted by a repressor monomer. The N-terminal domain of repressor contains a helix-turn-helix motif that contacts DNA. Helix-3 is the recognition helix, responsible for making specific contacts with base pairs in the operator. Helix-2 is involved in positioning helix-3; it is also involved in contacting RNA polymerase at  $P_{RM}$ . The C-terminal domain is required for dimerization. Induction is caused by cleavage between the N- and C-terminal domains, which prevents the DNA-binding regions from functioning in dimeric form, thereby reducing their affinity for DNA and making it impossible to maintain lysogeny. Repressor-operator binding is cooperative, so that once one dimer has bound to the first site, a second dimer binds more readily to the adjacent site.

The helix-turn-helix motif is used by other DNA-binding proteins, including lambda Cro, which binds to the same operators, but has a different affinity for the individual operator sites, determined by the sequence of helix-3. Cro binds individually to operator sites, starting with  $O_3$ , in a noncooperative manner. It is needed for progression through the lytic cycle. Its binding to  $O_3$  first prevents synthesis of repressor from  $P_{RM}$ ; then its binding to  $O_2$  and  $O_1$  prevents continued expression

of early genes, an effect also seen in its binding to  $O_L1$  and  $O_L2$ .

Establishment of repressor synthesis requires use of the promoter  $P_{RE}$ , which is activated by the product of the *cII* gene. The product of *cIII* is required to stabilize the *cII* product against degradation. By turning off *cII* and *cIII* expression, Cro acts to prevent lysogeny. By turning off all transcription except that of its own gene, repressor acts to prevent the lytic cycle. The choice between lysis and lysogeny depends on whether repressor or Cro gains occupancy of the operators in a particular infection. The stability of cII protein in the infected cell is a primary determinant of the outcome.

## THE REPLICON

### 4.13.1 Introduction

---

#### Key Terms

The **replicon** is a unit of the genome in which DNA is replicated. Each replicon contains an origin for initiation of replication.

The **origin** is a sequence of DNA at which replication is initiated.

A **terminus** is a segment of DNA at which replication ends.

**Single copy** replication describes a control system in which there is only one copy of a replicon per unit bacterium. The bacterial chromosome and some plasmids have this type of regulation.

A plasmid is said to be under **multicopy control** when the control system allows the plasmid to exist in more than one copy per individual bacterial cell.

---

Whether a cell has only one chromosome (as in prokaryotes) or has many chromosomes (as in eukaryotes), the entire genome must be replicated precisely once for every cell division. How is the act of replication linked to the cell cycle?

Two general principles are used to compare the state of replication with the condition of the cell cycle:

- *Initiation of DNA replication commits the cell (prokaryotic or eukaryotic) to a further division.* From this standpoint, the number of descendants that a cell generates is determined by a series of decisions on whether or not to initiate DNA replication. Replication is controlled at the stage of initiation. *Once replication has started, it continues until the entire genome has been duplicated.*
- If replication proceeds, the consequent division cannot be permitted to occur until the replication event has been completed. Indeed, the completion of replication may provide a trigger for cell division. Then the duplicate genomes are segregated one to each daughter cell. The unit of segregation is the chromosome.

In prokaryotes, the initiation of replication is a single event involving a unique site on the bacterial chromosome, and the process of division is accomplished by the development of a septum that grows from the cell wall and divides the cell into two. In eukaryotic cells, initiation of replication is identified by the start of S phase, a protracted period during which DNA synthesis occurs, and which involves many individual initiation events. The act of division is accomplished by the reorganization of the cell at mitosis. In this chapter, we are concerned with the regulation of DNA replication. How is a cycle of replication initiated? What controls its progress and how is its termination signaled? In *Molecular Biology 6.29 Cell cycle and growth regulation*, we discuss the regulatory processes in eukaryotic cells that control entry into S phase and into mitosis, and also the "checkpoints" that postpone these actions until the appropriate conditions have been fulfilled.

The unit of DNA in which an individual act of replication occurs is called the **replicon**. Each replicon "fires" once and only once in each cell cycle. The replicon is defined by its possession of the control elements needed for replication. It has an **origin** at which replication is initiated. It may also have a **terminus** at which replication stops (535).

Any sequence attached to an origin – or, more precisely, not separated from an origin by a terminus – is replicated as part of that replicon. The origin is a *cis*-acting site, able to affect only that molecule of DNA on which it resides.

(The original formulation of the replicon [in prokaryotes] viewed it as a unit possessing both the origin *and* the gene coding for the regulator protein. Now, however, "replicon" is usually applied to eukaryotic chromosomes to describe a unit of replication that contains an origin; *trans*-acting regulator protein(s) may be coded elsewhere.)

A genome in a prokaryotic cell constitutes a single replicon; so the units of replication and segregation coincide. Initiation at a single origin sponsors replication of the entire genome, once for every cell division. Each haploid bacterium has a single chromosome, so this type of replication control is called **single copy**.

Bacteria may contain additional genetic information in the form of plasmids. A *plasmid is an autonomous circular DNA genome that constitutes a separate replicon* (see **Figure 12.2**). A plasmid replicon may show single copy control, which means that it replicates once every time the bacterial chromosome replicates. Or it may be under **multicopy control**, when it is present in a greater number of copies than the bacterial chromosome. Each phage or virus DNA also constitutes a replicon, able to initiate many times during an infectious cycle. Perhaps a better way to view the prokaryotic replicon, therefore, is to reverse the definition: *any DNA molecule that contains an origin can be replicated autonomously in the cell*.

A major difference in the organization of bacterial and eukaryotic genomes is seen in their replication. Each eukaryotic chromosome contains a large number of replicons. So the unit of segregation includes many units of replication. This adds another dimension to the problem of control. All the replicons on a chromosome must be fired during one cell cycle, although they are not active simultaneously, but are activated over a fairly protracted period. *Yet each of these replicons must be activated no more than once in each cell cycle*.

Some signal must distinguish replicated from nonreplicated replicons, so that replicons do not fire a second time. And because many replicons are activated independently, another signal must exist to indicate when the entire process of replicating all replicons has been completed.

We have begun to collect information about the construction of individual replicons, but we still have little information about the relationship between replicons. We do not know whether the pattern of replication is the same in every cell cycle. Are all origins always used or are some origins sometimes silent? Do origins always fire in the same order? If there are different classes of origins, what distinguishes them?

In contrast with nuclear chromosomes, which have a single-copy type of control, the

DNA of mitochondria and chloroplasts may be regulated more like plasmids that exist in multiple copies per bacterium. There are multiple copies of each organelle DNA per cell, and the control of organelle DNA replication must be related to the cell cycle.

In all these systems, the key question is to define the sequences that function as origins and to determine how they are recognized by the appropriate proteins of the apparatus for replication. We start by considering the basic construction of replicons and the various forms that they take; following the consideration of the origin, we turn to the question of how replication of the genome is coordinated with bacterial division, and what is responsible for segregating the genomes to daughter bacteria.

## THE REPLICON

### 4.13.2 Replicons can be linear or circular

---

#### Key Terms

A **replication eye** is a region in which DNA has been replicated within a longer, unreplicated region.

A **replication fork (Growing point)** is the point at which strands of parental duplex DNA are separated so that replication can proceed. A complex of proteins including DNA polymerase is found at the fork.

**Unidirectional replication** refers to the movement of a single replication fork from a given origin.

**Bidirectional replication** describes a system in which an origin generates two replication forks that proceed away from the origin in opposite directions.

#### Key Concepts

- A replicated region appears as an eye within nonreplicated DNA.
- A replication fork is initiated at the origin and then moves sequentially along DNA.
- Replication is unidirectional when a single replication fork is created at an origin.
- Replication is bidirectional when an origin creates two replication forks that move in opposite directions.

---

A molecule of DNA engaged in replication has two types of regions. **Figure 13.1** shows that when replicating DNA is viewed by electron microscopy, the replicated region appears as a **replication eye** within the nonreplicated DNA. The nonreplicated region consists of the parental duplex; this opens into the replicated region where the two daughter duplexes have formed.

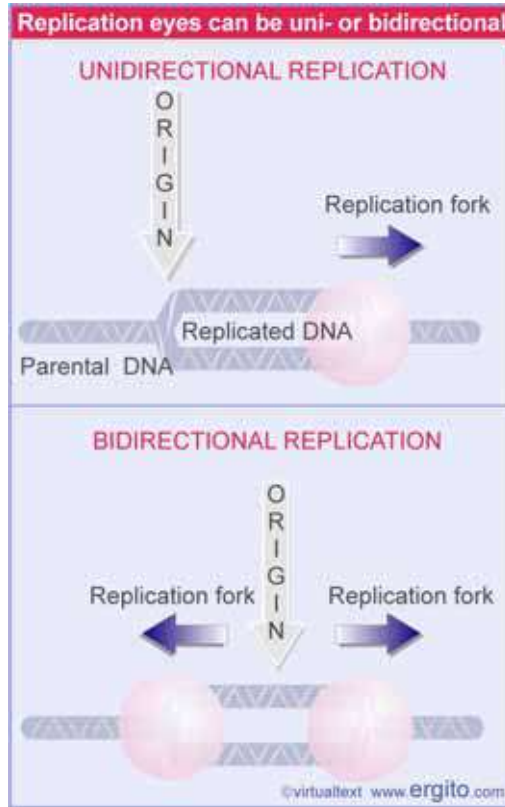

**Figure 13.1** Replicated DNA is seen as a replication eye flanked by nonreplicated DNA.

The point at which replication is occurring is called the **replication fork** (sometimes also known as the **growing point**). A *replication fork* moves sequentially along the DNA, from its starting point at the origin. The origin may be used to start either **unidirectional replication** or **bidirectional replication**. The type of event is determined by whether one or two replication forks set out from the origin. In unidirectional replication, one replication fork leaves the origin and proceeds along the DNA. In bidirectional replication, two replication forks are formed; they proceed away from the origin in opposite directions.

The appearance of a replication eye does not distinguish between unidirectional and bidirectional replication. As depicted in **Figure 13.2**, the eye can represent either of two structures. If generated by unidirectional replication, the eye represents one fixed origin and one moving replication fork. If generated by bidirectional replication, the eye represents a pair of replication forks. In either case, the progress of replication expands the eye until ultimately it encompasses the whole replicon.

**Figure 13.2** Replicons may be unidirectional or bidirectional, depending on whether one or two replication forks are formed at the origin.

When a replicon is circular, the presence of an eye forms the  $\theta$ -structure drawn in **Figure 13.3**. The successive stages of replication of the circular DNA of polyoma virus are visualized by electron microscopy in **Figure 13.4**.

**Figure 13.3** A replication eye forms a theta structure in circular DNA.

**Figure 13.4** The replication eye becomes larger as the replication forks proceed along the replicon. Note that the "eye" becomes larger than the nonreplicated segment. The two sides of the eye can be defined because they are both the same length. Photograph kindly provided by Bernard Hirt.

---

## THE REPLICON

### 4.13.3 Origins can be mapped by autoradiography and electrophoresis

---

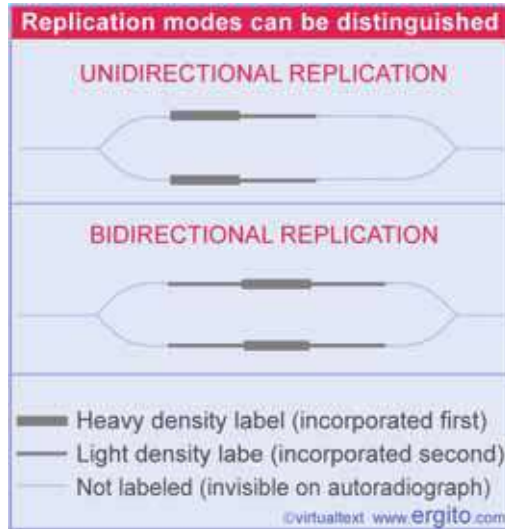

#### Key Concepts

- Replication fork movement can be detected by autoradiography using radioactive pulses.
  - Replication forks create Y-shaped structures that change the electrophoretic migration of DNA fragments.
- 

Whether a replicating eye has one or two replication forks can be determined in two ways. The choice of method depends on whether the DNA is a defined molecule or an unidentified region of a cellular genome.

With a defined linear molecule, we can use electron microscopy to measure the distance of each end of the eye from the end of the DNA. Then the positions of the ends of the eyes can be compared in molecules that have eyes of different sizes. If replication is unidirectional, only one of the ends will move; the other is the fixed origin. If replication is bidirectional, both will move; the origin is the point midway between them.

With undefined regions of large genomes, two successive pulses of radioactivity can be used to label the movement of the replication forks. If one pulse has a more intense label than the other, they can be distinguished by the relative intensities of labeling. These can be visualized by autoradiography. **Figure 13.5** shows that unidirectional replication causes one type of label to be followed by the other at *one* end of the eye. Bidirectional replication produces a (symmetrical) pattern at *both* ends of the eye. This is the pattern usually observed in replicons of eukaryotic chromosomes (537).

**Figure 13.5** Different densities of radioactive labeling can be used to distinguish unidirectional and bidirectional replication.

A more recent method for mapping origins with greater resolution takes advantage of the effects that changes in shape have upon electrophoretic migration of DNA. **Figure 13.6** illustrates the two dimensional mapping technique, in which restriction fragments of replicating DNA are electrophoresed in a first dimension that separates by mass, and a second dimension where movement is determined more by shape. Different types of replicating molecules follow characteristic paths, measured by their deviation from the line that would be followed by a linear molecule of DNA that doubled in size.

**Figure 13.6** The position of the origin and the number of replicating forks determine the shape of a replicating restriction fragment, which can be followed by its electrophoretic path (solid line). The dashed line shows the path for a linear DNA.

A simple Y-structure, in which one fork moves along a linear fragment, follows a continuous path. An inflection point occurs when all three branches are the same length, and the structure therefore deviates most extensively from linear DNA. Analogous considerations determine the paths of double Y-structures or bubbles. An asymmetric bubble follows a discontinuous path, with a break at the point at which the bubble is converted to a Y-structure as one fork runs off the end.

Taken together, the various techniques for characterizing replicating DNA show that origins are most often used to initiate bidirectional replication. From this level of resolution, we must now proceed to the molecular level, to identify the *cis*-acting sequences that comprise the origin, and the *trans*-acting factors that recognize it.

## THE REPLICON

### 4.13.4 The bacterial genome is a single circular replicon

---

#### Key Concepts

- Bacterial replicons are usually circles that are replicated bidirectionally from a single origin.
  - The origin of *E. coli*, *oriC*, is 245 bp in length.
  - The two replication forks usually meet halfway round the circle, but there are *ter* sites that cause termination if they go too far.
- 

To be properly inherited, a bacterial replicon should support several functions:

- Initiating a replication cycle.
- Controlling the frequency of initiation events.
- Segregating replicated chromosomes to daughter cells.

The first two functions both are properties of the origin. Segregation could be an independent function, but in prokaryotic systems it is usually determined by sequences in the vicinity of the origin. Origins in eukaryotes do not function in segregation, but are concerned only with replication.

As a general principle, the DNA constituting an origin can be isolated by its ability to support replication of any DNA sequence to which it is joined. When DNA from the origin is cloned into a molecule that lacks an origin, this will create a plasmid capable of autonomous replication *only if the DNA from the origin contains all the sequences needed to identify itself as an authentic origin for replication.*

Origins now have been identified in bacteria, yeast, chloroplasts, and mitochondria, although not in higher eukaryotes. A general feature is that the overall sequence composition is A·T-rich. We assume this is related to the need to melt the DNA duplex to initiate replication (539).

The genome of *E. coli* is replicated bidirectionally from a single origin, identified as the genetic locus *oriC*. The addition of *oriC* to any piece of DNA creates an artificial plasmid that can replicate in *E. coli*. By reducing the size of the cloned fragment of *oriC*, the region required to initiate replication has been equated with a fragment of 245 bp. (We discuss the properties of *oriC* and its interaction with the replication apparatus in more detail in *Molecular Biology 4.14.15 Creating the replication forks at an origin*.)

*Prokaryotic replicons are usually circular, so that the DNA forms a closed circle*

---

*with no free ends*. Circular structures include the bacterial chromosome itself, all plasmids, and many bacteriophages. They are also common in chloroplast and mitochondrial DNAs. Replication of a circular molecule avoids the problem of how to replicate the ends of a linear molecule, but poses the problem of how to terminate replication (534).

The bacterial chromosome is replicated bidirectionally as a single unit from *oriC*. Two replication forks initiate at *oriC* and move around the genome (at approximately the same speed) to a meeting point. Termination occurs in a discrete region. One interesting question is what ensures that the DNA is replicated right across the region where the forks meet. Following the termination of DNA replication itself, enzymes that manipulate higher-order structure of DNA are required for the two daughter chromosomes to be physically separated (540).

Sequences that cause termination are called *ter* sites. A *ter* site contains a short (~23 bp) sequence that causes termination *in vitro*. The termination sequences function in only one orientation. The *ter* site is recognized by a protein (called Tus in *E. coli* and RTP in *B. subtilis*) that recognizes the consensus sequence and prevents the replication fork from proceeding (see *Molecular Biology 4.14.17 The primosome is needed to restart replication*). However, deletion of the *ter* sites does not prevent normal replication cycles from occurring (2223), although it does affect segregation of the daughter chromosomes (see *Molecular Biology 4.13.19 Chromosomal segregation may require site-specific recombination*).

Termination in *E. coli* and *B. subtilis* has the interesting features reported in **Figure 13.7**. We know that the replication forks usually meet and halt replication at a point midway round the chromosome from the origin. But two termination regions (*terE,D,A* and *terC,B* in *E. coli*, and *terI, terII* and also some other sites in *B. subtilis*) have been identified, located ~100 kb on either side of this meeting point. Each contains multiple terminators. Each terminus is specific for one direction of fork movement, and they are arranged in such a way that each fork would have to pass the other in order to reach the terminus to which it is susceptible. This arrangement creates a "replication fork trap". If for some reason one fork is delayed, so that the forks fail to meet at the usual central position, the more rapid fork will be trapped at the *ter* region to wait for the arrival of the slow fork.

**Figure 13.7** Replication termini in *E. coli* are located beyond the point at which the replication forks actually meet.

What happens when a replication fork encounters a protein bound to DNA? We assume that repressors (for example) are displaced and then reattach. A particularly interesting question is what happens when a replication fork encounters an RNA polymerase engaged in transcription. A replication fork moves  $>10\times$  faster than RNA polymerase. If they are proceeding in the same direction, either the replication fork must displace the polymerase or it must slow down as it waits for the RNA polymerase to reach its terminator. It appears that a DNA polymerase moving in the same direction as an RNA polymerase can "bypass" it without disrupting transcription, but we do not understand how this happens (533; for review see 108).

A conflict arises when the replication fork meets an RNA polymerase traveling in the opposite direction, that is, toward it. Can it displace the RNA polymerase? Or do both replication and transcription come to a halt? An indication that these encounters cannot easily be resolved is provided by the organization of the *E. coli* chromosome. Almost all active transcription units are oriented so that they are expressed in the same direction as the replication fork that passes them. The exceptions all comprise small transcription units that are infrequently expressed. The difficulty of generating inversions containing highly expressed genes argues that head-on encounters between a replication fork and a series of transcribing RNA polymerases may be lethal.

## THE REPLICON

### 4.13.5 Each eukaryotic chromosome contains many replicons

---

#### Key Terms

**S phase** is the restricted part of the eukaryotic cell cycle during which synthesis of DNA occurs.

#### Key Concepts

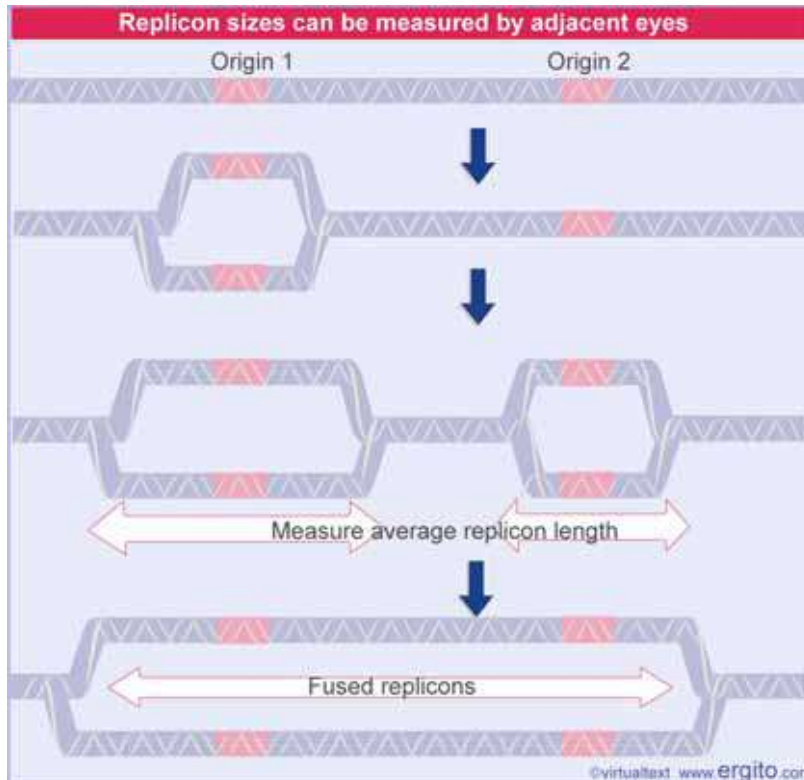

- Eukaryotic replicons are 40-100 kb in length.
- A chromosome is divided into many replicons.
- Individual replicons are activated at characteristic times during S phase.
- Regional activation patterns suggest that replicons near one another are activated at the same time.

---

In eukaryotic cells, the replication of DNA is confined to part of the cell cycle. **S phase** usually lasts a few hours in a higher eukaryotic cell. Replication of the large amount of DNA contained in a eukaryotic chromosome is accomplished by dividing it into many individual replicons. Only some of these replicons are engaged in replication at any point in S phase. Presumably each replicon is activated at a specific time during S phase, although the evidence on this issue is not decisive (for review see 114).

The start of S phase is signaled by the activation of the first replicons. Over the next few hours, initiation events occur at other replicons in an ordered manner. Much of our knowledge about the properties of the individual replicons is derived from autoradiographic studies, generally using the types of protocols illustrated in **Figure 13.5** and **Figure 13.6**. Chromosomal replicons usually display bidirectional replication.

How large is the average replicon, and how many are there in the genome? A difficulty in characterizing the individual unit is that adjacent replicons may fuse to give large replicated eyes, as illustrated in **Figure 13.8**. The approach usually used to distinguish individual replicons from fused eyes is to rely on stretches of DNA in which several replicons can be seen to be active, presumably captured at a stage when all have initiated around the same time, but before the forks of adjacent units have met.

**Figure 13.8** Measuring the size of the replicon requires a stretch of DNA in which adjacent replicons are active.

In groups of active replicons, the average size of the unit is measured by the distance between the origins (that is, between the midpoints of adjacent replicons). The rate at which the replication fork moves can be estimated from the maximum distance that the autoradiographic tracks travel during a given time.

Individual replicons in eukaryotic genomes are relatively small, typically ~40 kb in yeast or fly, ~100 kb in animal cells. However, they can vary >10-fold in length within a genome. The rate of replication is ~2000 bp/min, which is much slower than the 50,000 bp/min of bacterial replication fork movement.

From the speed of replication, it is evident that a mammalian genome could be replicated in ~1 hour if all replicons functioned simultaneously. But S phase actually lasts for >6 hours in a typical somatic cell, which implies that no more than 15% of the replicons are likely to be active at any given moment. There are some exceptional cases, such as the early embryonic divisions of *Drosophila* embryos, where the duration of S phase is compressed by the simultaneous functioning of a large number of replicons (558).

How are origins selected for initiation at different times during S phase? In *S. cerevisiae*, the default appears to be for origins to replicate early, but *cis*-acting sequences can cause origins linked to them to replicate at late times.

Available evidence suggests that chromosomal replicons do not have termini at which the replication forks cease movement and (presumably) dissociate from the

DNA. It seems more likely that a replication fork continues from its origin until it meets a fork proceeding toward it from the adjacent replicon. We have already mentioned the potential topological problem of joining the newly synthesized DNA at the junction of the replication forks.

The propensity of replicons located in the same vicinity to be active at the same time could be explained by "regional" controls, in which groups of replicons are initiated more or less coordinately, as opposed to a mechanism in which individual replicons are activated one by one in dispersed areas of the genome. Two structural features suggest the possibility of large-scale organization. Quite large regions of the chromosome can be characterized as "early replicating" or "late replicating," implying that there is little interspersion of replicons that fire at early or late times. And visualization of replicating forks by labeling with DNA precursors identifies 100-300 "foci" instead of uniform staining; each focus shown in **Figure 13.9** probably contains >300 replication forks. The foci could represent fixed structures through which replicating DNA must move.

**Figure 13.9** Replication forks are organized into foci in the nucleus. Cells were labeled with BrdU. The leftmost panel was stained with propidium iodide to identify bulk DNA. The right panel was stained using an antibody to BrdU to identify replicating DNA. Photographs kindly provided by A. D. Mills and Ron Laskey.

## THE REPLICON

### 4.13.6 Replication origins can be isolated in yeast

---

#### Key Terms

**ARS (autonomous replication sequence)** is an origin for replication in yeast. The common feature among different *ARS* sequences is a conserved 11 bp sequence called the A-domain.

The **A domain** is the conserved 11 bp sequence of A-T base pairs in the yeast *ARS* element that comprises the replication origin.

#### Key Concepts

- Origins in *S. cerevisiae* are short A·T-rich sequences that have an essential 11 bp sequence.
- The ORC is a complex of 6 proteins that binds to an *ARS*.

---

Any segment of DNA that has an origin should be able to replicate. So although plasmids are rare in eukaryotes, it may be possible to construct them by suitable manipulation *in vitro*. This has been accomplished in yeast, although not in higher eukaryotes.

*S. cerevisiae* mutants can be "transformed" to the wild phenotype by addition of DNA that carries a wild-type copy of the gene. The discovery of yeast origins resulted from the observation that some yeast DNA fragments (when circularized) are able to transform defective cells very efficiently. These fragments can survive in the cell in the unintegrated (autonomous) state, that is, as self-replicating plasmids.

A high-frequency transforming fragment possesses a sequence that confers the ability to replicate efficiently in yeast. This segment is called an **ARS** (for autonomously replicating sequence). *ARS* elements are derived from origins of replication.

Where *ARS* elements have been systematically mapped over extended chromosomal regions, it seems that only some of them are actually used to initiate replication. The others are silent, or possibly used only occasionally. If it is true that some origins have varying probabilities of being used, it follows that there can be no fixed termini between replicons. In this case, a given region of a chromosome could be replicated from different origins in different cell cycles.

An *ARS* element consists of an A·T-rich region that contains discrete sites in which mutations affect origin function. Base composition rather than sequence may be important in the rest of the region. **Figure 13.10** shows a systematic mutational analysis along the length of an origin. Origin function is abolished completely by mutations in a 14 bp "core" region, called the **A domain**, that contains an 11 bp consensus sequence consisting of A-T base pairs. This consensus sequence (sometimes called the *ACS* for *ARS* Consensus Sequence) is the only homology

between known *ARS* elements (541).

**Figure 13.10** An *ARS* extends for ~50 bp and includes a consensus sequence (A) and additional elements (B1-B3).

Mutations in three adjacent elements, numbered B1-B3, reduce origin function. An origin can function effectively with any 2 of the B elements, so long as a functional A element is present. (Imperfect copies of the core consensus, typically conforming at 9/11 positions, are found close to, or overlapping with, each B element, but they do not appear to be necessary for origin function.)

The ORC (origin recognition complex) is a complex of 6 proteins with a mass of ~400 kD (for review see 2222). ORC binds to the A and B1 elements on the A·T-rich strand, and is associated with *ARS* elements throughout the cell cycle. This means that initiation depends on changes in its condition rather than *de novo* association with an origin (see *Molecular Biology 4.14.21 Licensing factor consists of MCM proteins*). By counting the number of sites to which ORC binds, we can estimate that there are about 400 origins of replication in the yeast genome (2247). This means that the average length of a replicon is ~35,000 bp. Counterparts to ORC are found in higher eukaryotic cells (2199).

ORC was first found in *S. cerevisiae* (where it is called scORC), but similar complexes have now been characterized in *S. pombe* (spORC), *Drosophila* (DmORC) and *Xenopus* (XIORC). All of the ORC complexes bind to DNA.

Although none of the binding sites have been characterized in the same detail as in *S. cerevisiae*, in several cases they are at locations associated with the initiation of replication. It seems clear that ORC is an initiation complex whose binding identifies an origin of replication (for review see 3089). However, details of the interaction are clear only in *S. cerevisiae*; it is possible that additional components are required to recognize the origin in the other cases.

ARS elements satisfy the classic definition of an origin as a *cis*-acting sequence that causes DNA replication to initiate. Are similar elements to be found in higher eukaryotes? The conservation of the ORC suggests that origins are likely to take the same sort of form in other eukaryotes, but in spite of this, there is little conservation of sequence among putative origins in different organisms (for review see 4186).

Difficulties in finding consensus origin sequences cells suggest the possibility that origins may be more complex (or determined by features other than discrete *cis*-acting sequences). There are suggestions that some animal cell replicons may have complex patterns of initiation: in some cases, many small replication bubbles are found in one region, posing the question of whether there are alternative or multiple starts to replication, and whether there is a small discrete origin (for review see 116).

A reconciliation between this phenomenon and the use of ORCs is suggested by the discovery that environmental effects can influence the use of origins (4185). At one location where multiple bubbles are found, there is a primary origin that is used predominantly when the nucleotide supply is high. But when the nucleotide supply is limiting, many secondary origins are also used, giving rise to a pattern of multiple bubbles. One possible molecular explanation is that ORCs dissociate from the primary origin and initiate elsewhere in the vicinity if the supply of nucleotides is insufficient for the initiation reaction to occur quickly. At all events, it now seems likely that we will be able in due course to characterize discrete sequences that function as origins of replication in higher eukaryotes.

## THE REPLICON

### 4.13.7 D loops maintain mitochondrial origins

---

#### Key Terms

A **D loop** is a region within mitochondrial DNA in which a short stretch of RNA is paired with one strand of DNA, displacing the original partner DNA strand in this region. The same term is used also to describe the displacement of a region of one strand of duplex DNA by a complementary single-stranded invader.

#### Key Concepts

- Mitochondria use different origin sequences to initiate replication of each DNA strand.
  - Replication of the H-strand is initiated in a D-loop.
  - Replication of the L-strand is initiated when its origin is exposed by the movement of the first replication fork.
- 

The origins of replicons in both prokaryotic and eukaryotic chromosomes are static structures: they comprise sequences of DNA that are recognized in duplex form and used to initiate replication at the appropriate time. Initiation requires separating the DNA strands and commencing bidirectional DNA synthesis. A different type of arrangement is found in mitochondria.

Replication starts at a specific origin in the circular duplex DNA. But initially only one of the two parental strands (the H strand in mammalian mitochondrial DNA) is used as a template for synthesis of a new strand. Synthesis proceeds for only a short distance, displacing the original partner (L) strand, which remains single-stranded, as illustrated in **Figure 13.11**. The condition of this region gives rise to its name as the *displacement* or **D loop** (for review see 105; 113).

**Figure 13.11** The D loop maintains an opening in mammalian mitochondrial DNA, which has separate origins for the replication of each strand.

DNA polymerases cannot initiate synthesis, but require a priming 3' end (see *Molecular Biology 4.14.8 Priming is required to start DNA synthesis*). Replication at the H strand origin is initiated when RNA polymerase transcribes a primer. 3' ends are generated in the primer by an endonuclease that cleaves the DNA-RNA hybrid at several discrete sites. The endonuclease is specific for the triple structure of DNA-RNA hybrid plus the displaced DNA single strand. The 3' end is then extended into DNA by the DNA polymerase.

A single D loop is found as an opening of 500-600 bases in mammalian mitochondria. The short strand that maintains the D loop is unstable and turns over; it is frequently degraded and resynthesized to maintain the opening of the duplex at this site. Some mitochondrial DNAs possess several D loops, reflecting the use of multiple origins. The same mechanism is employed in chloroplast DNA, where (in higher plants) there are two D loops.

To replicate mammalian mitochondrial DNA, the short strand in the D loop is extended. The displaced region of the original L strand becomes longer, expanding the D loop. This expansion continues until it reaches a point about two-thirds of the way around the circle. Replication of this region exposes an origin in the displaced L strand. Synthesis of an H strand initiates at this site, which is used by a special primase that synthesizes a short RNA. The RNA is then extended by DNA polymerase, proceeding around the displaced single-stranded L template in the opposite direction from L-strand synthesis.

Because of the lag in its start, H-strand synthesis has proceeded only a third of the way around the circle when L-strand synthesis finishes. This releases one completed duplex circle and one gapped circle, which remains partially single-stranded until synthesis of the H strand is completed. Finally, the new strands are sealed to become covalently intact (for review see 122).

The existence of D loops exposes a general principle. *An origin can be a sequence of DNA that serves to initiate DNA synthesis using one strand as template.* The opening of the duplex does not necessarily lead to the initiation of replication on the other strand. In the case of mitochondrial DNA replication, the origins for replicating the complementary strands lie at different locations. Origins that sponsor replication of only one strand are also found in the rolling circle mode of replication (see *Molecular Biology 4.13.10 Rolling circles produce multimers of a replicon* ).

## THE REPLICON

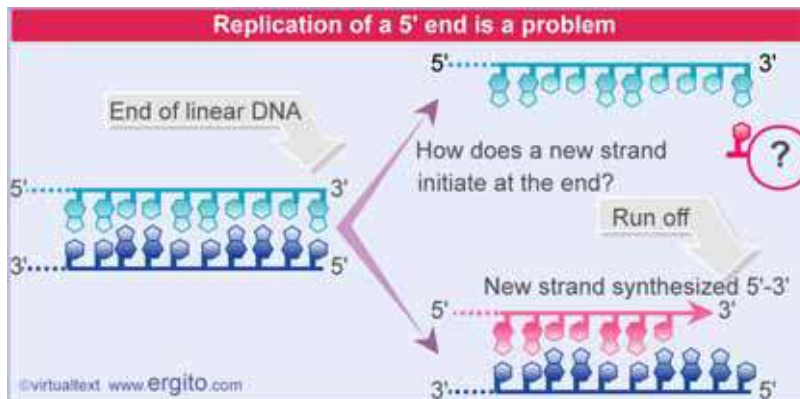

## 4.13.8 The ends of linear DNA are a problem for replication

### Key Concepts

- Special arrangements must be made to replicate the DNA strand with a 5' end.

None of the replicons that we have considered so far have a linear end: either they are circular (as in the *E. coli* or mitochondrial genomes) or they are part of longer segregation units (as in eukaryotic chromosomes). But linear replicons occur, in some cases as single extrachromosomal units, and of course at the ends of eukaryotic chromosomes.

The ability of all known nucleic acid polymerases, DNA or RNA, to proceed only in the 5' – 3' direction poses a problem for synthesizing DNA at the end of a linear replicon. Consider the two parental strands depicted in **Figure 13.12**. The lower strand presents no problem: it can act as template to synthesize a daughter strand that runs right up to the end, where presumably the polymerase falls off. But to synthesize a complement at the end of the upper strand, synthesis must start right at the very last base (or else this strand would become shorter in successive cycles of replication).

**Figure 13.12** Replication could run off the 3' end of a newly synthesized linear strand, but could it initiate at a 5' end?

We do not know whether initiation right at the end of a linear DNA is feasible. We usually think of a polymerase as binding at a site *surrounding* the position at which a base is to be incorporated. So a special mechanism must be employed for replication at the ends of linear replicons. Several types of solution may be imagined to accommodate the need to copy a terminus:

- The problem may be circumvented by converting a linear replicon into a circular or multimeric molecule. Phages such as T4 or lambda use such mechanisms (see

*Molecular Biology 4.13.10 Rolling circles produce multimers of a replicon ).*

- The DNA may form an unusual structure – for example, by creating a hairpin at the terminus, so that there is no free end. Formation of a crosslink is involved in replication of the linear mitochondrial DNA of *Paramecium*.
- Instead of being precisely determined, the end may be variable. Eukaryotic chromosomes may adopt this solution, in which the number of copies of a short repeating unit at the end of the DNA changes (see *Molecular Biology 5.19.18 Telomeres are synthesized by a ribonucleoprotein enzyme*). A mechanism to add or remove units makes it unnecessary to replicate right up to the very end.
- A protein may intervene to make initiation possible at the actual terminus. Several linear viral nucleic acids have proteins that are *covalently linked to the 5' terminal base*. The best characterized examples are adenovirus DNA, phage  $\phi$ 29 DNA, and poliovirus RNA.

*This content is available online at <http://www.ergito.com/main.jsp?bcs=MBIO.4.13.8>*

---

## THE REPLICON

### 4.13.9 Terminal proteins enable initiation at the ends of viral DNAs

---

#### Key Terms

**Strand displacement** is a mode of replication of some viruses in which a new DNA strand grows by displacing the previous (homologous) strand of the duplex.

A **terminal protein** allows replication of a linear phage genome to start at the very end. The protein attaches to the 5' end of the genome through a covalent bond, is associated with a DNA polymerase, and contains a cytosine residue that serves as a primer.

#### Key Concepts

- A terminal protein binds to the 5' end of DNA and provides a cytidine nucleotide with a 3' –OH end that primes replication.

---

An example of initiation at a linear end is provided by adenovirus and  $\phi 29$  DNAs, which actually replicate from both ends, using the mechanism of **strand displacement** illustrated in **Figure 13.13**. The same events can occur independently at either end. Synthesis of a new strand starts at one end, displacing the homologous strand that was previously paired in the duplex. When the replication fork reaches the other end of the molecule, the displaced strand is released as a free single strand. It is then replicated independently; this requires the formation of a duplex origin by base pairing between some short complementary sequences at the ends of the molecule.

**Figure 13.13** Adenovirus DNA replication is initiated separately at the two ends of the molecule and proceeds by strand displacement.

In several viruses that use such mechanisms, a protein is found covalently attached to each 5' end. In the case of adenovirus, a **terminal protein** is linked to the mature viral DNA via a phosphodiester bond to serine, as indicated in **Figure 13.14**.

**Figure 13.14** The 5' terminal phosphate at each end of adenovirus DNA is covalently linked to serine in the 55 kD Ad-binding protein.

How does the attachment of the protein overcome the initiation problem? The terminal protein has a dual role: it carries a cytidine nucleotide that provides the primer; and it is associated with DNA polymerase. In fact, linkage of terminal protein to a nucleotide is undertaken by DNA polymerase in the presence of adenovirus DNA. This suggests the model illustrated in **Figure 13.15**. The complex of polymerase and terminal protein, bearing the priming C nucleotide, binds to the end of the adenovirus DNA. The free 3' -OH end of the C nucleotide is used to prime the elongation reaction by the DNA polymerase. This generates a new strand whose 5' end is covalently linked to the initiating C nucleotide. (The reaction actually involves displacement of protein from DNA rather than binding *de novo*. The 5' end of adenovirus DNA is bound to the terminal protein that was used in the previous replication cycle. The old terminal protein is displaced by the new terminal protein for each new replication cycle.)

**Figure 13.15** Adenovirus terminal protein binds to the 5' end of DNA and provides a C-OH end to prime synthesis of a new DNA strand.

Terminal protein binds to the region located between 9 and 18 bp from the end of the DNA. The adjacent region, between positions 17 and 48, is essential for the binding of a host protein, nuclear factor I, which is also required for the initiation reaction. The initiation complex may therefore form between positions 9 and 48, a fixed distance from the actual end of the DNA.

*This content is available online at <http://www.ergito.com/main.jsp?bcs=MBIO.4.13.9>*

## THE REPLICON

### 4.13.10 Rolling circles produce multimers of a replicon

---

#### Key Terms

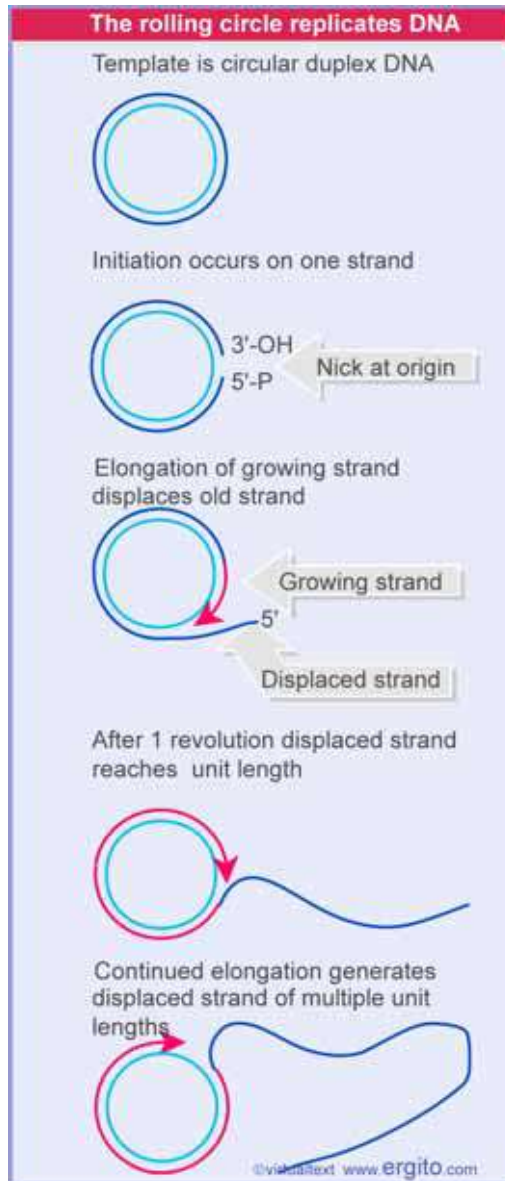

The **rolling circle** is a mode of replication in which a replication fork proceeds around a circular template for an indefinite number of revolutions; the DNA strand newly synthesized in each revolution displaces the strand synthesized in the previous revolution, giving a tail containing a linear series of sequences complementary to the circular template strand.

#### Key Concepts

- A rolling circle generates single-stranded multimers of the original sequence.
- 

The structures generated by replication depend on the relationship between the template and the replication fork. The critical features are whether the template is circular or linear, and whether the replication fork is engaged in synthesizing both strands of DNA or only one.

Replication of only one strand is used to generate copies of some circular molecules. A nick opens one strand, and then the free 3' -OH end generated by the nick is extended by the DNA polymerase. The newly synthesized strand displaces the original parental strand. The ensuing events are depicted in **Figure 13.16**.

**Figure 13.16** The rolling circle generates a multimeric single-stranded tail.

This type of structure is called a **rolling circle**, because the growing point can be envisaged as rolling around the circular template strand. It could in principle continue to do so indefinitely. As it moves, the replication fork extends the outer strand and displaces the previous partner (549). An example is shown in the electron micrograph of **Figure 13.17**.

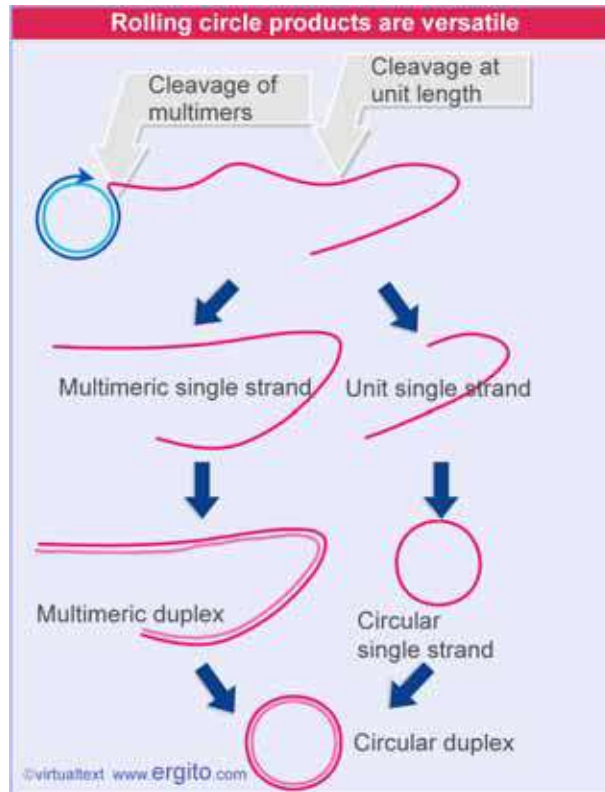

**Figure 13.17** A rolling circle appears as a circular molecule with a linear tail by electron microscopy. Photograph kindly provided by David Dressler.

Because the newly synthesized material is covalently linked to the original material, the displaced strand has the original unit genome at its 5' end. The original unit is followed by any number of unit genomes, synthesized by continuing revolutions of the template. Each revolution displaces the material synthesized in the previous cycle.

The rolling circle is put to several uses *in vivo*. Some pathways that are used to replicate DNA are depicted in **Figure 13.18**.

**Figure 13.18** The fate of the displaced tail determines the types of products generated by rolling circles. Cleavage at unit length generates monomers, which can be converted to duplex and circular forms. Cleavage of multimers generates a series of tandemly repeated copies of the original unit. Note that the conversion to double-stranded form could occur earlier, before the tail is cleaved from the rolling circle.

Cleavage of a unit length tail generates a copy of the original circular replicon in linear form. The linear form may be maintained as a single strand or may be converted into a duplex by synthesis of the complementary strand (which is identical in sequence to the template strand of the original rolling circle).

The rolling circle provides a means for amplifying the original (unit) replicon. This mechanism is used to generate amplified rDNA in the *Xenopus* oocyte. The genes for rRNA are organized as a large number of contiguous repeats in the genome. A single repeating unit from the genome is converted into a rolling circle. The displaced tail, containing many units, is converted into duplex DNA; later it is cleaved from the circle so that the two ends can be joined together to generate a large circle of amplified rDNA. The amplified material therefore consists of a large number of identical repeating units.

## THE REPLICON

### 4.13.11 Rolling circles are used to replicate phage genomes

---

#### Key Terms

A **relaxase** is an enzyme that cuts one strand of DNA, and binds to the free 5' end.

#### Key Concepts

- The  $\phi$ X A protein is a *cis*-acting relaxase that generates single-stranded circles from the tail produced by rolling circle replication.
- 

Replication by rolling circles is common among bacteriophages. Unit genomes can be cleaved from the displaced tail, generating monomers that can be packaged into phage particles or used for further replication cycles. A more detailed view of a phage replication cycle that is centered on the rolling circle is given in **Figure 13.19**.

**Figure 13.19**  $\phi$  X174 RF DNA is a template for synthesizing single-stranded viral circles. The A protein remains attached to the same genome through indefinite revolutions, each time nicking the origin on the viral (+) strand and transferring to the new 5' end. At the same time, the released viral strand is circularized.

*This is a static version of an interactive figure; see <http://www.ergito.com/main.jsp?bcs=MBIO.4.13.11> to view properly.*

Phage  $\phi$ X174 consists of a single-stranded circular DNA, known as the plus (+) strand. A complementary strand, called the minus (–) strand, is synthesized. This action generates the duplex circle shown at the top of the figure, which is then replicated by a rolling circle mechanism.

The duplex circle is converted to a covalently closed form, which becomes supercoiled. A protein coded by the phage genome, the A protein, nicks the (+) strand of the duplex DNA at a specific site that defines the origin for replication.

---

After nicking the origin, the A protein remains connected to the 5' end that it generates, while the 3' end is extended by DNA polymerase.

The structure of the DNA plays an important role in this reaction, for the DNA can be nicked *only when it is negatively supercoiled* (wound about its axis in space in the opposite sense from the handedness of the double helix; see *Molecular Biology 4.15.12 Supercoiling affects the structure of DNA*). The A protein is able to bind to a single-stranded decamer fragment of DNA that surrounds the site of the nick. This suggests that the supercoiling is needed to assist the formation of a single-stranded region that provides the A protein with its binding site. (An enzymatic activity in which a protein cleaves duplex DNA and binds to a released 5' end is sometimes called a **relaxase**.) The nick generates a 3' -OH end and a 5' -phosphate end (covalently attached to the A protein), both of which have roles to play in  $\phi$ X174 replication.

Using the rolling circle, the 3' -OH end of the nick is extended into a new chain. The chain is elongated around the circular (-) strand template, until it reaches the starting point and displaces the origin. Now the A protein functions again. It remains connected with the rolling circle as well as to the 5' end of the displaced tail, and it is therefore in the vicinity as the growing point returns past the origin. So the same A protein is available again to recognize the origin and nick it, now attaching to the end generated by the new nick. The cycle can be repeated indefinitely.

Following this nicking event, the displaced single (+) strand is freed as a circle. The A protein is involved in the circularization. In fact, the joining of the 3' and 5' ends of the (+) strand product is accomplished by the A protein as part of the reaction by which it is released at the end of one cycle of replication, and starts another cycle.

The A protein has an unusual property that may be connected with these activities. It is *cis-acting in vivo*. (This behavior is not reproduced *in vitro*, as can be seen from its activity on any DNA template in a cell-free system.) *The implication is that in vivo the A protein synthesized by a particular genome can attach only to the DNA of that genome*. We do not know how this is accomplished. However, its activity *in vitro* shows how it remains associated with the same parental (-) strand template. The A protein has two active sites; this may allow it to cleave the "new" origin while still retaining the "old" origin; then it ligates the displaced strand into a circle.

The displaced (+) strand may follow either of two fates after circularization. During the replication phase of viral infection, it may be used as a template to synthesize the complementary (-) strand. The duplex circle may then be used as a rolling circle to generate more progeny. During phage morphogenesis, the displaced (+) strand is packaged into the phage virion.

## THE REPLICON

### 4.13.12 The F plasmid is transferred by conjugation between bacteria

---

#### Key Terms

**Conjugation** is a process in which two cells come in contact and exchange genetic material. In bacteria, DNA is transferred from a donor to a recipient cell. In protozoa, DNA passes from each cell to the other.

The **F plasmid** is an episome that can be free or integrated in *E. coli*, and which in either form can sponsor conjugation.

The **transfer region** is a segment on the F plasmid that is required for bacterial conjugation.

A **pilus (pili)** is a surface appendage on a bacterium that allows the bacterium to attach to other bacterial cells. It appears like a short, thin, flexible rod. During conjugation, pili are used to transfer DNA from one bacterium to another.

**Pilin** is the subunit that is polymerized into the pilus in bacteria.

#### Key Concepts

- A free F factor is a replicon that is maintained at the level of one plasmid per bacterial chromosome.
- An F factor can integrate into the bacterial chromosome, in which case its own replication system is suppressed.
- The F factor codes for specific pili that form on the surface of the bacterium.
- An F-pilus enables an F-positive bacterium to contact an F-negative bacterium and to initiate conjugation.

---

Another example of a connection between replication and the propagation of a genetic unit is provided by bacterial **conjugation**, in which a plasmid genome or host chromosome is transferred from one bacterium to another.

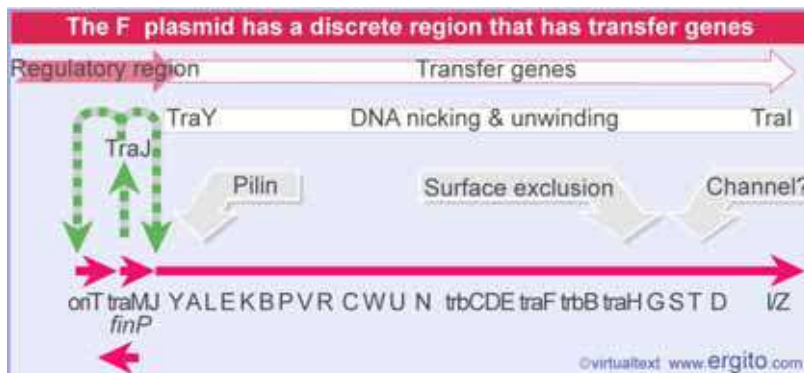

Conjugation is mediated by the **F plasmid**, which is the classic example of an episome, an element that may exist as a free circular plasmid, or that may become integrated into the bacterial chromosome as a linear sequence (like a lysogenic bacteriophage). The F plasmid is a large circular DNA, ~100 kb in length.

The F factor can integrate at several sites in the *E. coli* chromosome, often by a recombination event involving certain sequences (called IS sequences; see *Molecular Biology 4.16.5 Transposons cause rearrangement of DNA*) that are present on both the host chromosome and F plasmid. In its free (plasmid) form, the F plasmid utilizes its own replication origin (*oriV*) and control system, and is maintained at a level of one copy per bacterial chromosome. When it is integrated into the bacterial chromosome, this system is suppressed, and F DNA is replicated as a part of the

chromosome.

The presence of the F plasmid, whether free or integrated, has important consequences for the host bacterium. Bacteria that are F-positive are able to conjugate (or mate) with bacteria that are F-negative. Conjugation involves a contact between donor (F-positive) and recipient (F-negative) bacteria; contact is followed by transfer of the F factor. If the F factor exists as a free plasmid in the donor bacterium, it is transferred as a plasmid, and the infective process converts the F-negative recipient into an F-positive state. If the F factor is present in an integrated form in the donor, the transfer process may also cause some or all of the bacterial chromosome to be transferred. Many plasmids have conjugation systems that operate in a generally similar manner, but the F factor was the first to be discovered, and remains the paradigm for this type of genetic transfer (550).

A large (~33 kb) region of the F plasmid, called the **transfer region**, is required for conjugation. It contains ~40 genes that are required for the transmission of DNA; their organization is summarized in **Figure 13.20**. The genes are named as *tra* and *trb* loci. Most of them are expressed coordinately as part of a single 32 kb transcription unit (the *traY-I* unit). *traM* and *traJ* are expressed separately. *traJ* is a regulator that turns on both *traM* and *traY-I*. On the opposite strand, *finP* is a regulator that codes for a small antisense RNA that turns off *traJ*. Its activity requires expression of another gene, *finO*. Only four of the *tra* genes in the major transcription unit are concerned directly with the transfer of DNA; most are concerned with the properties of the bacterial cell surface and with maintaining contacts between mating bacteria.

**Figure 13.20** The *tra* region of the F plasmid contains the genes needed for bacterial conjugation.

F-positive bacteria possess surface appendages called pili (singular **pilus**) that are coded by the F factor. The gene *traA* codes for the single subunit protein, **pilin**, that is polymerized into the pilus. At least 12 *tra* genes are required for the modification and assembly of pilin into the pilus. The F-pili are hair-like structures, 2-3  $\mu\text{m}$  long, that protrude from the bacterial surface. A typical F-positive cell has 2-3 pili. The pilin subunits are polymerized into a hollow cylinder, ~8 nm in diameter, with a 2 nm axial hole.

Mating is initiated when the tip of the F-pilus contacts the surface of the recipient cell. **Figure 13.21** shows an example of *E. coli* cells beginning to mate. A donor cell does not contact other cells carrying the F factor, because the genes *traS* and *traT*

code for "surface exclusion" proteins that make the cell a poor recipient in such contacts. This effectively restricts donor cells to mating with F-negative cells. (And the presence of F-pili has secondary consequences; they provide the sites to which RNA phages and some single-stranded DNA phages attach, so F-positive bacteria are susceptible to infection by these phages, whereas F-negative bacteria are resistant.)

**Figure 13.21** Mating bacteria are initially connected when donor F pili contact the recipient bacterium. Photograph kindly provided by Ron Skurray.

The initial contact between donor and recipient cells is easily broken, but other *tra* genes act to stabilize the association, bringing the mating cells closer together. The F pili are essential for initiating pairing, but retract or disassemble as part of the process by which the mating cells are brought into close contact. There must be a channel through which DNA is transferred, but the pilus itself does not appear to provide it. TraD is an inner membrane protein in  $F^+$  bacteria that is necessary for transport of DNA and it may provide or be part of the channel.

## THE REPLICON

### 4.13.13 Conjugation transfers single-stranded DNA

---

#### Key Terms

An **Hfr** cell is a bacterium that has an integrated F plasmid within its chromosome. Hfr stands for high frequency recombination, referring to the fact that chromosomal genes are transferred from an Hfr cell to an F<sup>#</sup> cell much more frequently than from an F<sup>+</sup> cell.

#### Key Concepts

- Transfer of an F factor is initiated when rolling circle replication begins at *oriT*.
- The free 5' end initiates transfer into the recipient bacterium.
- The transferred DNA is converted into double-stranded form in the recipient bacterium.
- When an F factor is free, conjugation "infects" the recipient bacterium with a copy of the F factor.
- When an F factor is integrated, conjugation causes transfer of the bacterial chromosome until the process is interrupted by (random) breakage of the contact between donor and recipient bacteria.

---

Transfer of the F factor is initiated at a site called *oriT*, the origin of transfer, which is located at one end of the transfer region. The transfer process may be initiated when TraM recognizes that a mating pair has formed. Then TraY binds near *oriT* and causes TraI to bind. TraI is a relaxase, like  $\phi$ X174 A protein. TraI nicks *oriT* at a unique site (called *nic*), and then forms a covalent link to the 5' end that has been generated. TraI also catalyzes the unwinding of ~200 bp of DNA (this is a helicase activity; see *Molecular Biology 4.14.7 The  $\phi$ X model system shows how single-stranded DNA is generated for replication*). **Figure 13.22** shows that the freed 5' end leads the way into the recipient bacterium. A complement for the transferred single strand is synthesized in the recipient bacterium, which as a result is converted to the F-positive state (for review see 138).

**Figure 13.22** Transfer of DNA occurs when the F factor is nicked at *oriT* and a single strand is led by the 5' end into the recipient. Only one unit length is transferred. Complementary strands are synthesized to the single strand remaining in the donor and to the strand transferred into the recipient.

A complementary strand must be synthesized in the donor bacterium to replace the strand that has been transferred. If this happens concomitantly with the transfer process, the state of the F plasmid will resemble the rolling circle of **Figure 13.16** (and will not generate the extensive single-stranded regions shown in **Figure 13.22**). Conjugating DNA usually appears like a rolling circle, but replication as such is not necessary to provide the driving energy, and single-strand transfer is independent of DNA synthesis. Only a single unit length of the F factor is transferred to the recipient bacterium. This implies that some (unidentified) feature terminates the process after one revolution, after which the covalent integrity of the F plasmid is restored (for review see 106; 111).

When an integrated F plasmid initiates conjugation, the orientation of transfer is directed away from the transfer region, into the bacterial chromosome. **Figure 13.23** shows that, following a short leading sequence of F DNA, bacterial DNA is transferred. The process continues until it is interrupted by the breaking of contacts between the mating bacteria. It takes ~100 minutes to transfer the entire bacterial chromosome, and under standard conditions, contact is often broken before the completion of transfer (for review see 120).

**Figure 13.23** Transfer of chromosomal DNA occurs when an integrated F factor is nicked at *oriT*. Transfer of DNA starts with a short sequence of F DNA and continues until prevented by loss of contact between the bacteria.

Donor DNA that enters a recipient bacterium is converted to double-stranded form, and may recombine with the recipient chromosome. (Note that two recombination events are required to insert the donor DNA.) So conjugation affords a means to exchange genetic material between bacteria (a contrast with their usual asexual growth). A strain of *E. coli* with an integrated F factor supports such recombination at relatively high frequencies (compared to strains that lack integrated F factors);

such strains are described as **Hfr** (for high frequency recombination). Each position of integration for the F factor gives rise to a different Hfr strain, with a characteristic pattern of transferring bacterial markers to a recipient chromosome.

Contact between conjugating bacteria is usually broken before transfer of DNA is complete. As a result, the probability that a region of the bacterial chromosome will be transferred depends upon its distance from *oriT*. Bacterial genes located close to the site of F integration (in the direction of transfer) enter recipient bacteria first, and are therefore found at greater frequencies than those located farther away that enter later. This gives rise to a gradient of transfer frequencies around the chromosome, declining from the position of F integration. Marker positions on the donor chromosome can be assayed in terms of the time at which transfer occurs, and this gave rise to the standard description of the *E. coli* chromosome as a map divided into 100 minutes. The map refers to transfer times from a particular Hfr strain; the starting point for the gradient of transfer is different for each Hfr strain, being determined by the site where the F factor has integrated into the bacterial genome.

## THE REPLICON

### 4.13.14 Replication is connected to the cell cycle

---

#### Key Terms

The **doubling time** is the period (usually measured in minutes) that it takes for a bacterial cell to reproduce.

A **multiforked chromosome** (in bacterium) has more than one replication fork, because a second initiation has occurred before the first cycle of replication has been completed.

The **unit cell** describes the state of an *E. coli* bacterium generated by a new division. It is 1.7  $\mu\text{m}$  long and has a single replication origin.

#### Key Concepts

- The doubling time of *E. coli* can vary over a 10 $\times$  range, depending on growth conditions.
  - It requires 40 minutes to replicate the bacterial chromosome (at normal temperature).
  - Completion of a replication cycle triggers a bacterial division 20 minutes later.
  - If the doubling time is <60 minutes, a replication cycle is initiated before the division resulting from the previous replication cycle.
  - Fast rates of growth therefore produce multiforked chromosomes.
  - A replication cycle is initiated at a constant ratio of mass/number of chromosome origins.
  - There is one origin per unit cell of 1.7 $\mu\text{m}$  in length.
- 

Bacteria have two links between replication and cell growth:

- The frequency of initiation of cycles of replication is adjusted to fit the rate at which the cell is growing.
- The completion of a replication cycle is connected with division of the cell.

The rate of bacterial growth is assessed by the **doubling time**, the period required for the number of cells to double. The shorter the doubling time, the faster the growth rate. *E. coli* cells can grow at rates ranging from doubling times as fast as 18 minutes to slower than 180 minutes. Because the bacterial chromosome is a single replicon, the frequency of replication cycles is controlled by the number of initiation events at the single origin. The replication cycle can be defined in terms of two constants:

- $C$  is the fixed time of ~40 minutes required to replicate the entire bacterial chromosome. Its duration corresponds to a rate of replication fork movement of ~50,000 bp/minute. (The rate of DNA synthesis is more or less invariant at a constant temperature; it proceeds at the same speed unless and until the supply of precursors becomes limiting.)
- $D$  is the fixed time of ~20 minutes that elapses between the completion of a round of replication and the cell division with which it is connected. This period may represent the time required to assemble the components needed for division.

(The constants  $C$  and  $D$  can be viewed as representing the maximum speed with which the bacterium is capable of completing these processes. They apply for all growth rates between doubling times of 18 and 60 minutes, but both constant phases become longer when the cell cycle occupies >60 minutes.)

A cycle of chromosome replication must be initiated a fixed time before a cell division,  $C + D = 60$  minutes. For bacteria dividing more frequently than every 60 minutes, a cycle of replication must be initiated before the end of the preceding division cycle.

Consider the example of cells dividing every 35 minutes. The cycle of replication connected with a division must have been initiated 25 minutes before the preceding division. This situation is illustrated in **Figure 13.24**, which shows the chromosomal complement of a bacterial cell at 5-minute intervals throughout the cycle.

**Figure 13.24** The fixed interval of 60 minutes between initiation of replication and cell division produces multiforked chromosomes in rapidly growing cells. Note that only the replication forks moving in one direction are shown; actually the chromosome is replicated symmetrically by two sets of forks moving in opposite directions on circular chromosomes.

At division (35/0 minutes), the cell receives a partially replicated chromosome. The

---

replication fork continues to advance. At 10 minutes, when this "old" replication fork has not yet reached the terminus, initiation occurs at both origins on the partially replicated chromosome. The start of these "new" replication forks creates a **multiforked chromosome**.

At 15 minutes – that is, at 20 minutes before the next division – the old replication fork reaches the terminus. Its arrival allows the two daughter chromosomes to separate; each of them has already been partially replicated by the new replication forks (which now are the only replication forks). These forks continue to advance.

At the point of division, the two partially replicated chromosomes segregate. This recreates the point at which we started. The single replication fork becomes "old," it terminates at 15 minutes, and 20 minutes later there is a division. We see that the initiation event occurs  $1\frac{25}{35}$  cell cycles before the division event with which it is associated.

The general principle of the link between initiation and the cell cycle is that, as cells grow more rapidly (the cycle is shorter), the initiation event occurs an increasing number of cycles before the related division. There are correspondingly more chromosomes in the individual bacterium. This relationship can be viewed as the cell's response to its inability to reduce the periods of C and D to keep pace with the shorter cycle.

How does the cell know when to initiate the replication cycle? The initiation event occurs at a constant ratio of cell mass to the number of chromosome origins. Cells growing more rapidly are larger and possess a greater number of origins. The growth of the bacterium can be described in terms of the **unit cell**, an entity 1.7  $\mu\text{m}$  long. A bacterium contains one origin per unit cell; a rapidly growing cell with two origins will be 1.7-3.4  $\mu\text{m}$  long. In terms of **Figure 13.24**, it is at the point 10 minutes after division that the cell mass has increased sufficiently to support an initiation event at both available origins (543; 544).

How is cell mass titrated? An initiator protein could be synthesized continuously throughout the cell cycle; accumulation of a critical amount would trigger initiation. This explains why protein synthesis is needed for the initiation event. An alternative possibility is that an inhibitor protein might be synthesized at a fixed point, and diluted below an effective level by the increase in cell volume (for review see 117).

## THE REPLICON

### 4.13.15 The septum divides a bacterium into progeny each containing a chromosome

---

#### Key Terms

A **septum** is the structure that forms in the center of a dividing bacterium, providing the site at which the daughter bacteria will separate. The same term is used to describe the cell wall that forms between plant cells at the end of mitosis.

A **periseptal annulus** is an ring-like area where inner and outer membrane appear fused. Formed around the circumference of the bacterium, the periseptal annulus determines the location of the septum.

#### Key Concepts

- Septum formation is initiated at the annulus, which is a ring around the cell where the structure of the envelope is altered.
- New annuli are initiated at 50% of the distance from the septum to each end of the bacterium.
- When the bacterium divides, each daughter has an annulus at the mid center position.
- Septation starts when the cell reaches a fixed length.
- The septum consists of the same peptidoglycans that comprise the bacterial envelope.

---

Chromosome segregation in bacteria is especially interesting because the DNA itself is involved in the mechanism for partition. (This contrasts with eukaryotic cells, in which segregation is achieved by the complex apparatus of mitosis.) The bacterial apparatus is quite accurate, however; anucleate cells form <0.03% of a bacterial population.

The division of a bacterium into two daughter cells is accomplished by the formation of a **septum**, a structure that forms in the center of the cell as an invagination from the surrounding envelope. The septum forms an impenetrable barrier between the two parts of the cell and provides the site at which the two daughter cells eventually separate entirely. Two related questions address the role of the septum in division: what determines the location at which it forms; and what ensures that the daughter chromosomes lie on opposite sides of it?

The formation of the septum is preceded by the organization of the **periseptal annulus**. This is observed as a zone in *E. coli* or *S. typhimurium* in which the structure of the envelope is altered so that the inner membrane is connected more closely to the cell wall and outer membrane layer. As its name suggests, the annulus extends around the cell. **Figure 13.25** summarizes its development (for review see

112).

**Figure 13.25** Duplication and displacement of the periseptal annulus give rise to the formation of a septum that divides the cell.

*This is a static version of an interactive figure; see <http://www.ergito.com/main.jsp?bcs=MBIO.4.13.15> to view properly.*

The annulus starts at a central position in a new cell. As the cell grows, two events occur. A septum forms at the midcell position defined by the annulus. And new annuli form on either side of the initial annulus. These new annuli are displaced from the center and move along the cell to positions at  $1/4$  and  $3/4$  of the cell length. These will become the midcell positions after the next division. The displacement of the periseptal annulus to the correct position may be the crucial event that ensures the division of the cell into daughters of equal size. (The mechanism of movement is unknown.) Septation begins when the cell reaches a fixed length ( $2L$ ), and the distance between the new annuli is always  $L$ . We do not know how the cell measures length, but the relevant parameter appears to be linear distance as such (not area or volume).

The septum consists of the same components as the cell envelope: there is a rigid layer of peptidoglycan in the periplasm, between the inner and outer membranes. The peptidoglycan is made by polymerization of tri- or pentapeptide-disaccharide units in a reaction involving connections between both types of subunit (transpeptidation and transglycosylation). The rod-like shape of the bacterium is maintained by a pair of

activities, PBP2 and RodA. They are interacting proteins, coded by the same operon. RodA is a member of the SEDS family (SEDS stands for shape, elongation, division, and sporulation) that is present in all bacteria that have a peptidoglycan cell wall. Each SEDS protein functions together with a specific transpeptidase, which catalyzes the formation of the cross-links in the peptidoglycan. PBP2 (penicillin-binding protein 2) is the transpeptidase that interacts with RodA. Mutations in the gene for either protein cause the bacterium to lose its extended shape, becoming round (3082). This demonstrates the important principle that shape and rigidity can be determined by the simple extension of a polymeric structure. Another enzyme is responsible for generating the peptidoglycan in the septum (see *Molecular Biology 4.13.17 FtsZ is necessary for septum formation*). The septum initially forms as a double layer of peptidoglycan, and the protein EnvA is required to split the covalent links between the layers, so that the daughter cells may separate.

The behavior of the periseptal annulus suggests that the mechanism for measuring position is associated with the cell envelope. It is plausible to suppose that the envelope could also be used to ensure segregation of the chromosomes. A direct link between DNA and the membrane could account for segregation. If daughter chromosomes are attached to the membrane, they could be physically separated when the septum forms. **Figure 13.26** shows that the formation of a septum could segregate the chromosomes into the different daughter cells if the origins are connected to sites that lie on either side of the periseptal annulus.

**Figure 13.26** Attachment of bacterial DNA to the membrane could provide a mechanism for segregation.

## THE REPLICON

### 4.13.16 Mutations in division or segregation affect cell shape

---

#### Key Terms

A **minicell** is an anucleate bacterial (*E. coli*) cell produced by a division that generates a cytoplasm without a nucleus.

**Anucleate** bacteria lack a nucleoid, but are of similar shape to wild-type bacteria.

#### Key Concepts

- *fts* mutants form long filaments because the septum fails to form to divide the daughter bacteria.
- Minicells form in mutants that produce too many septa; they are small and lack DNA.
- Anucleate cells of normal size are generated by partition mutants in which the duplicate chromosomes fail to separate.

---

A difficulty in isolating mutants that affect cell division is that mutations in the critical functions may be lethal and/or pleiotropic. For example, if formation of the annulus occurs at a site that is essential for overall growth of the envelope, it would be difficult to distinguish mutations that specifically interfere with annulus formation from those that inhibit envelope growth generally. Most mutations in the division apparatus have been identified as conditional mutants (whose division is affected under nonpermissive conditions; typically they are temperature sensitive). Mutations that affect cell division or chromosome segregation cause striking phenotypic changes. **Figure 13.27** and **Figure 13.28** illustrate the opposite consequences of failure in the division process and failure in segregation:

**Figure 13.27** Failure of cell division generates multinucleated filaments. Photograph kindly provided by Sota Hiraga.

**Figure 13.28** *E. coli* generate anucleate cells when chromosome segregation fails. Cells with chromosomes stain blue; daughter cells lacking chromosomes have no blue stain. This field shows cells of the *mukB* mutant; both normal and abnormal divisions can be seen. Photograph kindly provided by Sota Hiraga.

- Long *filaments* form when septum formation is inhibited, but chromosome replication is unaffected. The bacteria continue to grow, and even continue to segregate their daughter chromosomes, but septa do not form, so the cell consists of a very long filamentous structure, with the nucleoids (bacterial chromosomes)

regularly distributed along the length of the cell. This phenotype is displayed by *fts* mutants (named for temperature-sensitive filamentation), which identify defect(s) that lie in the division process itself.

- **Minicells** form when septum formation occurs too frequently or in the wrong place, with the result that one of the new daughter cells lacks a chromosome. The minicell has a rather small size, and lacks DNA, but otherwise appears morphologically normal. **Anucleate** cells form when segregation is aberrant; like minicells, they lack a chromosome, but because septum formation is normal, their size is unaltered. This phenotype is caused by *par* (partition) mutants (named because they are defective in chromosome segregation) (542).

---

## THE REPLICON

### 4.13.17 FtsZ is necessary for septum formation

---

#### Key Terms

The **septal ring (Z-ring)** is a complex of several proteins coded by *fts* genes of *E. coli* that forms at the mid-point of the cell. It gives rise to the septum at cell division. The first of the proteins to be incorporated is FtsZ, which gave rise to the original name of the Z-ring.

#### Key Concepts

- The product of *ftsZ* is required for septum formation at pre-existing sites.
- FtsZ is a GTPase that forms a ring on the inside of the bacterial envelope. It is connected to other cytoskeletal components.

---

The gene *ftsZ* plays a central role in division. Mutations in *ftsZ* block septum formation and generate filaments. Overexpression induces minicells, by causing an increased number of septation events per unit cell mass. *ftsZ* mutants act at stages varying from the displacement of the periseptal annuli to septal morphogenesis. FtsZ is therefore required for usage of pre-existing sites for septum formation, but does not itself affect the formation of the periseptal annuli or their localization.

FtsZ functions at an early stage of septum formation. Early in the division cycle, FtsZ is localized throughout the cytoplasm. As the cell elongates and begins to constrict in the middle, FtsZ becomes localized in a ring around the circumference (3077). The structure is sometimes called the **Z-ring**. **Figure 13.29** shows that it lies in the position of the mid-center annulus of **Figure 13.25**. The formation of the Z-ring is the rate-limiting step in septum formation. In a typical division cycle, it forms in the center of cell 1-5 min after division, remains for 15 min, and then quickly constricts to pinch the cell into two.

**Figure 13.29** Immunofluorescence with an antibody against FtsZ shows that it is localized at the mid-cell. Photograph kindly provided by William Margolin (see 3076).

The structure of FtsZ resembles tubulin, suggesting that assembly of the ring could resemble the formation of microtubules in eukaryotic cells. FtsZ has GTPase activity, and GTP cleavage is used to support the oligomerization of FtsZ monomers into the ring structure. The Z-ring is a dynamic structure, in which there is continuous exchange of subunits with a cytoplasmic pool (3078; for review see 4526).

Two other proteins needed for division, ZipA and FtsA, interact directly and independently with FtsZ (3079). ZipA is an integral membrane protein, located in the inner bacterial membrane. It provides the means for linking FtsZ to the membrane. FtsA is a cytosolic protein, but is often found associated with the membrane. The Z-ring can form in the absence of either ZipA or FtsA, but cannot form if both are absent (3080). This suggests that they have overlapping roles in stabilizing the Z-ring, and perhaps in linking it to the membrane.

The products of several other *fts* genes join the Z-ring in a defined order after FtsA has been incorporated (for review see 123; 982). They are all transmembrane proteins. The final structure is sometimes called the **septal ring**. It consists of a multiprotein complex that is presumed to have the ability to constrict the membrane. One of the last components to be incorporated into the septal ring is FtsW, which is a protein belonging to the SEDS family *ftsW* is expressed as part of an operon with *ftsI*, which codes for a transpeptidase (also called PBP3 for penicillin-binding protein 3), a membrane-bound protein that has its catalytic site in the periplasm. FtsW is responsible for incorporating FtsI into the septal ring (3081). This suggests a model for septum formation in which the transpeptidase activity then causes the peptidoglycan to grow inward, thus pushing the inner membrane and pulling the outer membrane.

FtsZ is the major cytoskeletal component of septation. It is common in bacteria, and is found also in chloroplasts. **Figure 13.30** shows the localization of the plant homologues to a ring at the mid-point of the chloroplast. Chloroplasts also have other genes related to the bacterial division genes. Consistent with the common

evolutionary origins of bacteria and chloroplasts, the apparatus for division seems generally to have been conserved.

**Figure 13.30** Immunofluorescence with antibodies against the *Arabidopsis* proteins FtsZ1 and FtsZ2 show that they are localized at the mid point of the chloroplast (top panel). The bright field image (lower panel) shows the outline of the chloroplast more clearly. Photograph kindly provided by Katherine Osteryoung (see 3075).

Mitochondria, which also share an evolutionary origin with bacteria, usually do not have FtsZ. Instead, they use a variant of the protein dynamin, which is involved in pinching off vesicles from membranes of eukaryotic cytoplasm (see *Molecular Biology 6.27.5 Different types of coated vesicles exist in each pathway*). This functions from the outside of the organelle, squeezing the membrane to generate a constriction.

The common feature, then, in the division of bacteria, chloroplasts, and mitochondria is the use of a cytoskeletal protein that forms a ring round the organelle, and either pulls or pushes the membrane to form a constriction.

**THE REPLICON****4.13.18 *min* genes regulate the location of the septum**

---

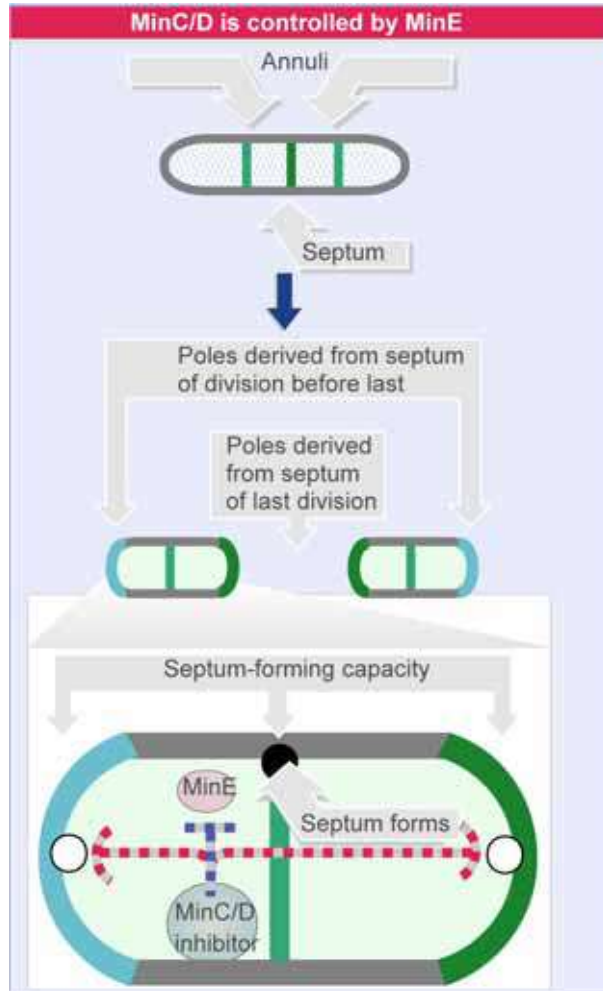

**Key Concepts**

- The location of the septum is controlled by *minC,D,E*.
- The number and location of septa is determined by the ratio of MinE/MinC,D.
- The septum forms where MinE is able to form a ring.
- At normal concentrations, MinC/D allows a mid-center ring, but prevents additional rings of MinE from forming at the poles.

---

Information about the localization of the septum is provided by minicell mutants. The original minicell mutation lies in the locus *minB*; deletion of *minB* generates minicells by allowing septation to occur at the poles as well as (or instead of) at midcell. This suggests that the cell possesses the ability to initiate septum formation either at midcell or at the poles; and the role of the wild-type *minB* locus is to suppress septation at the poles. In terms of the events depicted in **Figure 13.25**, this implies that a new born cell has potential septation sites associated both with the annulus at mid-center and with the poles. One pole was formed from the septum of the previous division; the other pole represents the septum from the division before that. Perhaps the poles retain remnants of the annuli from which they were derived, and these remnants can nucleate septation.

The *minB* locus consists of three genes, *minC,D,E*. Their roles are summarized in **Figure 13.31**. The products of *minC* and *minD* form a division inhibitor. MinD is required to activate MinC, which prevents FtsZ from polymerizing into the Z-ring (3084; 3083).

**Figure 13.31** MinC/D is a division inhibitor, whose action is confined to the polar sites by MinE.

Expression of MinCD in the absence of MinE, or overexpression even in the presence of MinE, causes a generalized inhibition of division. The resulting cells grow as long filaments without septa. Expression of MinE at levels comparable to MinCD confines the inhibition to the polar regions, so restoring normal growth. MinE protects the midcell sites from inhibition. Overexpression of MinE induces minicells, because the presence of excess MinE counteracts the inhibition at the poles as well as at midcell, allowing septa to form at both locations (546).

The determinant of septation at the proper (midcell) site is therefore the ratio of MinCD to MinE. The wild-type level prevents polar septation, while permitting midcell septation. The effects of MinC/D and MinE are inversely related; absence of MinCD or too much MinE causes indiscriminate septation, forming minicells; too much MinCD or absence of MinE inhibits midcell as well as polar sites, resulting in filamentation.

MinE forms a ring at the septal position. Its accumulation suppresses the action of MinCD in the vicinity, thus allowing formation of the septal ring (which includes FtsZ and ZipA). Curiously, MinD is required for formation of the MinE ring (548).

## THE REPLICON

## 4.13.19 Chromosomal segregation may require site-specific recombination

### Key Terms

**Site-specific recombination (Specialized recombination)** occurs between two specific sequences, as in phage integration/excision or resolution of cointegrate structures during transposition.

### Key Concepts

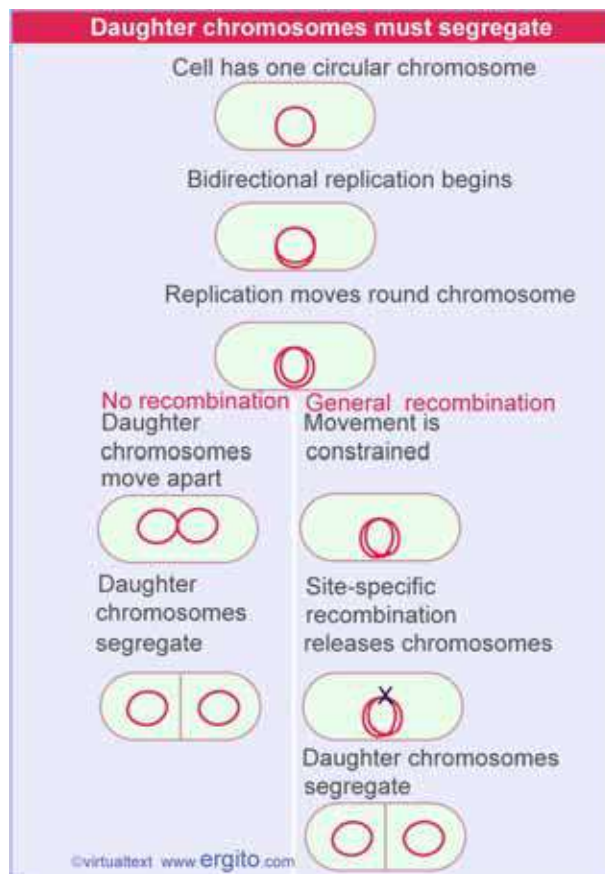

- The Xer site-specific recombination system acts on a target sequence near the chromosome terminus to recreate monomers if a generalized recombination event has converted the bacterial chromosome to a dimer.

Because the multiple copies of a plasmid in a bacterium consist of the same DNA sequences, they are able to recombine. **Figure 13.32** demonstrates the consequences. A single intermolecular recombination event between two circles generates a dimeric circle; further recombination can generate higher multimeric forms. Such an event reduces the number of physically segregating units. In the extreme case of a single-copy plasmid that has just replicated, formation of a dimer by recombination means that the cell only has one unit to segregate, and the plasmid therefore must inevitably be lost from one daughter cell. To counteract this effect, plasmids often have **site-specific recombination** systems that act upon particular sequences to sponsor an intramolecular recombination that restores the monomeric condition.

**Figure 13.32** Intermolecular recombination merges monomers into dimers, and intramolecular recombination releases individual units from oligomers.

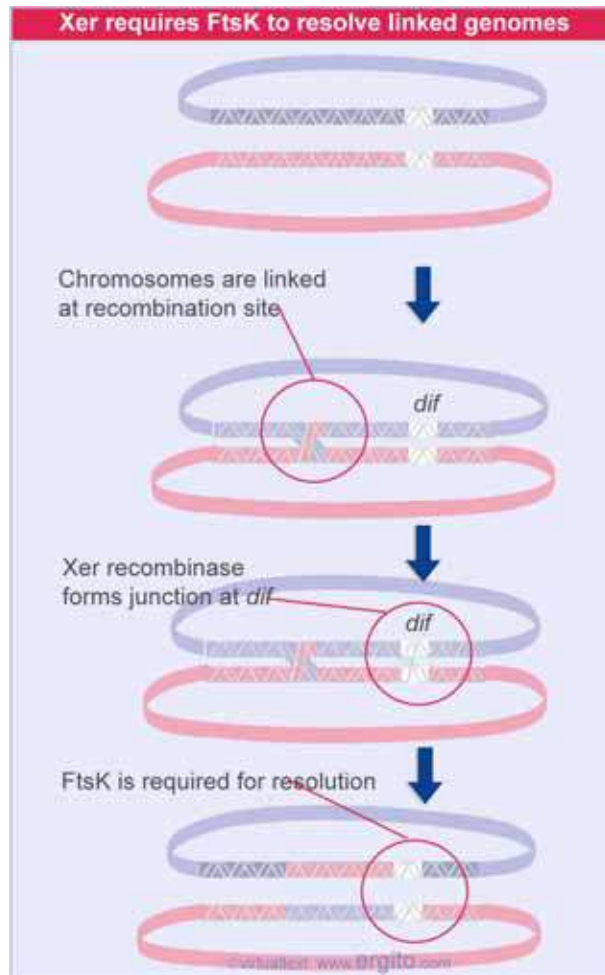

The same types of event can occur with the bacterial chromosome, and **Figure 13.33** shows how they affect its segregation. If no recombination occurs, there is no problem, and the separate daughter chromosomes can segregate to the daughter cells. But a dimer will be produced if homologous recombination occurs between the daughter chromosomes produced by a replication cycle. If there has been such a recombination event, the daughter chromosomes cannot separate. In this case, a second recombination is required to achieve resolution in the same way as a plasmid dimer.

**Figure 13.33** A circular chromosome replicates to produce two monomeric daughters that segregate to daughter cells. However, a generalized recombination event generates a single dimeric molecule. This can be resolved into two monomers by a site-specific recombination.

Most bacteria with circular chromosomes possess the Xer site-specific recombination system. In *E. coli*, this consists of two recombinases, XerC and XerD, which act on a 28 bp target site, called *dif*, that is located in the terminus region of the chromosome (3127). The use of the Xer system is related in an interesting way to cell division. The relevant events are summarized in **Figure 13.34**. XerC can bind to a pair of *dif* sequences and form a Holliday junction between them. The complex may form soon after the replication fork passes over the *dif* sequence, which explains how the two copies of the target sequence can find one another consistently. However, resolution of the junction to give recombinants occurs only in the presence of FtsK, a protein located in the septum that is required for chromosome segregation and cell division.

(1671). Also, the *dif* target sequence must be located in a region of ~30 kb; if it is moved outside of this region, it cannot support the reaction.

**Figure 13.34** A recombination event creates two linked chromosomes. Xer creates a Holliday junction at the *dif* site, but can resolve it only in the presence of FtsK.

So there is a site-specific recombination available when the terminus sequence of the chromosome is close to the septum. But the bacterium wants to have a recombination only when there has already been a general recombination event to generate a dimer. (Otherwise the site-specific recombination would create the dimer!) How does the system know whether the daughter chromosomes exist as independent monomers or have been recombined into a dimer?

The answer may be that segregation of chromosomes starts soon after replication. If there has been no recombination, the two chromosomes move apart from one another. But the ability of the relevant sequences to move apart from one another may be constrained if a dimer has been formed. This forces them to remain in the vicinity of the septum, where they are exposed to the Xer system.

Bacteria that have the Xer system always have an FtsK homolog, and vice-versa,

which suggests that the system has evolved so that resolution is connected to the septum. FtsK is a large transmembrane protein. Its N-terminal domain is associated with the membrane, and causes it to be localized to the septum. Its C-terminal domain has two functions (2400). One is to causes Xer to resolve a dimer into two monomers. It also has an ATPase activity, which it can use to translocate along DNA *in vitro*. This could be used to pump DNA through the septum (in the same way that SpoIIIE transports DNA from the mother compartment into the prespore during sporulation (see *Molecular Biology 4.13.20 Partitioning involves separation of the chromosomes*).

## THE REPLICON

### 4.13.20 Partitioning involves separation of the chromosomes

---

#### Key Concepts

- Replicon origins may be attached to the inner bacterial membrane
  - Chromosomes make abrupt movements from the mid-center to the  $\frac{1}{4}$  and  $\frac{3}{4}$  positions.
- 

Partitioning is the process by which the two daughter chromosomes find themselves on either side of the position at which the septum forms. Two types of event are required for proper partitioning:

- The two daughter chromosomes must be released from one another so that they can segregate following termination. This requires disentangling of DNA regions that are coiled around each other in the vicinity of the terminus. Most mutations affecting partitioning map in genes coding for topoisomerases—enzymes with the ability to pass DNA strands through one another. The mutations prevent the daughter chromosomes from segregating, with the result that the DNA is located in a single large mass at midcell. Septum formation then releases an anucleate cell and a cell containing both daughter chromosomes. This tells us that the bacterium must be able to disentangle its chromosomes topologically in order to be able to segregate them into different daughter cells.
- Mutations that affect the partition process itself are rare. We expect to find two classes. *cis*-acting mutations should occur in DNA sequences that are the targets for the partition process. *trans*-acting mutations should occur in genes that code for the protein(s) that cause segregation, which could include proteins that bind to DNA or activities that control the locations on the envelope to which DNA might be attached. Both types of mutation have been found in the systems responsible for partitioning plasmids but only *trans*-acting functions have been found in the bacterial chromosome (for review see 115; 121). In addition, mutations in plasmid site-specific recombination systems increase plasmid loss (because the dividing cell has only one dimer to partition instead of two monomers), and therefore have a phenotype that is similar to partition mutants.

The original form of the model for chromosome segregation shown in **Figure 13.26** suggested that the envelope grows by insertion of material between the attachment sites of the two chromosomes, thus pushing them apart. But in fact the cell wall and membrane grow heterogeneously over the whole cell surface. Furthermore, the replicated chromosomes are capable of abrupt movements to their final positions at  $\frac{1}{4}$  and  $\frac{3}{4}$  cell length. If protein synthesis is inhibited before the termination of replication, the chromosomes fail to segregate and remain close to the midcell position. But when protein synthesis is allowed to resume, the chromosomes move to the quarter positions in the absence of any further envelope elongation. This suggests

that an active process, requiring protein synthesis, may move the chromosomes to specific locations (for review see 3126; 3125).

Segregation is interrupted by mutations of the *muk* class, which give rise to anucleate progeny at a much increased frequency: both daughter chromosomes remain on the same side of the septum instead of segregating. Mutations in the *muk* genes are not lethal, and may identify components of the apparatus that segregates the chromosomes. The gene *mukA* is identical with the gene for a known outer membrane protein (*tolC*), whose product could be involved with attaching the chromosome to the envelope. The gene *mukB* codes for a large (180 kD) globular protein, which has the same general type of organization as the two groups of SMC proteins that are involved in condensing and in holding together eukaryotic chromosomes (see *Molecular Biology* 5.23.18 *Chromosome condensation is caused by condensins*). SMC-like proteins have also been found in other bacteria. (MukB also has some sequence relationship to the mechanochemical enzyme dynamin, which provides a "motor" for microtubule-associated objects, but it is now thought that this is not significant.)

The insight into the role of MukB was the discovery that some mutations in *mukB* can be suppressed by mutations in *topA*, the gene coding for topoisomerase I (2461). This led to the model that the function of MukBEF proteins is to condense the nucleoid. A defect in this function is the cause of failure to segregate properly. The defect can be compensated by preventing topoisomerases from relaxing negative supercoils; the resulting increase in supercoil density helps to restore the proper state of condensation and thus to allow segregation.

We still do not understand how genomes are positioned in the cell, but the process may be connected with condensation. **Figure 13.35** shows a current model. The parental genome is centrally positioned. It must be decondensed in order to pass through the replication apparatus. The daughter chromosomes emerge from replication, are disentangled by topoisomerases, and then passed in an uncondensed state to MukBEF, which causes them to form condensed masses at the positions that will become the centers of the daughter cells.

**Figure 13.35** The DNA of a single parental nucleoid becomes decondensed during replication. MukB is an essential component of the apparatus that recondenses the daughter nucleoids. (After 2462.)

There have been suspicions for years that a physical link exists between bacterial

DNA and the membrane, but the evidence remains indirect. Bacterial DNA can be found in membrane fractions, which tend to be enriched in genetic markers near the origin, the replication fork, and the terminus. The proteins present in these membrane fractions may be affected by mutations that interfere with the initiation of replication. The growth site could be a structure on the membrane to which the origin must be attached for initiation (536).

During sporulation in *B. subtilis*, one daughter chromosome must be segregated into the small forespore compartment (see **Figure 9.41**). This is an unusual process that involves transfer of the chromosome across the nascent septum. One of the sporulation genes, *spoIIIE*, is required for this process. The SpoIIIE protein is located at the septum and is probably has a translocation function that pumps DNA through (2224; for review see 3448).

## THE REPLICON

### 4.13.21 Single-copy plasmids have a partitioning system

---

#### Key Terms

The **copy number** is the number of copies of a plasmid that is maintained in a bacterium (relative to the number of copies of the origin of the bacterial chromosome).

An **addiction system** is a survival mechanism used by plasmids. The mechanism kills the bacterium upon loss of the plasmid.

#### Key Concepts

- Single copy plasmids exist at one plasmid copy per bacterial chromosome origin.
- Multicopy plasmids exist at >1 plasmid copy per bacterial chromosome origin.
- Homologous recombination between circular plasmids generates dimers and higher multimers.
- Plasmids have site-specific recombination systems that undertake intramolecular recombination to regenerate monomers.
- Partition systems ensure that duplicate plasmids are segregated to different daughter cells produced by a division.

---

The type of system that a plasmid uses to ensure that it is distributed to both daughter cells at division depends upon its type of replication system. Each type of plasmid is maintained in its bacterial host at a characteristic **copy number**:

- Single-copy control systems resemble that of the bacterial chromosome and result in one replication per cell division. A single-copy plasmid effectively maintains parity with the bacterial chromosome.
- Multicopy control systems allow multiple initiation events per cell cycle, with the result that there are several copies of the plasmid per bacterium. Multicopy plasmids exist in a characteristic number (typically 10-20) per bacterial chromosome.

Copy number is primarily a consequence of the type of replication control mechanism. The system responsible for initiating replication determines how many origins can be present in the bacterium. Since each plasmid consists of a single replicon, the number of origins is the same as the number of plasmid molecules.

Single-copy plasmids have a system for replication control whose consequences are similar to that governing the bacterial chromosome. A single origin can be replicated once; then the daughter origins are segregated to the different daughter cells.

Multicopy plasmids have a replication system that allows a pool of origins to exist. If the number is great enough (in practice >10 per bacterium), an active segregation system becomes unnecessary, because even a statistical distribution of plasmids to daughter cells will result in the loss of plasmids at frequencies  $<10^{-6}$ .

Plasmids are maintained in bacterial populations with very low rates of loss ( $<10^{-7}$  per cell division is typical, even for a single-copy plasmid). The systems that control plasmid segregation can be identified by mutations that increase the frequency of loss, but that do not act upon replication itself. Several types of mechanism are used to ensure the survival of a plasmid in a bacterial population. It is common for a plasmid to carry several systems, often of different types, all acting independently to ensure its survival. Some of these systems act indirectly, while others are concerned directly with regulating the partition event. However, in terms of evolution, all serve the same purpose: to help ensure perpetuation of the plasmid to the maximum number of progeny bacteria.

Single-copy plasmids require partitioning systems to ensure that the duplicate copies find themselves on opposite sides of the septum at cell division, and are therefore segregated to a different daughter cell. In fact, functions involved in partitioning were first identified in plasmids. The components of a common system are summarized in **Figure 13.36**. Typically there are two *trans*-acting loci (*parA* and *parB*) and a *cis*-acting element (*parS*) located just downstream of the two genes. ParA is an ATPase. It binds to ParB, which binds to the *parS* site on DNA (3086). Deletions of any of the three loci prevent proper partition of the plasmid. Systems of this type have been characterized for the plasmids F, P1, and R1. In spite of their overall similarities, there are no significant sequence homologies between the corresponding genes or *cis*-acting sites (for review see 115; 3126; 3125).

**Figure 13.36** A common segregation system consists of genes *parA* and *parB* and the target site *parS*.

*parS* plays a role for the plasmid that is equivalent to the centromere in a eukaryotic cell. Binding of the ParB protein to it creates a structure that segregates the plasmid copies to opposite daughter cells. A bacterial protein, IHF, also binds at this site to form part of the structure (3087). The complex of ParB and IHF with *parS* is called the partition complex. *parS* is a 34 bp sequence containing the IHF-binding site flanked on either side by sequences called *boxA* and *boxB* that are bound by ParB.

IHF is the integration host factor, named for the role in which it was first discovered (forming a structure that is involved in the integration of phage lambda DNA into the

host chromosome). IHF is a heterodimer with has the capacity to form a large structure in which DNA is wrapped on the surface. The role of IHF is to bend the DNA so that ParB can bind simultaneously to the separated *boxA* and *boxB* sites, as indicated in **Figure 13.37**. Complex formation is initiated when *parS* is bound by a heterodimer of IHF together with a dimer of ParB (3088). This enables further dimers of ParB to bind cooperatively. The interaction of ParA with the partition complex structure is essential but transient.

**Figure 13.37** The partition complex is formed when IHF binds to DNA at *parS* and bends it so that ParB can bind to sites on either side. The complex is initiated by a heterodimer of IHF and a dimer of ParB, and then more ParB dimers bind.

The protein-DNA complex that assembles on IHF during phage lambda integration binds two DNA molecules to enable them to recombine (see *Molecular Biology 4.15.19 Lambda recombination occurs in an intasome*). The role of the partition complex is different: to ensure that two DNA molecules segregate apart from one another. We do not know yet how the formation of the individual complex accomplishes this task. One possibility is that it attaches the DNA to some physical site – for example, on the membrane – and then the sites of attachment are segregated by growth of the septum.

Proteins related to ParA and ParB are found in several bacteria. In *B. subtilis*, they are called Soj and SpoOJ, respectively. Mutations in these loci prevent sporulation, because of a failure to segregate one daughter chromosome into the forespore (see **Figure 9.42**). In sporulating cells, SpoOJ localizes at the pole and may be responsible for localizing the origin there. SpoOJ binds to a sequence that is present in multiple copies, dispersed over ~20% of the chromosome in the vicinity of the origin. It is possible that SpoOJ binds both old and newly synthesized origins, maintaining a status equivalent to chromosome pairing, until the chromosomes are segregated to the opposite poles. In *C. crescentus*, ParA and ParB localize to the poles of the bacterium, and ParB binds sequences close to the origin, thus localizing the origin to the pole. These results suggest that a specific apparatus is responsible for localizing the origin to the pole. The next stage of the analysis will be to identify the cellular components with which this apparatus interacts (547).

The importance to the plasmid of ensuring that all daughter cells gain replica plasmids is emphasized by the existence of multiple, independent systems in individual plasmids that ensure proper partition. **Addiction systems**, operating on the basis that "we hang together or we hang separately," ensure that a bacterium carrying a plasmid can survive only so long as it retains the plasmid. There are several ways

to ensure that a cell dies if it is "cured" of a plasmid, all sharing the principle illustrated in **Figure 13.38** that the plasmid produces both a poison and an antidote. The poison is a killer substance that is relatively stable, whereas the antidote consists of a substance that blocks killer action, but is relatively short lived. When the plasmid is lost, the antidote decays, and then the killer substance causes death of the cell. So bacteria that lose the plasmid inevitably die, and the population is condemned to retain the plasmid indefinitely. These systems take various forms. One specified by the F plasmid consists of killer and blocking proteins. The plasmid R1 has a killer that is the mRNA for a toxic protein, while the antidote is a small antisense RNA that prevents expression of the mRNA.

**Figure 13.38** Plasmids may ensure that bacteria cannot live without them by synthesizing a long-lived killer and a short-lived antidote.

## THE REPLICON

### 4.13.22 Plasmid incompatibility is determined by the replicon

---

#### Key Terms

A **compatibility group** of plasmids contains members unable to coexist in the same bacterial cell.

#### Key Concepts

- Plasmids in a single compatibility group have origins that are regulated by a common control system.

---

The phenomenon of plasmid incompatibility is related to the regulation of plasmid copy number and segregation. A **compatibility group** is defined as a set of plasmids whose members are unable to coexist in the same bacterial cell. The reason for their incompatibility is that they cannot be distinguished from one another at some stage that is essential for plasmid maintenance. DNA replication and segregation are stages at which this may apply (for review see 107; 109).

The negative control model for plasmid incompatibility follows the idea that copy number control is achieved by synthesizing a repressor that measures the concentration of origins. (Formally this is the same as the titration model for regulating replication of the bacterial chromosome.)

The introduction of a new origin in the form of a second plasmid of the same compatibility group mimics the result of replication of the resident plasmid; two origins now are present. So any further replication is prevented until after the two plasmids have been segregated to different cells to create the correct prereplication copy number as illustrated in **Figure 13.39**.

**Figure 13.39** Two plasmids are incompatible (they belong to the same compatibility group) if their origins cannot be distinguished at the stage of initiation. The same model could apply to segregation.

A similar effect would be produced if the system for segregating the products to daughter cells could not distinguish between two plasmids. For example, if two plasmids have the same *cis*-acting partition sites, competition between them would ensure that they would be segregated to different cells, and therefore could not survive in the same line.

The presence of a member of one compatibility group does not directly affect the survival of a plasmid belonging to a different group. Only one replicon of a given compatibility group (of a single-copy plasmid) can be maintained in the bacterium, but it does not interact with replicons of other compatibility groups.

**THE REPLICON****4.13.23 The ColE1 compatibility system is controlled by an RNA regulator**

---

**Key Terms**

A **countertranscript** is an RNA molecule that prevents an RNA primer from initiating transcription by base pairing with the primer.

**Key Concepts**

- Replication of ColE1 requires transcription to pass through the origin, where the transcript is cleaved by RNAaseH to generate a primer end.
- The regulator RNA I is a short antisense RNA that pairs with the transcript and prevents the cleavage that generates the priming end.
- The Rom protein enhances pairing between RNA I and the transcript.

---

The best characterized copy number and incompatibility system is that of the plasmid ColE1, a multicopy plasmid that is maintained at a steady level of ~20 copies per *E. coli* cell. The system for maintaining the copy number depends on the mechanism for initiating replication at the ColE1 origin, as illustrated in **Figure 13.40**.

**Figure 13.40** Replication of ColE1 DNA is initiated by cleaving the primer RNA to generate a 3' -OH end. The primer forms a persistent hybrid in the origin region.

Replication starts with the transcription of an RNA that initiates 555 bp upstream of the origin. Transcription continues through the origin. The enzyme RNAase H (whose name reflects its specificity for a substrate of RNA hybridized with DNA) cleaves the transcript at the origin. This generates a 3' -OH end that is used as the "primer" at which DNA synthesis is initiated (the use of primers is discussed in more detail in *Molecular Biology 4.14.8 Priming is required to start DNA synthesis*). The primer RNA forms a persistent hybrid with the DNA. Pairing between the RNA and DNA occurs just upstream of the origin (around position -20) and also farther upstream (around position -265).

Two regulatory systems exert their effects on the RNA primer. One involves synthesis of an RNA complementary to the primer; the other involves a protein coded by a nearby locus.

The regulatory species RNA I is a molecule of ~108 bases, coded by the opposite strand from that specifying primer RNA. The relationship between the primer RNA and RNA I is illustrated in **Figure 13.41**. The RNA I molecule is initiated within the primer region and terminates close to the site where the primer RNA initiates. So RNA I is complementary to the 5' -terminal region of the primer RNA. Base pairing between the two RNAs controls the availability of the primer RNA to initiate a cycle of replication (551; 552).

**Figure 13.41** The sequence of RNA I is complementary to the 5' region of primer RNA.

An RNA molecule such as RNA I that functions by virtue of its complementarity with another RNA coded in the same region is called a **countertranscript**. This type of mechanism, of course, is another example of the use of antisense RNA (see *Molecular Biology 3.11.19 Small RNA molecules can regulate translation*).

Mutations that reduce or eliminate incompatibility between plasmids can be obtained by selecting plasmids of the same group for their ability to coexist. Incompatibility mutations in ColE1 map in the region of overlap between RNA I and primer RNA. Because this region is represented in two different RNAs, either or both might be involved in the effect.

When RNA I is added to a system for replicating ColE1 DNA *in vitro*, it inhibits the formation of active primer RNA. But the presence of RNA I does not inhibit the initiation or elongation of primer RNA synthesis. This suggests that RNA I prevents RNAase H from generating the 3' end of the primer RNA. The basis for this effect lies in base pairing between RNA I and primer RNA.

Both RNA molecules have the same potential secondary structure in this region, with three duplex hairpins terminating in single-stranded loops. Mutations reducing incompatibility are located in these loops, which suggests that the initial step in base pairing between RNA I and primer RNA is contact between the unpaired loops.

How does pairing with RNA I prevent cleavage to form primer RNA? A model is illustrated in **Figure 13.42**. In the absence of RNA I, the primer RNA forms its own secondary structure (involving loops and stems). But when RNA I is present, the two molecules pair, and become completely double-stranded for the entire length of RNA I. The new secondary structure prevents the formation of the primer, probably by affecting the ability of the RNA to form the persistent hybrid.

**Figure 13.42** Base pairing with RNA I may change the secondary structure of the primer RNA sequence and thus prevent cleavage from generating a 3' -OH end.

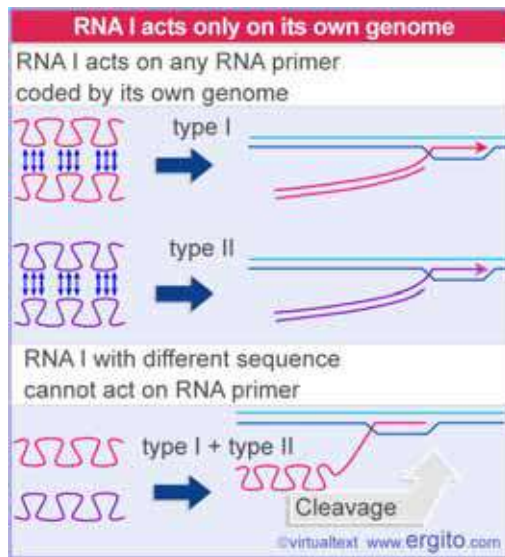

The model resembles the mechanism involved in attenuation of transcription, in which the alternative pairings of an RNA sequence permit or prevent formation of the secondary structure needed for termination by RNA polymerase (see *Molecular Biology 3.11.14 Alternative secondary structures control attenuation*). The action of RNA I is exercised by its ability to affect distant regions of the primer precursor.

Formally, the model is equivalent to postulating a control circuit involving two RNA species. A large RNA primer precursor is a positive regulator, needed to initiate replication. The small RNA I is a negative regulator, able to inhibit the action of the positive regulator.

In its ability to act on any plasmid present in the cell, RNA I provides a repressor that prevents newly introduced DNA from functioning, analogous to the role of the lambda lysogenic repressor (see *Molecular Biology 3.12.10 The repressor and its operators define the immunity region*). Instead of a repressor protein that binds the new DNA, an RNA binds the newly synthesized precursor to the RNA primer.

Binding between RNA I and primer RNA can be influenced by the Rom protein, coded by a gene located downstream of the origin. Rom enhances binding between RNA I and primer RNA transcripts of >200 bases. The result is to inhibit formation of the primer.

How do mutations in the RNAs affect incompatibility? **Figure 13.43** shows the situation when a cell contains two types of RNA I/primer RNA sequence. The RNA I and primer RNA made from each type of genome can interact, but RNA I from one genome does not interact with primer RNA from the other genome. This situation would arise when a mutation in the region that is common to RNA I and primer RNA occurred at a location that is involved in the base pairing between them. Each RNA I would continue to pair with the primer RNA coded by the same plasmid, but might be unable to pair with the primer RNA coded by the other plasmid. This would cause the original and the mutant plasmids to behave as members of different compatibility groups.

**Figure 13.43** Mutations in the region coding for RNA I and the primer precursor need not affect their ability to pair; but they may prevent pairing with the complementary RNA coded by a different plasmid.

## THE REPLICON

### 4.13.24 How do mitochondria replicate and segregate?

---

#### Key Concepts

- mtDNA replication and segregation to daughter mitochondria is stochastic.
  - Mitochondrial segregation to daughter cells is also stochastic.
- 

Mitochondria must be duplicated during the cell cycle and segregated to the daughter cells. We understand some of the mechanics of this process, but not its regulation.

At each stage in the duplication of mitochondria – DNA replication, DNA segregation to duplicate mitochondria, organelle segregation to daughter cells – the process appears to be stochastic, governed by a random distribution of each copy (for review see 2288). The theory of distribution in this case is analogous that of multicopy bacterial plasmids, with the same conclusion that >10 copies are required to ensure that each daughter gains at least one copy (see *Molecular Biology 4.13.21 Single-copy plasmids have a partitioning system*). When there are mtDNAs with allelic variations (either because of inheritance from different parents or because of mutation), the stochastic distribution may generate cells that have only one of the alleles.

Replication of mtDNA may be stochastic because there is no control over which particular copies are replicated, so that in any cycle some mtDNA molecules may replicate more times than others. The total number of copies of the genome may be controlled by titrating mass in a way similar to bacteria (see *Molecular Biology 4.13.14 Replication is connected to the cell cycle*).

A mitochondrion divides by developing a ring around the organelle that constricts to pinch it into two halves. The mechanism is similar in principle to that involved in bacterial division. The apparatus that is used in plant cell mitochondria is similar to bacteria and uses a homologue of the bacterial protein FtsZ (see *Molecular Biology 4.13.17 FtsZ is necessary for septum formation*). The molecular apparatus is different in animal cell mitochondria, and uses the protein dynamin that is involved in formation of membranous vesicles (see *Molecular Biology 6.27.5 Different types of coated vesicles exist in each pathway*). An individual organelle may have more than one copy of its genome.

We do not know whether there is a partitioning mechanism for segregating mtDNA molecules within the mitochondrion, or whether they are simply inherited by daughter mitochondria according to which half of the mitochondrion they happen to lie in. **Figure 13.44** shows that the combination of replication and segregation mechanisms can result in a stochastic assignment of DNA to each of the copies, that is, so that the distribution of mitochondrial genomes to daughter mitochondria does not depend on their parental origins.

**Figure 13.44** Mitochondrial DNA replicates by increasing the number of genomes in proportion to mitochondrial mass, but without ensuring that each genome replicates the same number of times. This can lead to changes in the representation of alleles in the daughter mitochondria.

The assignment of mitochondria to daughter cells at mitosis also appears to be random. Indeed, it was the observation of somatic variation in plants that first suggested the existence of genes that could be lost from one of the daughter cells because they were not inherited according to Mendel's laws (see **Figure 3.37**).

In some situations a mitochondrion has both paternal and maternal alleles. This has two requirements: that both parents provide alleles to the zygote (which of course is not the case when there is maternal inheritance; see *Molecular Biology 1.3.19 Organelles have DNA*); and that the parental alleles are found in the same mitochondrion. For this to happen, parental mitochondria must have fused.

The size of the individual mitochondrion may not be precisely defined. Indeed, there is a continuing question as to whether an individual mitochondrion represents a unique and discrete copy of the organelle or whether it is in a dynamic flux in which it can fuse with other mitochondria. We know that mitochondria can fuse in yeast, because recombination between mtDNAs can occur after two haploid yeast strains

have mated to produce a diploid strain. This implies that the two mtDNAs must have been exposed to one another in the same mitochondrial compartment. Attempts have been made to test for the occurrence of similar events in animal cells by looking for complementation between alleles after two cells have been fused, but the results are not clear.

## THE REPLICON

### 4.13.25 Summary

---

The entire chromosome is replicated once for every cell division cycle. Initiation of replication commits the cell to a cycle of division; completion of replication may provide a trigger for the actual division process. The bacterial chromosome consists of a single replicon, but a eukaryotic chromosome is divided into many replicons that function over the protracted period of S phase. The problem of replicating the ends of a linear replicon is solved in a variety of ways, most often by converting the replicon to a circular form. Some viruses have special proteins that recognize ends. Eukaryotic chromosomes encounter the problem at their terminal replicons.

Eukaryotic replication is (at least) an order of magnitude slower than bacterial replication. Origins sponsor bidirectional replication, and are probably used in a fixed order during S phase. The only eukaryotic origins identified at the sequence level are those of *S. cerevisiae*, which have a core consensus sequence consisting of 11 base pairs, mostly A·T.

The minimal *E. coli* origin consists of ~245 bp and initiates bidirectional replication. Any DNA molecule with this sequence can replicate in *E. coli*. Two replication forks leave the origin and move around the chromosome, apparently until they meet, although *ter* sequences that would cause the forks to terminate after meeting have been identified. Transcription units are organized so that transcription usually proceeds in the same direction as replication.

The rolling circle is an alternative form of replication for circular DNA molecules in which an origin is nicked to provide a priming end. One strand of DNA is synthesized from this end, displacing the original partner strand, which is extruded as a tail. Multiple genomes can be produced by continuing revolutions of the circle.

Rolling circles are used to replicate some phages. The A protein that nicks the  $\phi$ X174 origin has the unusual property of *cis*-action. It acts only on the DNA from which it was synthesized. It remains attached to the displaced strand until an entire strand has been synthesized, and then nicks the origin again, releasing the displaced strand and starting another cycle of replication.

Rolling circles also are involved in bacterial conjugation, when an F plasmid is transferred from a donor to a recipient cell, following the initiation of contact between the cells by means of the F-pili. A free F plasmid infects new cells by this means; an integrated F factor creates an Hfr strain that may transfer chromosomal DNA. In the case of conjugation, replication is used to synthesize complements to the single strand remaining in the donor and to the single strand transferred to the recipient, but does not provide the motive power.

A fixed time of 40 minutes is required to replicate the *E. coli* chromosome and a further 20 minutes is required before the cell can divide. When cells divide more rapidly than every 60 minutes, a replication cycle is initiated before the end of the preceding division cycle. This generates multiforked chromosomes. The initiation

event depends on titration of cell mass, probably by accumulating an initiator protein. Initiation may occur at the cell membrane, since the origin is associated with the membrane for a short period after initiation.

The septum that divides the cell grows at a location defined by the pre-existing periseptal annulus; a locus of three genes (*minCDE*) codes for products that regulate whether the midcell periseptal annulus or the polar sites derived from previous annuli are used for septum formation. Absence of septum formation generates multinucleated filaments; excess of septum formation generates anucleate minicells.

Many transmembrane proteins interact to form the septum. ZipA is located in the inner bacterial membrane and binds to FtsZ, which is a tubulin-like protein that can polymerize into a filamentous structure called a Z-ring. FtsA is a cytosolic protein that binds to FtsZ. Several other *fts* products, all transmembrane proteins, join the Z-ring in an ordered process that generates a septal ring. The last proteins to bind are the SEDS protein FtsW and the transpeptidase ftsI (PBP3), which together function to produce the peptidoglycans of the septum. Chloroplasts use a related division mechanism that has an FtsZ-like protein, but mitochondria use a different process in which the membrane is constricted by a dynamin-like protein.

Plasmids and bacteria have site-specific recombination systems that regenerate pairs of monomers by resolving dimers created by general recombination. The Xer system acts on a target sequence located in the terminus region of the chromosome. The system is active only in the presence of the FtsK protein of the septum, which may ensure that it acts only when a dimer needs to be resolved.

Partitioning involves the interaction of the ParB protein with the *parS* target site to build a structure that includes the IHF protein. This partition complex ensures that replica chromosomes segregate into different daughter cells. The mechanism of segregation may involve movement of DNA, possibly by the action of MukB in condensing chromosomes into masses at different locations as they emerge from replication.

Plasmids have a variety of systems that ensure or assist partition, and an individual plasmid may carry systems of several types. The copy number of a plasmid describes whether it is present at the same level as the bacterial chromosome (one per unit cell) or in greater numbers. Plasmid incompatibility can be a consequence of the mechanisms involved in either replication or partition (for single-copy plasmids). Two plasmids that share the same control system for replication are incompatible because the number of replication events ensures that there is only one plasmid for each bacterial genome.

*This content is available online at <http://www.ergito.com/main.jsp?bcs=MBIO.4.13.25>*

## DNA REPLICATION

### 4.14.1 Introduction

---

#### Key Terms

The **replisome** is the multiprotein structure that assembles at the bacterial replicating fork to undertake synthesis of DNA. It contains DNA polymerase and other enzymes.

A **dna mutant** of bacteria is temperature-sensitive; it cannot synthesize DNA at 42°C, but can do so at 37°C.

A **quick-stop mutant** is a type of DNA replication temperature-sensitive mutant (*dna*) in *E. coli* that immediately stops DNA replication when the temperature is increased to 42°C.

A **slow-stop mutant** is a type of DNA replication temperature-sensitive mutant in *E. coli* that can finish a round of replication at the unpermissive temperature, but cannot start another.

**In vitro complementation** is a functional assay used to identify components of a process. The reaction is reconstructed using extracts from a mutant cell. Fractions from wild-type cells are then tested for restoration of activity.

---

Replication of duplex DNA is a complex endeavor involving a conglomerate of enzyme activities. Different activities are involved in the stages of initiation, elongation, and termination.

- Initiation involves recognition of an origin by a complex of proteins. Before DNA synthesis begins, the parental strands must be separated and (transiently) stabilized in the single-stranded state. Then synthesis of daughter strands can be initiated at the replication fork.
- Elongation is undertaken by another complex of proteins. The **replisome** exists only as a protein complex associated with the particular structure that DNA takes at the replication fork. It does not exist as an independent unit (for example, analogous to the ribosome). As the replisome moves along DNA, the parental strands unwind and daughter strands are synthesized.
- At the end of the replicon, joining and/or termination reactions are necessary. Following termination, the duplicate chromosomes must be separated from one another, which requires manipulation of higher-order DNA structure.

Inability to replicate DNA is fatal for a growing cell. Mutants in replication must therefore be obtained as conditional lethals. These are able to accomplish replication under permissive conditions (provided by the normal temperature of incubation), but they are defective under nonpermissive conditions (provided by the higher temperature of 42°C). A comprehensive series of such temperature-sensitive mutants in *E. coli* identifies a set of loci called the *dna* genes. The **dna mutants** distinguish two stages of replication by their behavior when the temperature is raised (545):

- The major class of **quick-stop mutants** cease replication immediately on a temperature rise. They are defective in the components of the replication apparatus, typically in the enzymes needed for elongation (but also include defects in the supply of essential precursors).
- The smaller class of **slow-stop mutants** complete the current round of replication, but cannot start another. They are defective in the events involved in initiating a cycle of replication at the origin.

An important assay used to identify the components of the replication apparatus is called ***in vitro* complementation**. An *in vitro* system for replication is prepared from a *dna* mutant and operated under conditions in which the mutant gene product is inactive. Extracts from wild-type cells are tested for their ability to restore activity. The protein coded by the *dna* locus can be purified by identifying the active component in the extract.

Each component of the bacterial replication apparatus is now available for study *in vitro* as a biochemically pure product, and is implicated *in vivo* by mutations in its gene. Eukaryotic replication systems are highly purified, and usually have components analogous to the bacterial proteins, but have not necessarily reached the stage of identification of every single component.

## DNA REPLICATION

### 4.14.2 DNA polymerases are the enzymes that make DNA

---

#### Key Terms

**Replication** of duplex DNA takes place by synthesis of two new strands that are complementary to the parental strands. The parental duplex is replaced by two identical daughter duplexes, each of which has one parental strand and one newly synthesized strand. Replication is called semiconservative because the conserved units are the single strands of the parental duplex.

**Repair** of damaged DNA can take place by repair synthesis, when a strand that has been damaged is excised and replaced by the synthesis of a new stretch. It can also take place by recombination reactions, when the duplex region containing the damaged is replaced by an undamaged region from another copy of the genome.

A **DNA polymerase** is an enzyme that synthesizes a daughter strand(s) of DNA (under direction from a DNA template). Any particular enzyme may be involved in repair or replication (or both).

A **DNA replicase** is a DNA-synthesizing enzyme required specifically for replication.

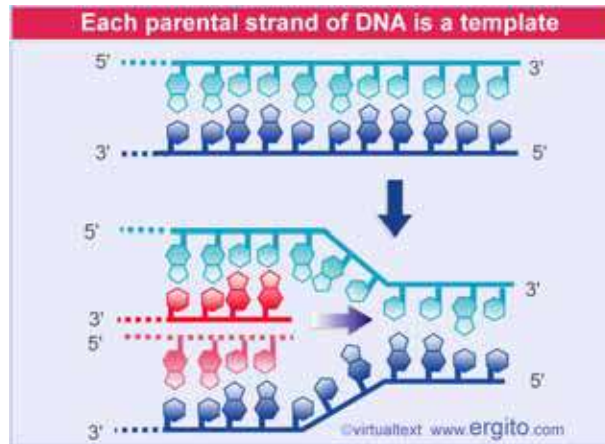

#### Key Concepts

- DNA is synthesized in both semiconservative replication and repair reactions.
- A bacterium or eukaryotic cell has several different DNA polymerase enzymes.
- One bacterial DNA polymerase undertakes semiconservative replication; the others are involved in repair reactions.
- Eukaryotic nuclei, mitochondria, and chloroplasts each have a single unique DNA polymerase required for replication, and other DNA polymerases involved in ancillary or repair activities.

---

There are two basic types of DNA synthesis.

**Figure 14.1** shows the result of semiconservative **replication**. The two strands of the parental duplex are separated, and each serves as a template for synthesis of a new strand. The parental duplex is replaced with two daughter duplexes, each of which has one parental strand and one newly synthesized strand.

**Figure 14.1** Semiconservative replication synthesizes two new strands of DNA.

**Figure 14.2** shows the consequences of a **repair** reaction. One strand of DNA has been damaged. It is excised and new material is synthesized to replace it. (Repair synthesis is not the only way to replace damaged DNA; the reactions involved in replacement of damaged sequences are discussed in *Molecular Biology 4.15 Recombination and repair*.)

**Figure 14.2** Repair synthesis replaces a short stretch of one strand of DNA containing a damaged base.

An enzyme that can synthesize a new DNA strand on a template strand is called a **DNA polymerase**. Both prokaryotic and eukaryotic cells contain multiple DNA polymerase activities. Only some of these enzymes actually undertake replication; sometimes they are called **DNA replicases**. The others are involved in subsidiary roles in replication and/or participate in repair synthesis.

All prokaryotic and eukaryotic DNA polymerases share the same fundamental type of synthetic activity. Each can extend a DNA chain by adding nucleotides one at a time to a 3' –OH end, as illustrated diagrammatically in **Figure 14.3**. The choice of the nucleotide to add to the chain is dictated by base pairing with the template strand.

**Figure 14.3** DNA synthesis occurs by adding nucleotides to the 3' -OH end of the growing chain, so that the new chain grows in the 5' → 3' direction. The precursor for DNA synthesis is a nucleoside triphosphate, which loses the terminal two phosphate groups in the reaction.

Some DNA polymerases function as independent enzymes, but others (most notably the replicases) are incorporated into large protein assemblies. The DNA-synthesizing subunit is only one of several functions of the replicase, which typically contains many other activities concerned with unwinding DNA, initiating new strand synthesis, and so on.

**Figure 14.4** summarizes the DNA polymerases that have been characterized in *E. coli*. DNA polymerase III, a multisubunit protein, is the replicase responsible for *de novo* synthesis of new strands of DNA. DNA polymerase I (coded by *polA*) is involved in the repair of damaged DNA and, in a subsidiary role, in semiconservative replication. DNA polymerase II is required to restart a replication fork when its progress is blocked by damage in DNA. DNA polymerases IV and V are involved in allowing replication to bypass certain types of damage.

E. coli has 5 DNA polymerases		
Enzyme	Gene	Function
I	<i>polA</i>	major repair enzyme
II	<i>polB</i>	replication restart
III	<i>polC</i>	replicase
IV	<i>dinB</i>	translesion replication
V	<i>umuD<sub>2</sub>C</i>	translesion replication

©virtualtext www.ergito.com

**Figure 14.4** Only one DNA polymerase is the replicase. The others participate in repair of damaged DNA, restarting stalled replication forks, or bypassing damage in DNA.

When extracts of *E. coli* are assayed for their ability to synthesize DNA, the predominant enzyme activity is DNA polymerase I. Its activity is so great that it makes it impossible to detect the activities of the enzymes actually responsible for DNA replication! To develop *in vitro* systems in which replication can be followed, extracts are therefore prepared from *polA* mutant cells.

Some phages code for DNA polymerases. They include T4, T5, T7, and SPO1. The enzymes all possess 5'–3' synthetic activities and 3'–5' exonuclease proofreading activities (see *Molecular Biology 4.14.3 DNA polymerases have various nuclease activities*). In each case, a mutation in the gene that codes for a single phage polypeptide prevents phage development. Each phage polymerase polypeptide associates with other proteins, of either phage or host origin, to make the intact enzyme.

Several classes of eukaryotic DNA polymerases have been identified. DNA polymerases  $\delta$  and  $\epsilon$  are required for nuclear replication; DNA polymerase  $\alpha$  is concerned with "priming" (initiating) replication. Other DNA polymerases are involved in repairing damaged nuclear DNA ( $\beta$  and also  $\epsilon$ ) or with mitochondrial DNA replication ( $\gamma$ ).

---

## DNA REPLICATION

### 4.14.3 DNA polymerases have various nuclease activities

---

#### Key Terms

**Nick translation** describes the ability of *E. coli* DNA polymerase I to use a nick as a starting point from which one strand of a duplex DNA can be degraded and replaced by resynthesis of new material; is used to introduce radioactively labeled nucleotides into DNA *in vitro*.

#### Key Concepts

- DNA polymerase I has a unique 5'–3' exonuclease activity that can be combined with DNA synthesis to perform nick translation.

---

Replicases often have nuclease activities as well as the ability to synthesize DNA. A 3'–5' exonuclease activity is typically used to excise bases that have been added to DNA incorrectly. This provides a "proofreading" error-control system (see *Molecular Biology 4.14.4 DNA polymerases control the fidelity of replication*).

The first DNA-synthesizing enzyme to be characterized was DNA polymerase I, which is a single polypeptide of 103 kD. The chain can be cleaved into two parts by proteolytic treatment. The C-terminal two-thirds of the protein contains the polymerase active site, while the N-terminal third contains the proofreading exonuclease.

The larger cleavage product (68 kD) is called the Klenow fragment. It is used in synthetic reactions *in vitro*. It contains the polymerase and the 3'–5' exonuclease activities. The active sites are ~30 Å apart in the protein, indicating that there is spatial separation between adding a base and removing one.

The small fragment (35 kD) possesses a 5'–3' exonucleolytic activity, which excises small groups of nucleotides, up to ~10 bases at a time. This activity is coordinated with the synthetic/proofreading activity. It provides DNA polymerase I with a unique ability to start replication *in vitro* at a nick in DNA. (No other DNA polymerase has this ability.) At a point where a phosphodiester bond has been broken in a double-stranded DNA, the enzyme extends the 3'–OH end. As the new segment of DNA is synthesized, it displaces the existing homologous strand in the duplex.

This process of **nick translation** is illustrated in **Figure 14.5**. The displaced strand is degraded by the 5'–3' exonucleolytic activity of the enzyme. The properties of the DNA are unaltered, except that a segment of one strand has been replaced with newly synthesized material, and the position of the nick has been moved along the duplex. This is of great practical use; nick translation has been a major technique for introducing radioactively labeled nucleotides into DNA *in vitro*.

**Figure 14.5** Nick translation replaces part of a pre-existing strand of duplex DNA with newly synthesized material.

The 5' → 3' synthetic/3' → 5' exonucleolytic action is probably used *in vivo* mostly for filling in short single-stranded regions in double-stranded DNA. These regions arise during replication, and also when bases that have been damaged are removed from DNA (see *Molecular Biology 4.15 Recombination and repair*).

This content is available online at <http://www.ergito.com/main.jsp?bcs=MBIO.4.14.3>

## DNA REPLICATION

### 4.14.4 DNA polymerases control the fidelity of replication

---

#### Key Terms

**Processivity** describes the ability of an enzyme to perform multiple catalytic cycles with a single template instead of dissociating after each cycle.

**Proofreading** refers to any mechanism for correcting errors in protein or nucleic acid synthesis that involves scrutiny of individual units *after* they have been added to the chain.

#### Key Concepts

- DNA polymerases often have a 3'–5' exonuclease activity that is used to excise incorrectly paired bases.
- The fidelity of replication is improved by proofreading by a factor of ~100.

---

The fidelity of replication poses the same sort of problem we have encountered already in considering (for example) the accuracy of translation. It relies on the specificity of base pairing. Yet when we consider the interactions involved in base pairing, we would expect errors to occur with a frequency of  $\sim 10^{-3}$  per base pair replicated. The actual rate in bacteria seems to be  $\sim 10^{-8}$ - $10^{-10}$ . This corresponds to  $\sim 1$  error per genome per 1000 bacterial replication cycles, or  $\sim 10^{-6}$  per gene per generation.

We can divide the errors that DNA polymerase makes during replication into two classes.

- Frameshifts occur when an extra nucleotide is inserted or omitted. Fidelity with regard to frameshifts is affected by the **processivity** of the enzyme: the tendency to remain on a single template rather than to dissociate and reassociate. This is particularly important for the replication of a homopolymeric stretch, for example, a long sequence of  $dT_n:dA_n$ , in which "replication slippage" can change the length of the homopolymeric run. As a general rule, increased processivity reduces the likelihood of such events. In multimeric DNA polymerases, processivity is usually increased by a particular subunit that is not needed for catalytic activity *per se*.
- Substitutions occur when the wrong (improperly paired) nucleotide is incorporated. The error level is determined by the efficiency of **proofreading**, in which the enzyme scrutinizes the newly formed base pair and removes the nucleotide if it is mispaired.

All of the bacterial enzymes possess a 3'–5' exonucleolytic activity that proceeds in the reverse direction from DNA synthesis. This provides the proofreading function

illustrated diagrammatically in **Figure 14.6**. In the chain elongation step, a precursor nucleotide enters the position at the end of the growing chain. A bond is formed. The enzyme moves one base pair farther, ready for the next precursor nucleotide to enter. If a mistake has been made, however, the enzyme uses the exonucleolytic activity to excise the last base that was added.

**Figure 14.6** Bacterial DNA polymerases scrutinize the base pair at the end of the growing chain and excise the nucleotide added in the case of a misfit.

Different DNA polymerases handle the relationship between the polymerizing and proofreading activities in different ways. In some cases, the activities are part of the same protein subunit, but in others they are contained in different subunits. Each DNA polymerase has a characteristic error rate that is reduced by its proofreading activity. Proofreading typically decreases the error rate in replication from  $\sim 10^{-5}$  to  $\sim 10^{-7}$  per base pair replicated. Systems that recognize errors and correct them following replication then eliminate some of the errors, bringing the overall rate to  $< 10^{-9}$  per base pair replicated (see *Molecular Biology 4.15.24 Controlling the*

*direction of mismatch repair* ).

The replicase activity of DNA polymerase III was originally discovered by a lethal mutation in the *dnaE* locus, which codes for the 130 kD  $\alpha$  subunit that possesses the DNA synthetic activity. The 3'–5' exonucleolytic proofreading activity is found in another subunit,  $\epsilon$ , coded by *dnaQ*. The basic role of the  $\epsilon$  subunit in controlling the fidelity of replication *in vivo* is demonstrated by the effect of mutations in *dnaQ*: the frequency with which mutations occur in the bacterial strain is increased by  $>10^3$ -fold.

## DNA REPLICATION

### 4.14.5 DNA polymerases have a common structure

#### Key Concepts

- Many DNA polymerases have a large cleft composed of three domains that resemble a hand.
- DNA lies across the "palm" in a groove created by the "fingers" and "thumb".

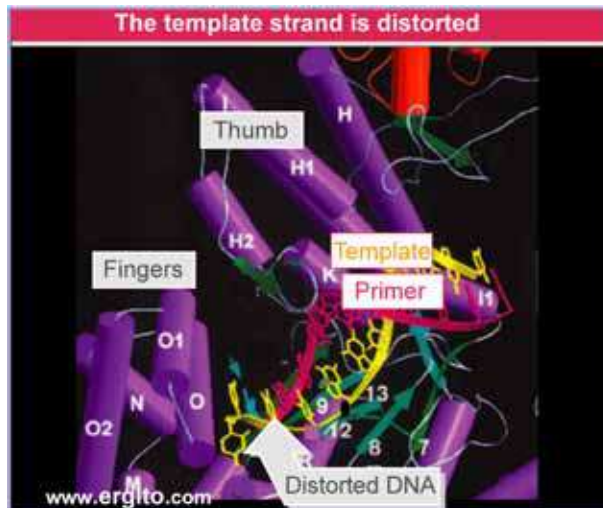

**Figure 14.7** shows that all DNA polymerases share some common structural features (3091; 3092). The enzyme structure can be divided into several independent domains, which are described by analogy with a human right hand. DNA binds in a large cleft composed of three domains. The "palm" domain has important conserved sequence motifs that provide the catalytic active site. The "fingers" are involved in positioning the template correctly at the active site. The "thumb" binds the DNA as it exits the enzyme, and is important in processivity. The most important conserved regions of each of these three domains converge to form a continuous surface at the catalytic site. The exonuclease activity resides in an independent domain with its own catalytic site. The N-terminal domain extends into the nuclease domain. DNA polymerases fall into five families based on sequence homologies; the palm is well conserved among them, but the thumb and fingers provide analogous secondary structure elements from different sequences.

**Figure 14.7** The common organization of DNA polymerases has a palm that contains the catalytic site, fingers that position the template, a thumb that binds DNA and is important in processivity, an exonuclease domain with its own active site, and an N-terminal domain.

The catalytic reaction in a DNA polymerase occurs at an active site in which a nucleotide triphosphate pairs with an (unpaired) single strand of DNA. The DNA lies

across the palm in a groove that is created by the thumb and fingers. **Figure 14.8** shows the crystal structure of the T7 enzyme complexed with DNA (in the form of a primer annealed to a template strand) and an incoming nucleotide that is about to be added to the primer. The DNA is in the classic B-form duplex up to the last 2 base pairs at the 3' end of the primer, which are in the more open A-form. A sharp turn in the DNA exposes the template base to the incoming nucleotide. The 3' end of the primer (to which bases are added) is anchored by the fingers and palm. The DNA is held in position by contacts that are made principally with the phosphodiester backbone (thus enabling the polymerase to function with DNA of any sequence).

**Figure 14.8** The crystal structure of phage T7 DNA polymerase shows that the template strand takes a sharp turn in order to be exposed to the incoming nucleotide. Photograph kindly provided by Charles Richardson and Tom Ellenberger (see 3748).

In structures of DNA polymerases of this family complexed only with DNA (that is, lacking the incoming nucleotide), the orientation of the fingers and thumb relative to the palm is more open, with the O helix (O, O1, O2; see **Figure 14.8**) rotated away from the palm. This suggests that an inward rotation of the O helix occurs to grasp the incoming nucleotide and create the active catalytic site. When a nucleotide binds, the fingers domain rotates 60° toward the palm, with the tops of the fingers moving by 30 Å. The thumb domain also rotates toward the palm by 8°. These changes are cyclical: they are reversed when the nucleotide is incorporated into the DNA chain, which then translocates through the enzyme to recreate an empty site.

The exonuclease activity is responsible for removing mispaired bases. But the catalytic site of the exonuclease domain is distant from the active site of the catalytic domain. The enzyme alternates between polymerizing and editing modes, as determined by a competition between the two active sites for the 3' primer end of the DNA (3093). Amino acids in the active site contact the incoming base in such a way that the enzyme structure is affected by a mismatched base. When a mismatched base pair occupies the catalytic site, the fingers cannot rotate toward the palm to bind the incoming nucleotide. This leaves the 3' end free to bind to the active site in the exonuclease domain, which is accomplished by a rotation of the DNA in the enzyme structure (3094).

## DNA REPLICATION

### 4.14.6 DNA synthesis is semidiscontinuous

---

#### Key Terms

The **leading strand** of DNA is synthesized continuously in the 5'–3' direction.

The **lagging strand** of DNA must grow overall in the 3'–5' direction and is synthesized discontinuously in the form of short fragments (5'–3') that are later connected covalently.

**Okazaki fragments** are the short stretches of 1000–2000 bases produced during discontinuous replication; they are later joined into a covalently intact strand.

**Semidiscontinuous replication** is mode in which one new strand is synthesized continuously while the other is synthesized discontinuously.

#### Key Concepts

- The DNA replicase advances continuously when it synthesizes the leading strand (5'–3'), but synthesizes the lagging strand by making short fragments that are subsequently joined together.

---

The antiparallel structure of the two strands of duplex DNA poses a problem for replication. As the replication fork advances, daughter strands must be synthesized on both of the exposed parental single strands. The fork moves in the direction from 5'–3' on one strand, and in the direction from 3'–5' on the other strand. Yet nucleic acids are synthesized only from a 5' end toward a 3' end. The problem is solved by synthesizing the strand that grows overall from 3'–5' in a series of short fragments, each actually synthesized in the "backwards" direction, that is, with the customary 5'–3' polarity.

Consider the region immediately behind the replication fork, as illustrated in **Figure 14.9**. We describe events in terms of the different properties of each of the newly synthesized strands:

**Figure 14.9** The leading strand is synthesized continuously while the lagging strand is synthesized discontinuously.

- On the **leading strand** DNA synthesis can proceed continuously in the 5' to 3' direction as the parental duplex is unwound.
- On the **lagging strand** a stretch of single-stranded parental DNA must be exposed, and then a segment is synthesized in the reverse direction (relative to fork movement). A series of these fragments are synthesized, each 5'–3'; then they are joined together to create an intact lagging strand.

Discontinuous replication can be followed by the fate of a very brief label of radioactivity. The label enters newly synthesized DNA in the form of short fragments, sedimenting in the range of 7-11S, corresponding to ~1000-2000 bases in length. These **Okazaki fragments** are found in replicating DNA in both prokaryotes and eukaryotes. After longer periods of incubation, the label enters larger segments of DNA. The transition results from covalent linkages between Okazaki fragments.

(The lagging strand *must* be synthesized in the form of Okazaki fragments. For a long time it was unclear whether the leading strand is synthesized in the same way or is synthesized continuously. All newly synthesized DNA is found as short fragments in *E. coli*. Superficially, this suggests that both strands are synthesized discontinuously. However, it turns out that not all of the fragment population represents *bona fide* Okazaki fragments; some are pseudofragments, generated by breakage in a DNA strand that actually was synthesized as a continuous chain. The source of this breakage is the incorporation of some uracil into DNA in place of thymine. When the uracil is removed by a repair system, the leading strand has breaks until a thymine is inserted.)

So the lagging strand is synthesized discontinuously and the leading strand is synthesized continuously. This is called **semidiscontinuous replication**.

This content is available online at <http://www.ergito.com/main.jsp?bcs=MBIO.4.14.6>

## DNA REPLICATION

### 4.14.7 The $\phi$ X model system shows how single-stranded DNA is generated for replication

---

#### Key Terms

A **helicase** is an enzyme that uses energy provided by ATP hydrolysis to separate the strands of a nucleic acid duplex.

The **single-strand binding protein (SSB)** attaches to single-stranded DNA, thereby preventing the DNA from forming a duplex.

#### Key Concepts

- Replication requires a helicase to separate the strands of DNA using energy provided by hydrolysis of ATP.
- A single-strand binding protein is required to maintain the separated strands.
- The combination of helicase, SSB, and A protein separates a  $\phi$ X174 duplex into a single-stranded circle and a single-stranded linear strand.

---

As the replication fork advances, it unwinds the duplex DNA. One of the template strands is rapidly converted to duplex DNA as the leading daughter strand is synthesized. The other remains single-stranded until a sufficient length has been exposed to initiate synthesis of an Okazaki fragment of the lagging strand in the backward direction. The generation and maintenance of single-stranded DNA is therefore a crucial aspect of replication. Two types of function are needed to convert double-stranded DNA to the single-stranded state:

- A **helicase** is an enzyme that separates the strands of DNA, usually using the hydrolysis of ATP to provide the necessary energy.
- A **single-strand binding protein (SSB)** binds to the single-stranded DNA, preventing it from reforming the duplex state. The SSB binds as a monomer, but typically in a cooperative manner in which the binding of additional monomers to the existing complex is enhanced.

Helicases separate the strands of a duplex nucleic acid in a variety of situations, ranging from strand separation at the growing point of a replication fork to catalyzing migration of Holliday (recombination) junctions along DNA. There are 12 different helicases in *E. coli*. A helicase is generally multimeric. A common form of helicase is a hexamer (1195). This typically translocates along DNA by using its multimeric structure to provide multiple DNA-binding sites.

**Figure 14.10** shows a generalized schematic model for the action of a hexameric helicase. It is likely to have one conformation that binds to duplex DNA and another that binds to single-stranded DNA. Alternation between them drives the motor that

melts the duplex, and requires ATP hydrolysis – typically 1 ATP is hydrolyzed for each base pair that is unwound (1194). A helicase usually initiates unwinding at a single-stranded region adjacent to a duplex, and may function with a particular polarity, preferring single-stranded DNA with a 3' end (3'–5' helicase) or with a 5' end (5'–3' helicase).

**Figure 14.10** A hexameric helicase moves along one strand of DNA. It probably changes conformation when it binds to the duplex, uses ATP hydrolysis to separate the strands, and then returns to the conformation it has when bound only to a single strand.

The conversion of  $\phi$ X174 double-stranded DNA into individual single strands illustrates the features of the strand separation process. **Figure 14.11** shows that a single strand is peeled off the circular strand, resembling the rolling circle described previously in **Figure 13.16**. The reaction can occur in the absence of DNA synthesis when the appropriate 3 proteins are provided *in vitro*.

**Figure 14.11**  $\phi$  X174 DNA can be separated into single strands by the combined effects of 3 functions: nicking with A protein, unwinding by Rep, and single-strand stabilization by SSB.

The phage A protein nicks the viral (+) strand at the origin of replication. In the presence of 2 host proteins, Rep and SSB, and ATP, the nicked DNA unwinds. The Rep protein provides a helicase that separates the strands; the SSB traps them in single-stranded form. The *E. coli* SSB is a tetramer of 74 kD that binds cooperatively to single-stranded DNA.

The significance of the cooperative mode of binding is that the binding of one protein molecule makes it much easier for another to bind. So once the binding reaction has started on a particular DNA molecule, it is rapidly extended until all of the single-stranded DNA is covered with the SSB protein. Note that this protein is not a DNA-unwinding protein; its function is to stabilize DNA that is already in the single-stranded condition.

Under normal circumstances *in vivo*, the unwinding, coating, and replication

reactions proceed in tandem. The SSB binds to DNA as the replication fork advances, keeping the two parental strands separate so that they are in the appropriate condition to act as templates. SSB is needed in stoichiometric amounts at the replication fork. It is required for more than one stage of replication; *ssb* mutants have a quick-stop phenotype, and are defective in repair and recombination as well as in replication. (Some phages use different SSB proteins, notably T4; this shows that there may be specific interactions between components of the replication apparatus and the SSB; see *Molecular Biology 4.14.14 Phage T4 provides its own replication apparatus*).

## DNA REPLICATION

### 4.14.8 Priming is required to start DNA synthesis

#### Key Terms

A **primer** is a short sequence (often of RNA) that is paired with one strand of DNA and provides a free 3' -OH end at which a DNA polymerase starts synthesis of a deoxyribonucleotide chain.

The **primase** is a type of RNA polymerase that synthesizes short segments of RNA that will be used as primers for DNA replication.

#### Key Concepts

- All DNA polymerases require a 3' -OH priming end to initiate DNA synthesis.
- The priming end can be provided by an RNA primer, a nick in DNA, or a priming protein.
- For DNA replication, a special RNA polymerase called a primase synthesizes an RNA chain that provides the priming end.
- *E. coli* has two types of priming reaction, which occur at the bacterial origin (*oriC*) and the  $\phi$ X174 origin.
- Priming of replication on double-stranded DNA always requires a replicase, SSB, and primase.
- DnaB is the helicase that unwinds DNA for replication in *E. coli*.

A common feature of all DNA polymerases is that they cannot initiate synthesis of a chain of DNA *de novo*. **Figure 14.12** shows the features required for initiation. Synthesis of the new strand can only start from a pre-existing 3' -OH end; and the template strand must be converted to a single-stranded condition.

**Figure 14.12** A DNA polymerase requires a 3' -OH end to initiate replication.

The 3' -OH end is called a **primer**. The primer can take various forms. Types of priming reaction are summarized in **Figure 14.13**:

**Figure 14.13** There are several methods for providing the free 3' -OH end that DNA polymerases require to initiate DNA synthesis.

- A sequence of RNA is synthesized on the template, so that the free 3' -OH end of the RNA chain is extended by the DNA polymerase. This is commonly used in replication of cellular DNA, and by some viruses (see **Figure 13.40** in *Molecular Biology 4.13.23 The ColE1 compatibility system is controlled by an RNA regulator*).

- A preformed RNA pairs with the template, allowing its 3' –OH end to be used to prime DNA synthesis. This mechanism is used by retroviruses to prime reverse transcription of RNA (see **Figure 17.6** in *Molecular Biology 4.17.4 Viral DNA is generated by reverse transcription*).
- A primer terminus is generated within duplex DNA. The most common mechanism is the introduction of a nick, as used to initiate rolling circle replication (see **Figure 13.16**). In this case, the pre-existing strand is displaced by new synthesis. (Note the difference from nick translation shown in **Figure 14.5**, in which DNA polymerase I simultaneously synthesizes and degrades DNA from a nick.)
- A protein primes the reaction directly by presenting a nucleotide to the DNA polymerase. This reaction is used by certain viruses (see **Figure 13.15** in *Molecular Biology 4.13.8 The ends of linear DNA are a problem for replication*).

Priming activity is required to provide 3' –OH ends to start off the DNA chains on both the leading and lagging strands. The leading strand requires only one such initiation event, which occurs at the origin. But there must be a series of initiation events on the lagging strand, since each Okazaki fragment requires its own start *de novo*. Each Okazaki fragment starts with a primer sequence of RNA, ~10 bases long, that provides the 3' –OH end for extension by DNA polymerase.

A **primase** is required to catalyze the actual priming reaction. This is provided by a special RNA polymerase activity, the product of the *dnaG* gene. The enzyme is a single polypeptide of 60 kD (much smaller than RNA polymerase). The primase is an RNA polymerase that is used only under specific circumstances, that is, to synthesize short stretches of RNA that are used as primers for DNA synthesis. DnaG primase associates transiently with the replication complex, and typically synthesizes an 11-12 base primer. Primers start with the sequence pppAG, opposite the sequence 3' –GTC-5' in the template.

(Some systems use alternatives to the DnaG primase. In the examples of the two phages M13 and G4, which were used for early work on replication, an interesting difference emerged. G4 priming uses DnaG, but M13 priming uses bacterial RNA polymerase. These phages have another unusual feature, which is that the site of priming is indicated by a region of secondary structure.)

There are two types of priming reaction in *E. coli*.

- The *oriC* system, named for the bacterial origin, basically involves the association of the DnaG primase with the protein complex at the replication fork.
- The  $\phi$ X system, named for phage  $\phi$ X174, requires an initiation complex consisting of additional components, called the primosome (see *Molecular Biology 4.14.17 The primosome is needed to restart replication*).

Sometimes replicons are referred to as being of the  $\phi$ X or *oriC* type.

The types of activities involved in the initiation reaction are summarized in **Figure 14.14**. Although other replicons in *E. coli* may have alternatives for some of these particular proteins, the same general types of activity are required in every case. A helicase is required to generate single strands, a single-strand binding protein is required to maintain the single-stranded state, and the primase synthesizes the RNA primer.

**Figure 14.14** Initiation requires several enzymatic activities, including helicases, single-strand binding proteins, and synthesis of the primer.

DnaB is the central component in both  $\phi X$  and *oriC* replicons. It provides the 5'–3' helicase activity that unwinds DNA. Energy for the reaction is provided by cleavage of ATP. Basically DnaB is the active component of the growing point. In *oriC* replicons, DnaB is initially loaded at the origin as part of a large complex (see *Molecular Biology 4.14.15 Creating the replication forks at an origin*). It forms the growing point at which the DNA strands are separated as the replication fork advances. It is part of the DNA polymerase complex and interacts with the DnaG primase to initiate synthesis of each Okazaki fragment on the lagging strand.

## DNA REPLICATION

### 4.14.9 Coordinating synthesis of the lagging and leading strands

#### Key Concepts

- Different enzyme units are required to synthesize the leading and lagging strands.
- In *E. coli* both these units contain the same catalytic subunit (DnaE).
- In other organisms, different catalytic subunits may be required for each strand.

Each new DNA strand is synthesized by an individual catalytic unit. **Figure 14.15** shows that the behavior of these two units is different because the new DNA strands are growing in opposite directions. One enzyme unit is moving with the unwinding point and synthesizing the leading strand continuously. The other unit is moving "backwards," relative to the DNA, along the exposed single strand. Only short segments of template are exposed at any one time. When synthesis of one Okazaki fragment is completed, synthesis of the next Okazaki fragment is required to start at a new location approximately in the vicinity of the growing point for the leading strand. This requires a translocation relative to the DNA of the enzyme unit that is synthesizing the lagging strand.

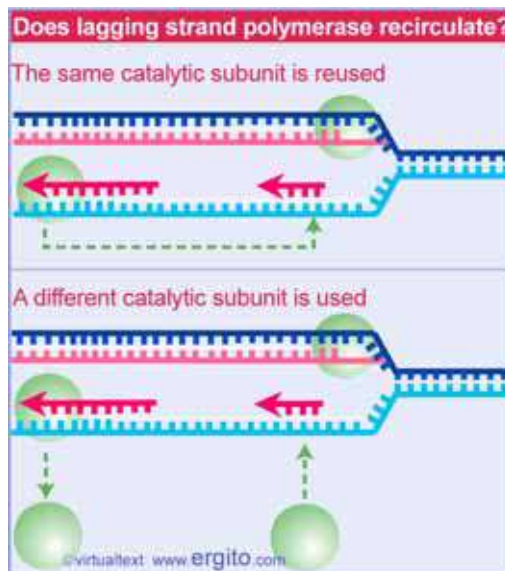

**Figure 14.15** Leading and lagging strand polymerases move apart.  
This is a static version of an interactive figure; see <http://www.ergito.com/main.jsp?bcs=MBIO.4.14.9> to view properly.

The term "enzyme unit" avoids the issue of whether the DNA polymerase that synthesizes the leading strand is the same type of enzyme as the DNA polymerase that synthesizes the lagging strand. In the case that we know best, *E. coli*, there is only a single type of DNA polymerase catalytic subunit used in replication, the DnaE protein. The active replicase is a dimer, and each half of the dimer contains DnaE as the catalytic subunit, supported by other proteins (which differ between the leading and lagging strands).

The use of a single type of catalytic subunit, however, may be atypical. In the bacterium *B. subtilis*, there are two different catalytic subunits (2184). PolC is the homologue to *E. coli*'s DnaE, and is responsible for synthesizing the leading strand. A related protein, DnaE<sub>BS</sub>, is the catalytic subunit that synthesizes the lagging strand. Eukaryotic DNA polymerases have the same general structure, with different enzyme

units synthesizing the leading and lagging strands, but it is not clear whether the same or different types of catalytic subunits are used (see *Molecular Biology 4.14.13 Separate eukaryotic DNA polymerases undertake initiation and elongation*).

A major problem of the semidiscontinuous mode of replication follows from the use of different enzyme units to synthesize each new DNA strand: how is synthesis of the lagging strand coordinated with synthesis of the leading strand? As the replisome moves along DNA, unwinding the parental strands, one enzyme unit elongates the leading strand. Periodically the primosome activity initiates an Okazaki fragment on the lagging strand, and the other enzyme unit must then move in the reverse direction to synthesize DNA. **Figure 14.16** proposes two types of model for what happens to this enzyme unit when it completes synthesis of an Okazaki fragment. The same complex may be reutilized for synthesis of successive Okazaki fragments. Or the complex might dissociate from the template, so that a new complex must be assembled to elongate the next Okazaki fragment. We see in the *Molecular Biology 4.14.11 The clamp controls association of core enzyme with DNA* that the first model applies.

**Figure 14.16** The upper model for the action of lagging strand polymerase is that when an enzyme unit completes one Okazaki fragment, it moves to a new position to synthesize the next fragment. The lower model is that the lagging strand polymerase dissociates when it completes an Okazaki fragment, and a new enzyme unit associates with DNA to synthesize the next Okazaki fragment.

## DNA REPLICATION

### 4.14.10 DNA polymerase holoenzyme has 3 subcomplexes

---

#### Key Terms

The **clamp loader** is a 5 subunit protein complex which is responsible for loading the  $\beta$  clamp on to DNA at the replication fork.

#### Key Concepts

- The *E. coli* replicase DNA polymerase III is a 900 kD complex with a dimeric structure.
- Each monomeric unit has a catalytic core, a dimerization subunit, and a processivity component.
- A clamp loader places the processivity subunits on DNA, and they form a circular clamp around the nucleic acid.
- One catalytic core is associated with each template strand.

---

We can now relate the subunit structure of *E. coli* DNA polymerase III to the activities required for DNA synthesis and propose a model for its action. The holoenzyme is a complex of 900 kD that contains 10 proteins organized into four types of subcomplex:

- There are two copies of the catalytic core. Each catalytic core contains the  $\alpha$  subunit (the DNA polymerase activity),  $\epsilon$  subunit (3'  $\rightarrow$  5' proofreading exonuclease), and  $\theta$  subunit (stimulates exonuclease).
- There are two copies of the dimerizing subunit,  $\tau$ , which link the two catalytic cores together (2185).
- There are two copies of the *clamp*, which is responsible for holding catalytic cores on to their template strands. Each clamp consists of a homodimer of  $\beta$  subunits that binds around the DNA and ensures processivity.
- The  $\gamma$  complex is a group of 5 proteins, the **Clamp loader**, that places the clamp on DNA (2185).

A model for the assembly of DNA polymerase III is shown in **Figure 14.17**. The holoenzyme assembles on DNA in three stages:

**Figure 14.17** DNA polymerase III holoenzyme assembles in stages, generating an enzyme complex that synthesizes the DNA of both new strands.

- First the clamp loader uses hydrolysis of ATP to bind  $\beta$  subunits to a template-primer complex.
- Binding to DNA changes the conformation of the site on  $\beta$  that binds to the clamp loader, and as a result it now has a high affinity for the core polymerase. This enables core polymerase to bind, and this is the means by which the core polymerase is brought to DNA.
- A  $\tau$  dimer binds to the core polymerase, and provides a dimerization function that binds a second core polymerase (associated with another  $\beta$  clamp). The holoenzyme is asymmetric, because it has only 1 clamp loader. The clamp loader is responsible for adding a pair of  $\beta$  dimers to each parental strand of DNA.

Each of the core complexes of the holoenzyme synthesizes one of the new strands of DNA. Because the clamp loader is also needed for unloading the  $\beta$  complex from DNA, the two cores have different abilities to dissociate from DNA. This corresponds to the need to synthesize a continuous leading strand (where polymerase

remains associated with the template) and a discontinuous lagging strand (where polymerase repetitively dissociates and reassociates). The clamp loader is associated with the core polymerase that synthesizes the lagging strand, and plays a key role in the ability to synthesize individual Okazaki fragments (2186).

## DNA REPLICATION

### 4.14.11 The clamp controls association of core enzyme with DNA

---

#### Key Concepts

- The core on the leading strand is processive because its clamp keeps it on the DNA.
- The clamp associated with the core on the lagging strand dissociates at the end of each Okazaki fragment and reassembles for the next fragment.
- The helicase DnaB is responsible for interacting with the primase DnaG to initiate each Okazaki fragment.

---

The  $\beta$  dimer makes the holoenzyme highly processive.  $\beta$  is strongly bound to DNA, but can slide along a duplex molecule. The crystal structure of  $\beta$  shows that it forms a ring-shaped dimer (2187). The model in **Figure 14.18** shows the  $\beta$ -ring in relationship to a DNA double helix. The ring has an external diameter of 80 Å and an internal cavity of 35 Å, almost twice the diameter of the DNA double helix (20 Å). The space between the protein ring and the DNA is filled by water. Each of the  $\beta$  subunits has three globular domains with similar organization (although their sequences are different). As a result, the dimer has 6-fold symmetry, reflected in 12  $\alpha$ -helices that line the inside of the ring.

**Figure 14.18** The  $\beta$  subunit of DNA polymerase III holoenzyme consists of a head to tail dimer (the two subunits are shown in red and orange) that forms a ring completely surrounding a DNA duplex (shown in the center). Photograph kindly provided by John Kuriyan.

The dimer surrounds the duplex, providing the "sliding clamp" that allows the holoenzyme to slide along DNA. The structure explains the high processivity – there is no way for the enzyme to fall off! The  $\alpha$ -helices on the inside have some positive charges that may interact with the DNA via the intermediate water molecules. Because the protein clamp does not directly contact the DNA, it may be able to "ice-skate" along the DNA, making and breaking contacts via the water molecules.

How does the clamp get on to the DNA? Because the clamp is a circle of subunits surrounding DNA, its assembly or removal requires the use of an energy-dependent process by the clamp loader. The  $\gamma$  clamp loader is a pentameric circular structure that binds an open form of the  $\beta$  ring preparatory to loading it on to DNA (2188). In effect, the ring is opened at one of the interfaces between the two  $\beta$  subunits by the  $\delta$  subunit of the clamp loader. The clamp loader uses hydrolysis of ATP to provide the energy to open the ring of the clamp and insert DNA into its central cavity.

The relationship between the  $\beta$  clamp and the  $\gamma$  clamp loader is a paradigm for similar systems used by DNA replicases ranging from bacteriophages to animal cells. The clamp is a heteromer (sometimes a dimer, sometimes a trimer) that forms a ring around DNA with a set of 12  $\alpha$ -helices forming 6-fold symmetry for the structure as

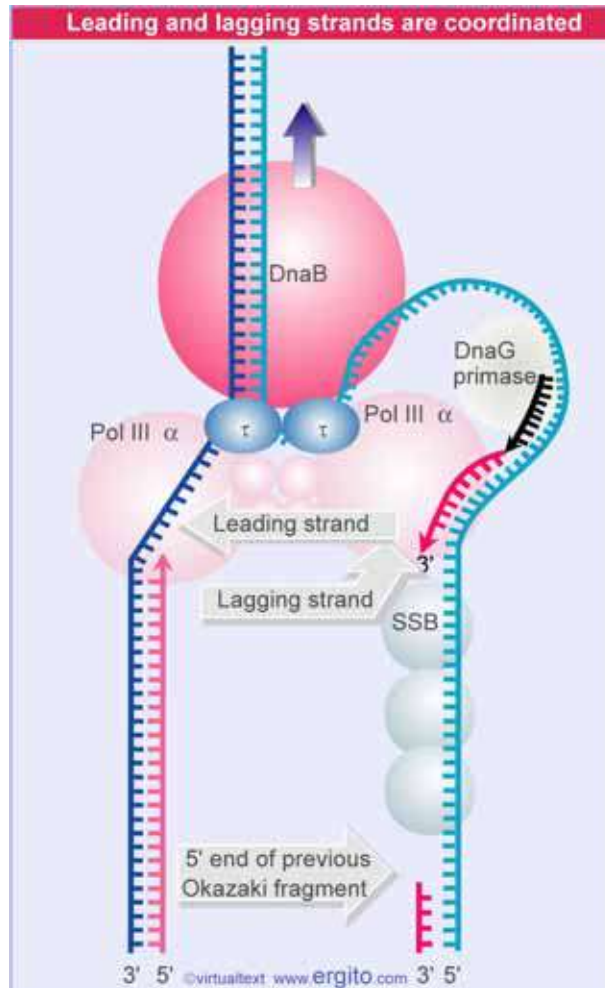

a whole. The clamp loader has some subunits that hydrolyze ATP to provide energy for the reaction (for review see 3441).

The basic principle that is established by the dimeric polymerase model is that, while one polymerase subunit synthesizes the leading strand continuously, the other cyclically initiates and terminates the Okazaki fragments of the lagging strand within a large single-stranded loop formed by its template strand. **Figure 14.19** draws a generic model for the operation of such a replicase. The replication fork is created by a helicase, typically forming a hexameric ring, that translocates in the 5' → 3' direction on the template for the lagging strand. The helicase is connected to two DNA polymerase catalytic subunits, each of which is associated with a sliding clamp.

**Figure 14.19** The helicase creating the replication fork is connected to two DNA polymerase catalytic subunits, each of which is held on to DNA by a sliding clamp. The polymerase that synthesizes the leading strand moves continuously. The polymerase that synthesizes the lagging strand dissociates at the end of an Okazaki fragment and then reassociates with a primer in the single-stranded template loop to synthesize the next fragment.

We can describe this model for DNA polymerase III in terms of the individual components of the enzyme complex, as illustrated in **Figure 14.20**. A catalytic core is associated with each template strand of DNA. The holoenzyme moves continuously along the template for the leading strand; the template for the lagging strand is "pulled through," creating a loop in the DNA. DnaB creates the unwinding point, and translocates along the DNA in the "forward" direction (for review see 2279)

**Figure 14.20** Each catalytic core of Pol III synthesizes a daughter strand. DnaB is responsible for forward movement at the replication fork.

DnaB contacts the  $\tau$  subunit(s) of the clamp loader. This establishes a direct connection between the helicase-primase complex and the catalytic cores. This link has two effects. One is to increase the speed of DNA synthesis by increasing the rate of movement by DNA polymerase core by 10 $\times$ . The second is to prevent the leading strand polymerase from falling off, that is, to increase its processivity.

Synthesis of the leading strand creates a loop of single-stranded DNA that provides the template for lagging strand synthesis, and this loop becomes larger as the unwinding point advances. After initiation of an Okazaki fragment, the lagging strand core complex pulls the single-stranded template through the  $\beta$  clamp while synthesizing the new strand. The single-stranded template must extend for the length of at least one Okazaki fragment before the lagging polymerase completes one fragment and is ready to begin the next.

What happens to the loop when the Okazaki fragment is completed? **Figure 14.21** suggests that the core complex dissociates when it completes synthesis of each fragment, releasing the loop. The core complex then associates with a  $\beta$  clamp to

initiate the next Okazaki fragment. Probably a new  $\beta$  clamp will already be present at the next initiation site, and the  $\beta$  clamp that has lost its core complex will dissociate from the template (with the assistance of the clamp loader complex) to be used again. So the lagging strand polymerase will probably transfer from one  $\beta$  clamp to the next in each cycle, without dissociating from the replicating complex.

**Figure 14.21** Core polymerase and the  $\beta$  clamp dissociate at completion of Okazaki fragment synthesis and reassociate at the beginning.

What is responsible for recognizing the sites for initiating synthesis of Okazaki fragments? In *oriC* replicons, the connection between priming and the replication fork is provided by the dual properties of DnaB: it is the helicase that propels the replication fork; and it interacts with the DnaG primase at an appropriate site. Following primer synthesis, the primase is released. The length of the priming RNA is limited to 8-14 bases. Apparently DNA polymerase III is responsible for displacing the primase.

## DNA REPLICATION

### 4.14.12 Okazaki fragments are linked by ligase

---

#### Key Terms

**DNA ligase** makes a bond between an adjacent 3' -OH and 5' -phosphate end where there is a nick in one strand of duplex DNA.

#### Key Concepts

- Each Okazaki fragment starts with a primer and stops before the next fragment.
  - DNA polymerase I removes the primer and replaces it with DNA in an action that resembles nick translation.
  - DNA ligase makes the bond that connects the 3' end of one Okazaki fragment to the 5' beginning of the next fragment.
- 

We can now expand our view of the actions involved in joining Okazaki fragments, as illustrated in **Figure 14.22**. The complete order of events is uncertain, but must involve synthesis of RNA primer, its extension with DNA, removal of the RNA primer, its replacement by a stretch of DNA, and the covalent linking of adjacent Okazaki fragments.

**Figure 14.22** Synthesis of Okazaki fragments requires priming, extension, removal of RNA, gap filling, and nick ligation.

The figure suggests that synthesis of an Okazaki fragment terminates just before the start of the RNA primer of the preceding fragment. When the primer is removed, there will be a gap. The gap is filled by DNA polymerase I; *polA* mutants fail to join their Okazaki fragments properly. The 5'–3' exonuclease activity removes the RNA primer while simultaneously replacing it with a DNA sequence extended from the 3'–OH end of the next Okazaki fragment. This is equivalent to nick translation, except that the new DNA replaces a stretch of RNA rather than a segment of DNA. In mammalian systems (where the DNA polymerase does not have a 5'–3' exonuclease activity), Okazaki fragments are removed by a two-step process. First RNAase HI (an enzyme that is specific for a DNA-RNA hybrid substrate) makes an endonucleolytic cleavage; then a 5'–3' exonuclease called FEN1 removes the RNA.

Once the RNA has been removed and replaced, the adjacent Okazaki fragments must be linked together. The 3'–OH end of one fragment is adjacent to the 5'–phosphate end of the previous fragment. The responsibility for sealing this nick lies with the enzyme **DNA ligase**. Ligases are present in both prokaryotes and eukaryotes. Unconnected fragments persist in *lig*<sup>–</sup> mutants, because they fail to join Okazaki fragments together.

The *E. coli* and T4 ligases share the property of sealing nicks that have 3'–OH and 5

'-phosphate termini, as illustrated in **Figure 14.23**. Both enzymes undertake a two-step reaction, involving an enzyme-AMP complex. (The *E. coli* and T4 enzymes use different cofactors. The *E. coli* enzyme uses NAD [nicotinamide adenine dinucleotide] as a cofactor, while the T4 enzyme uses ATP.) The AMP of the enzyme complex becomes attached to the 5' -phosphate of the nick; and then a phosphodiester bond is formed with the 3' -OH terminus of the nick, releasing the enzyme and the AMP.

**Figure 14.23** DNA ligase seals nicks between adjacent nucleotides by employing an enzyme-AMP intermediate.

## DNA REPLICATION

### 4.14.13 Separate eukaryotic DNA polymerases undertake initiation and elongation

---

#### Key Concepts

- A replication fork has 1 complex of DNA polymerase  $\alpha$ /primase and 2 complexes of DNA polymerase  $\delta$  and/or  $\epsilon$ .
  - The DNA polymerase  $\alpha$ /primase complex initiates the synthesis of both DNA strands.
  - DNA polymerase  $\delta$  elongates the leading strand and a second DNA polymerase  $\delta$  or DNA polymerase  $\epsilon$  elongates the lagging strand
- 

Eukaryotic cells have a large number of DNA polymerases (for review see 3092). They can be broadly divided into those required for semiconservative replication and those involved in synthesizing material to repair damaged DNA. Nuclear DNA replication requires DNA polymerases  $\alpha$ ,  $\delta$ , and  $\epsilon$ , and mitochondrial replication requires DNA polymerase  $\gamma$ . All the other enzymes are concerned with synthesizing stretches of new DNA to replace damaged material. **Figure 14.24** shows that all of the nuclear replicases are large heterotetrameric enzymes. In each case, one of the subunits has the responsibility for catalysis, and the others are concerned with ancillary functions, such as priming, processivity, or proofreading. These enzymes all replicate DNA with high fidelity, as does the slightly less complex mitochondrial enzyme. The repair polymerases have much simpler structures, often consisting of a single monomeric subunit (although it may function in the context of a complex of other repair enzymes). Of the enzymes involved in repair, only DNA polymerase  $\beta$  has a fidelity approaching the replicases: all of the others have much greater error rates (for review see 3097).

DNA polymerases undertake replication or repair		
DNA polymerase	Function	Structure
<b>High fidelity replicases</b>		
$\alpha$	Nuclear replication	350 kD tetramer
$\delta$	"	250 kD tetramer
$\epsilon$	"	350 kD tetramer
$\gamma$	Mitochondrial replication	200 kD dimer
<b>High fidelity repair</b>		
$\beta$	Base excision repair	39 kD monomer
<b>Low fidelity repair</b>		
$\zeta$	Thymine dimer bypass	heteromer
$\eta$	Base damage repair	monomer
$\iota$	Required in meiosis	monomer
$\kappa$	Deletion and base substitution	monomer

**Figure 14.24** Eukaryotic cells have many DNA polymerases. The replicative enzymes operate with high fidelity. Except for the  $\beta$  enzyme, the repair enzymes all have low fidelity. Replicative enzymes have large structures, with separate subunits for different activities. Repair enzymes have much simpler structures.

Each of the three nuclear DNA replicases has a different function:

- DNA polymerase  $\alpha$  initiates the synthesis of new strands.
- DNA polymerase  $\delta$  elongates the leading strand.
- DNA polymerase  $\epsilon$  may be involved in lagging strand synthesis, but also has other roles.

DNA polymerase  $\alpha$  is unusual because it has the ability to initiate a new strand. It is used to initiate both the leading and lagging strands. The enzyme exists as a complex consisting of a 180 kD catalytic subunit, associated with the B subunit that appears necessary for assembly, and two smaller proteins that provide a primase activity. Reflecting its dual capacity to prime and extend chains, it is sometimes called pol  $\alpha$ /primase.

The pol  $\alpha$ /primase enzyme binds to the initiation complex at the origin and synthesizes a short strand consisting of ~10 bases of RNA followed by 20-30 bases of DNA (sometimes called iDNA). Then it is replaced by an enzyme that will extend the chain. On the leading strand, this is DNA polymerase  $\delta$ . This event is called the pol switch. It involves interactions among several components of the initiation complex.

DNA polymerase  $\delta$  is a highly processive enzyme that continuously synthesizes the leading strand. Its processivity results from its interaction with two other proteins, RF-C and PCNA.

The roles of RF-C and PCNA are analogous to the *E. coli*  $\gamma$  clamp loader and  $\beta$  processivity unit (see *Molecular Biology 4.14.11 The clamp controls association of core enzyme with DNA*). RF-C is a clamp loader that catalyzes the loading of PCNA on to DNA. It binds to the 3' end of the iDNA and uses ATP-hydrolysis to open the ring of PCNA so that it can encircle the DNA (3095). The processivity of DNA polymerase  $\delta$  is maintained by PCNA, which tethers DNA polymerase  $\delta$  to the template. (PCNA is called proliferating cell nuclear antigen for historical reasons.) The crystal structure of PCNA closely resembles the *E. coli*  $\beta$  subunit: a trimer forms a ring that surrounds the DNA. Although the sequence and subunit organization are different from the dimeric  $\beta$  clamp, the function is likely to be similar.

We are less certain about events on the lagging strand. One possibility is that DNA polymerase  $\delta$  also elongates the lagging strand. It has the capability to dimerize, which suggests a model analogous to the behavior of *E. coli* replicase (see *Molecular Biology 4.14.10 DNA polymerase holoenzyme has 3 subcomplexes*) (3096). However, there are some indications that DNA polymerase  $\epsilon$  may elongate the lagging strand (2189; 2208), although it also has been identified with other roles.

A general model suggests that a replication fork contains 1 complex of DNA polymerase  $\alpha$ /primase and two other DNA polymerase complexes. One is DNA polymerase  $\delta$  and the other is either a second DNA polymerase  $\delta$  or may possibly be a DNA polymerase  $\epsilon$ . The two complexes of DNA polymerase  $\delta/\epsilon$  behave in the same way as the two complexes of DNA polymerase III in the *E. coli* replisome: one synthesizes the leading strand, and the other synthesizes Okazaki fragments on the lagging strand. The exonuclease MF1 removes the RNA primers of Okazaki fragments. The enzyme DNA ligase I is specifically required to seal the nicks between the completed Okazaki fragments.

## DNA REPLICATION

### 4.14.14 Phage T4 provides its own replication apparatus

---

#### Key Concepts

- Phage T4 provides its own replication apparatus, which consists of DNA polymerase, the gene 32 SSB, a helicase, a primase, and accessory proteins that increase speed and processivity.

---

When phage T4 takes over an *E. coli* cell, it provides several functions of its own that either replace or augment the host functions. The phage places little reliance on expression of host functions. The degradation of host DNA is important in releasing nucleotides that are reused in the synthesis of phage DNA. (The phage DNA differs in base composition from cellular DNA in using hydroxymethylcytosine instead of the customary cytosine.)

The phage-coded functions concerned with DNA synthesis in the infected cell can be identified by mutations that impede the production of mature phages. Essential phage functions are identified by conditional lethal mutations, which fall into three phenotypic classes:

- Those in which there is no DNA synthesis at all identify genes whose products either are components of the replication apparatus or are involved in the provision of precursors (especially the hydroxymethylcytosine).
- Those in which the onset of DNA synthesis is delayed are concerned with the initiation of replication.
- Those in which DNA synthesis starts but then is arrested include regulatory functions, the DNA ligase, and some of the enzymes concerned with host DNA degradation.
- There are also nonessential genes concerned with replication; for example, including those involved in glucosylating the hydroxymethylcytosine in the DNA.

Synthesis of T4 DNA is catalyzed by a multienzyme aggregate assembled from the products of a small group of essential genes.

The gene 32 protein (gp32) is a highly cooperative single-strand binding protein, needed in stoichiometric amounts. It was the first example of its type to be characterized. The geometry of the T4 replication fork may specifically require the phage-coded protein, since the *E. coli* SSB cannot substitute. The gp32 forms a complex with the T4 DNA polymerase; this interaction could be important in constructing the replication fork.

The T4 system uses an RNA priming event that is similar to that of its host. With single-stranded T4 DNA as template, the gene *41* and *61* products act together to synthesize short primers. Their behavior is analogous to that of DnaB and DnaG in *E. coli*. The gene *41* protein is the counterpart to DnaB. It is a hexameric helicase that uses hydrolysis of GTP to provide the energy to unwind DNA (3100). The p41/p61 complex moves processively in the 5'–3' direction in lagging strand synthesis, periodically initiating Okazaki fragments. Another protein, the product of gene *59*, loads the p41/p61 complex on to DNA; it is required to displace the p32 protein in order to allow the helicase to assemble on DNA (3099).

The gene *61* protein is needed in much smaller amounts than most of the T4 replication proteins. There are as few as 10 copies of gp61 per cell. (This impeded its characterization. It is required in such small amounts that originally it was missed as a necessary component, because enough was present as a contaminant of the gp32 preparation!) Gene *61* protein has the primase activity, analogous to DnaG of *E. coli*. The primase recognizes the template sequence 3'–TTG–5' and synthesizes pentaribonucleotide primers that have the general sequence pppApCpNpNpNp. If the complete replication apparatus is present, these primers are extended into DNA chains.

The gene *43* DNA polymerase has the usual 5'–3' synthetic activity, associated with a 3'–5' exonuclease proofreading activity. It catalyzes DNA synthesis and removes the primers. When T4 DNA polymerase uses a single-stranded DNA as template, its rate of progress is uneven. The enzyme moves rapidly through single-stranded regions, but proceeds much more slowly through regions that have a base-paired intrastrand secondary structure. The accessory proteins assist the DNA polymerase in passing these roadblocks, and maintaining its speed.

The remaining three proteins are referred to as "polymerase accessory proteins". They increase the affinity of the DNA polymerase for the DNA, and also its processivity and speed. The gene *45* product is a trimer that acts as a sliding clamp. The structure of the trimer is similar to that of the *E. coli*  $\beta$  dimer, forming a circle around DNA that holds the DNA polymerase subunit more tightly on the template.

The products of genes *44* and *62* form a tight complex, which has ATPase activity. They are the equivalent of the  $\gamma\delta$  clamp loader complex, and their role is to load p45 on to DNA. Four molecules of ATP are hydrolyzed in loading the p45 clamp and the p43 DNA polymerase on to DNA.

The overall structure of the replisome is similar to that of *E. coli*. It consists of two coupled holoenzyme complexes, one synthesizing the leading strand and the other synthesizing the lagging strand. In this case, the dimerization involves a direct interaction between the p43 DNA polymerase subunits, and p32 plays a role in coordinating the actions of the two DNA polymerase units (3101).

We have dealt with DNA replication so far solely in terms of the progression of the replication fork. The need for other functions is shown by the DNA-delay and DNA-arrest mutants. The four genes of the DNA-delay mutants include *39*, *52*, and *60*, which code for the three subunits of T4 topoisomerase II, an activity needed for removing supercoils in the template (see *Molecular Biology 4.15.13 Topoisomerases relax or introduce supercoils in DNA*). The essential role of this enzyme suggests

that T4 DNA does not remain in a linear form, but becomes topologically constrained during some stage of replication. The topoisomerase could be needed to allow rotation of DNA ahead of the replication fork.

Comparison of the T4 apparatus with the *E. coli* apparatus suggests that DNA replication poses a set of problems that are solved in analogous ways in different systems. We may now compare the enzymatic and structural activities found at the replication fork in *E. coli*, T4, and HeLa (human) cells. **Figure 14.25** summarizes the functions and assigns them to individual proteins. We can interpret the known properties of replication complex proteins in terms of similar functions, involving the unwinding, priming, catalytic, and sealing reactions. The components of each system interact in restricted ways, as shown by the fact that phage T4 requires its own helicase, primase, clamp, etc., and the bacterial proteins cannot substitute for their phage counterparts.

Replication requires a common set of functions			
Function	<i>E. coli</i>	HeLa/SV40	Phage T4
Helicase	DnaB	T antigen	41
Loading helicase/primase	DnaC	T antigen	59
Single strand maintenance	SSB	RPA	32
Priming	DnaG	Pol $\alpha$ /primase	61
Sliding clamp	$\beta$	PCNA	45
Clamp loading (ATPase)	$\gamma\delta$ complex	RFC	44/62
Catalysis	Pol III core	Pol $\delta$	43
Holoenzyme dimerization	$\tau$	?	43
RNA removal	Pol I	MF1	43
Ligation	Ligase	Ligase 1	T4 ligase

©virtualtext www.ergito.com

**Figure 14.25** Similar functions are required at all replication forks.

## DNA REPLICATION

### 4.14.15 Creating the replication forks at an origin

---

#### Key Concepts

- Initiation at *oriC* requires the sequential assembly of a large protein complex.
  - DnaA binds to short repeated sequences and forms an oligomeric complex that melts DNA.
  - 6 DnaC monomers bind each hexamer of DnaB and this complex binds to the origin.
  - A hexamer of DnaB forms the replication fork. Gyrase and SSB are also required.
- 

Starting a cycle of replication of duplex DNA requires several successive activities:

- The two strands of DNA must suffer their initial separation. This is in effect a melting reaction over a short region.
- An unwinding point begins to move along the DNA; this marks the generation of the replication fork, which continues to move during elongation.
- The first nucleotides of the new chain must be synthesized into the primer. This action is required once for the leading strand, but is repeated at the start of each Okazaki fragment on the lagging strand.

Some events that are required for initiation therefore occur uniquely at the origin; others recur with the initiation of each Okazaki fragment during the elongation phase.

Plasmids carrying the *E. coli oriC* sequence have been used to develop a cell-free system for replication. Initiation of replication at *oriC in vitro* starts with formation of a complex that requires six proteins: DnaA, DnaB, DnaC, HU, Gyrase, and SSB. Of the six proteins involved in prepriming, DnaA draws our attention as the only one uniquely involved in initiation vis-à-vis elongation. DnaB/DnaC provides the "engine" of initiation at the origin.

The first stage in complex formation is binding to *oriC* by DnaA protein (3102). The reaction involves action at two types of sequences: 9 bp and 13 bp repeats. Together the 9 bp and 13 bp repeats define the limits of the 245 bp minimal origin, as indicated in **Figure 14.26**. An origin is activated by the sequence of events summarized in **Figure 14.27**, in which binding of DnaA is succeeded by association with the other proteins.

**Figure 14.26** The minimal origin is defined by the distance between the outside members of the 13-mer and 9-mer repeats.

**Figure 14.27** Prepriming involves formation of a complex by sequential association of proteins, leading to the separation of DNA strands.

The four 9 bp consensus sequences on the right side of *oriC* provide the initial binding sites for DnaA. It binds cooperatively to form a central core around which *oriC* DNA is wrapped. Then DnaA acts at three A-T-rich 13 bp tandem repeats located in the left side of *oriC*. In the presence of ATP, DnaA melts the DNA strands at each of these sites to form an open complex (3103; 3104). All three 13 bp repeats must be opened for the reaction to proceed to the next stage.

Altogether, 2-4 monomers of DnaA bind at the origin, and they recruit 2

"prepriming" complexes of DnaB-DnaC to bind, so that there is one for each of the two (bidirectional) replication forks. Each DnaB-DnaC complex consists of 6 DnaC monomers bound to a hexamer of DnaB. Each DnaB-DnaC complex transfers a hexamer of DnaB to an opposite strand of DNA. DnaC hydrolyzes ATP in order to release DnaB (3106).

The prepriming complex generates a protein aggregate of 480 kD, corresponding to a sphere of radius 6 nm (3107). The formation of a complex at *oriC* is detectable in the form of the large protein blob visualized in **Figure 14.28**. When replication begins, a replication bubble becomes visible next to the blob.

**Figure 14.28** The complex at *oriC* can be detected by electron microscopy. Both complexes were visualized with antibodies against DnaB protein. Photographs kindly provided by Barbara Funnell.

The region of strand separation in the open complex is large enough for both DnaB hexamers to bind, initiating the two replication forks. As DnaB binds, it displaces DnaA from the 13 bp repeats, and extends the length of the open region. Then it uses its helicase activity to extend the region of unwinding. Each DnaB activates a DnaG primase, in one case to initiate the leading strand, and in the other to initiate the first Okazaki fragment of the lagging strand.

Two further proteins are required to support the unwinding reaction. Gyrase provides a swivel that allows one strand to rotate around the other (a reaction discussed in more detail in *Molecular Biology 4.15.15 Gyrase functions by coil inversion*); without this reaction, unwinding would generate torsional strain in the DNA. The protein SSB stabilizes the single-stranded DNA as it is formed. The length of duplex

---

DNA that usually is unwound to initiate replication is probably <60 bp.

The protein HU is a general DNA-binding protein in *E. coli* (see *Molecular Biology 4.18 Rearrangement of DNA*). Its presence is not absolutely required to initiate replication *in vitro*, but it stimulates the reaction. HU has the capacity to bend DNA, and is involved in building the structure that leads to formation of the open complex.

Input of energy in the form of ATP is required at several stages for the prepriming reaction. It is required for unwinding DNA. The helicase action of DnaB depends on ATP hydrolysis; and the swivel action of gyrase requires ATP hydrolysis. ATP is also needed for the action of primase and to activate DNA polymerase III.

Following generation of a replication fork as indicated in **Figure 14.27**, the priming reaction occurs to generate a leading strand. We know that synthesis of RNA is used for the priming event, but the details of the reaction are not known. Some mutations in *dnaA* can be suppressed by mutations in RNA polymerase, which suggests that DnaA could be involved in an initiation step requiring RNA synthesis *in vivo*.

RNA polymerase could be required to read into the origin from adjacent transcription units; by terminating at sites in the origin, it could provide the 3' -OH ends that prime DNA polymerase III. (An example is provided by the use of D loops at mitochondrial origins, as discussed in *Molecular Biology 4.13.7 D loops maintain mitochondrial origins*.) Alternatively, the act of transcription could be associated with a structural change that assists initiation. This latter idea is supported by observations that transcription does not have to proceed into the origin; it is effective up to 200 bp away from the origin, and can use either strand of DNA as template *in vitro*. The transcriptional event is inversely related to the requirement for supercoiling *in vitro*, which suggests that it acts by changing the local DNA structure so as to aid melting of DNA.

**DNA REPLICATION****4.14.16 Common events in priming replication at the origin****Key Concepts**

- The general principle of bacterial initiation is that the origin is initially recognized by a protein that forms a large complex with DNA.
- A short region of A-T-rich DNA is melted.
- DnaB is bound to the complex and creates the replication fork.

Another system for investigating interactions at the origin is provided by phage lambda. A map of the region is shown in **Figure 14.29**. Initiation of replication at the lambda origin requires "activation" by transcription starting from  $P_R$ . As with the events at *oriC*, this does not necessarily imply that the RNA provides a primer for the leading strand. Analogies between the systems suggest that RNA synthesis could be involved in promoting some structural change in the region.

**Figure 14.29** Transcription initiating at  $P_R$  is required to activate the origin of lambda DNA.

Initiation requires the products of phage genes *O* and *P*, as well as several host functions. The phage *O* protein binds to the lambda origin; the phage *P* protein interacts with the *O* protein and with the bacterial proteins. The origin lies within gene *O*, so the protein acts close to its site of synthesis.

Variants of the phage called  $\lambda dv$  consist of shorter genomes that carry all the information needed to replicate, but lack infective functions.  $\lambda dv$  DNA survives in the bacterium as a plasmid, and can be replicated *in vitro* by a system consisting of the phage-coded proteins *O* and *P* together with bacterial replication functions.

Lambda proteins *O* and *P* form a complex together with DnaB at the lambda origin, *ori*  $\lambda$ . The origin consists of two regions; as illustrated in **Figure 14.30**, a series of four binding sites for the *O* protein is adjacent to an A-T-rich region.

**Figure 14.30** The lambda origin for replication comprises two regions. Early events are catalyzed by O protein, which binds to a series of 4 sites; then DNA is melted in the adjacent A-T-rich region. Although the DNA is drawn as a straight duplex, it is actually bent at the origin.

The first stage in initiation is the binding of O to generate a roughly spherical structure of diameter ~11 nm, sometimes called the O-some. The O-some contains ~100 bp or 60 kD of DNA. There are four 18 bp binding sites for O protein, which is ~34 kD. Each site is palindromic, and probably binds a symmetrical O dimer. The DNA sequences of the O-binding sites appear to be bent, and binding of O protein induces further bending.

If the DNA is supercoiled, binding of O protein causes a structural change in the origin. The A-T-rich region immediately adjacent to the O-binding sites becomes susceptible to S1 nuclease, an enzyme that specifically recognizes unpaired DNA. This suggests that a melting reaction occurs next to the complex of O proteins.

The role of the O protein is analogous to that of DnaA at *oriC*: it prepares the origin for binding of DnaB. Lambda provides its own protein, P, which substitutes for DnaC, and brings DnaB to the origin. When lambda P protein and bacterial DnaB proteins are added, the complex becomes larger and asymmetrical. It includes more DNA (a total of ~160 bp) as well as extra proteins. The  $\lambda$  P protein has a special role: it inhibits the helicase action of DnaB. Replication fork movement is triggered when P protein is released from the complex. Priming and DNA synthesis follow.

Some proteins are essential for replication without being directly involved in DNA synthesis as such. Interesting examples are provided by the DnaK and DnaJ proteins. DnaK is a chaperone, related to a common stress protein of eukaryotes. Its ability to interact with other proteins in a conformation-dependent manner plays a role in many cellular activities, including replication. The role of DnaK/DnaJ may be to disassemble the pre-priming complex; by causing the release of P protein, they allow replication to begin.

The initiation reactions at *oriC* and *ori*  $\lambda$  are similar. The same stages are involved, and rely upon overlapping components. The first step is recognition of the origin by a

protein that binds to form a complex with the DNA, DnaA for *oriC* and O protein for *ori λ*. A short region of A·T-rich DNA is melted. Then DnaB is loaded; this requires different functions at *oriC* and *ori λ* (and yet other proteins are required for this stage at other origins). When the helicase DnaB joins the complex, a replication fork is created. Finally an RNA primer is synthesized, after which replication begins.

The use of *oriC* and *ori λ* provides a general model for activation of origins. A similar series of events occurs at the origin of the virus SV40 in mammalian cells. Two hexamers of T antigen, a protein coded by the virus, bind to a series of repeated sites in DNA. In the presence of ATP, changes in DNA structure occur, culminating in a melting reaction. In the case of SV40, the melted region is rather short and is not A·T-rich, but it has an unusual composition in which one strand consists almost exclusively of pyrimidines and the other of purines. Near this site is another essential region, consisting of A·T base pairs, at which the DNA is bent; it is unwound by the binding of T antigen. An interesting difference from the prokaryotic systems is that T antigen itself possesses the helicase activity needed to extend unwinding, so that an equivalent for DnaB is not needed.

## DNA REPLICATION

### 4.14.17 The primosome is needed to restart replication

---

#### Key Terms

The **primosome** describes the complex of proteins involved in the priming action that initiates replication on  $\phi$ X-type origins. It is also involved in restarting stalled replication forks.

#### Key Concepts

- Initiation of  $\phi$ X replication requires the primosome complex to displace SSB from the origin.
- A replication fork stalls when it arrives at damaged DNA.
- After the damage has been repaired, the primosome is required to reinitiate replication.
- The Tus protein binds to *ter* sites and stops DnaB from unwinding DNA, which causes replication to terminate.

---

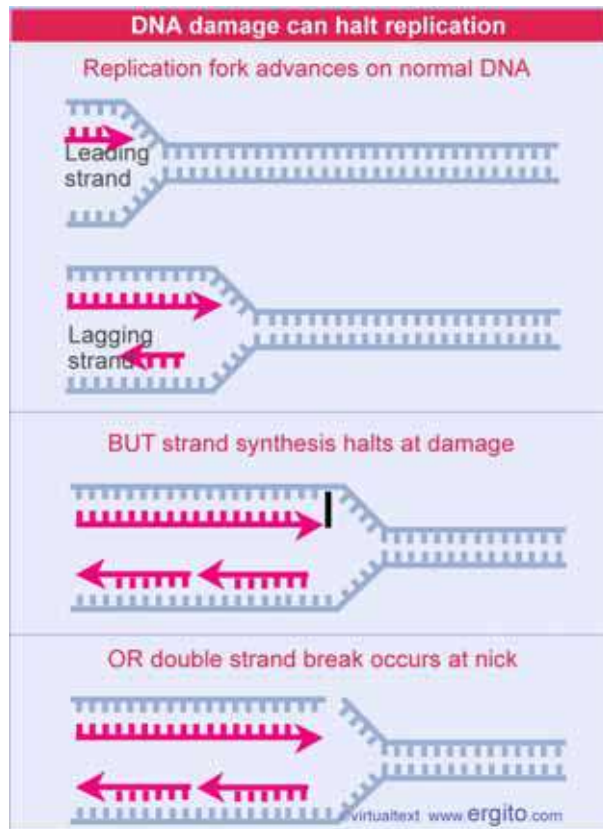

Early work on replication made extensive use of phage  $\phi$ X174, and led to the discovery of a complex system for priming.  $\phi$ X174 DNA is not by itself a substrate for the replication apparatus, because the naked DNA does not provide a suitable template. But once the single-stranded form has been coated with SSB, replication can proceed. A **primosome** assembles at a unique site on the single-stranded DNA, called the assembly site (*pas*). The *pas* is the equivalent of an origin for synthesis of the complementary strand of  $\phi$ X174. The primosome consists of six proteins: PriA, PriB, PriC, DnaT, DnaB, and DnaC. The key event in localizing the primosome is the ability of PriA to displace SSB from single-stranded DNA.

Although the primosome forms initially at the *pas* on  $\phi$ X174 DNA, primers are initiated at a variety of sites. PriA translocates along the DNA, displacing SSB, to reach additional sites at which priming occurs. As in *oriC* replicons, DnaB plays a key role in unwinding and priming in  $\phi$ X replicons. The role of PriA is to load DnaB to form a replication fork.

It has always been puzzling that  $\phi$ X origins should use a complex structure that is not required to replicate the bacterial chromosome. Why does the bacterium provide this complex?

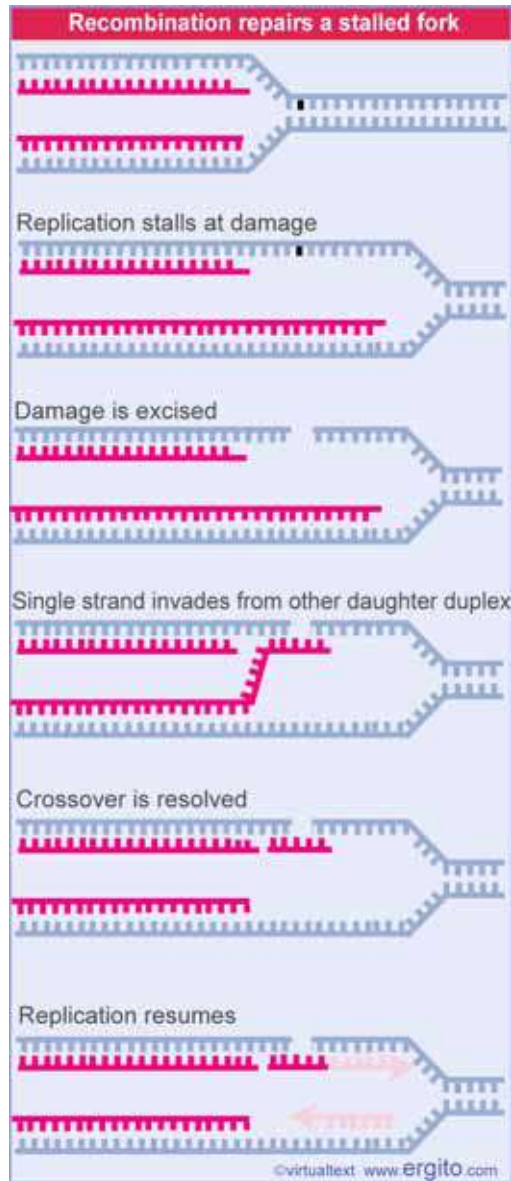

The answer is provided by the fate of stalled replication forks. **Figure 14.31** compares an advancing replication fork with what happens when there is damage to a base in the DNA or a nick in one strand. In either case, DNA synthesis is halted, and the replication fork is either stalled or disrupted. It is not clear whether the components of the fork remain associated with the DNA or disassemble. Replication fork stalling appears to be quite common; estimates for the frequency in *E. coli*

suggest that 18-50% of bacteria encounter a problem during a replication cycle (for review see 3442).

**Figure 14.31** Replication is halted by a damaged base or nick in DNA.

The situation is rescued by a recombination event that excises and replaces the damage or provides a new duplex to replace the region containing the double-strand break (958; see **Figure 15.48** in *Molecular Biology 4.15.25 Recombination-repair systems in E. coli*). The principle of the repair event is to use the built in redundancy of information between the two DNA strands. **Figure 14.32** shows the key events in such a repair event. Basically, information from the undamaged DNA daughter duplex is used to repair the damaged sequence. This creates a typical recombination-junction that is resolved by the same systems that perform homologous recombination. In fact, one view is that the major importance of these systems for the cell is in repairing damaged DNA at stalled replication forks (for review see 2287).

**Figure 14.32** When replication halts at damaged DNA, the damaged sequence is excised, and the complementary (newly synthesized) strand of the other daughter duplex crosses over to repair the gap. Replication can now resume, and the gaps are filled in.

After this the damage has been repaired, the replication fork must be restarted. **Figure 14.33** shows that this may be accomplished by assembly of the primosome, which in effect reloads DnaB so that helicase action can continue (957; 956).

**Figure 14.33** The primosome is required to restart a stalled replication fork after the DNA has been repaired. This is a static version of an interactive figure; see <http://www.ergito.com/main.jsp?bcs=MBIO.4.14.17> to view properly.

Replication fork reactivation is a common (and therefore important) reaction. It may be required in most chromosomal replication cycles. It is impeded by mutations in either the retrieval systems that replace the damaged DNA or in the components of the primosome.

Replication forks must stop and disassemble at the termination of replication. How is this accomplished?

Sequences that stop movement of replication forks have been identified in the form of the *ter* elements of the *E. coli* chromosome (see **Figure 13.7**) or equivalent sequences in some plasmids. The common feature of these elements is a 23 bp consensus sequence that provides the binding site for the product of the *tus* gene, a 36 kD protein that is necessary for termination. Tus binds to the consensus sequence, where it provides a contra-helicase activity and stops DnaB from unwinding DNA. The leading strand continues to be synthesized right up to the *ter* element, while the nearest lagging strand is initiated 50-100 bp before reaching *ter*.

The result of this inhibition is to halt movement of the replication fork and (presumably) to cause disassembly of the replication apparatus. **Figure 14.34** reminds us that Tus stops the movement of a replication fork in only one direction. The crystal structure of a Tus-*ter* complex shows that the Tus protein binds to DNA

asymmetrically;  $\alpha$ -helices of the protein protrude around the double helix at the end that blocks the replication fork. Presumably a fork proceeding in the opposite direction can displace Tus and thus continue. A difficulty in understanding the function of the system *in vivo* is that it appears to be dispensable, since mutations in the *ter* sites or in *tus* are not lethal.

**Figure 14.34** Tus binds to *ter* asymmetrically and blocks replication in only one direction.

**DNA REPLICATION****4.14.18 Does methylation at the origin regulate initiation?****Key Terms**

**Hemimethylated** DNA is methylated on one strand of a target sequence that has a cytosine on each strand.

**Key Concepts**

- *oriC* contains 11 **GATC** repeats that are methylated on adenine on both strands.  
**CTAG**
- Replication generates hemimethylated DNA, which cannot initiate replication.
- There is a 13 min delay before the **GATC** repeats are remethylated.  
**CTAG**

What feature of a bacterial (or plasmid) origin ensures that it is used to initiate replication only once per cycle? Is initiation associated with some change that marks the origin so that a replicated origin can be distinguished from a nonreplicated origin?

Some sequences that are used for this purpose are included in the origin. *oriC* contains 11 copies of the sequence **GATC**, which is a target for methylation at the

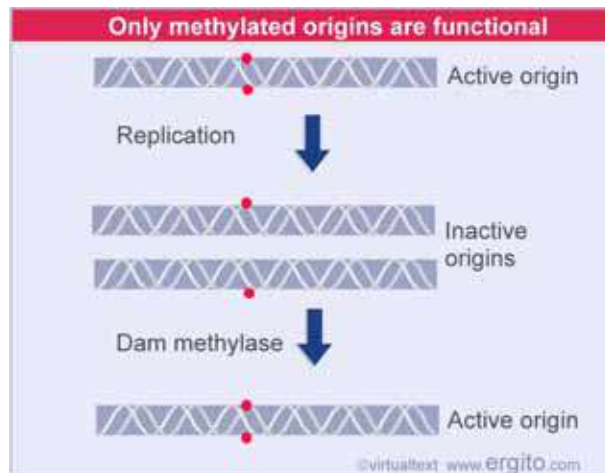

N<sub>6</sub> position of adenine by the Dam methylase. The reaction is illustrated in **Figure 14.35**.

**Figure 14.35** Replication of methylated DNA gives hemimethylated DNA, which maintains its state at GATC sites until the Dam methylase restores the fully methylated condition.

Before replication, the palindromic target site is methylated on the adenines of each strand. Replication inserts the normal (nonmodified) bases into the daughter strands, generating **hemimethylated** DNA, in which one strand is methylated and one strand is unmethylated. So the replication event converts Dam target sites from fully methylated to hemimethylated condition.

What is the consequence for replication? The ability of a plasmid relying upon *oriC* to replicate in *dam*<sup>-</sup>*E. coli* depends on its state of methylation. If the plasmid is methylated, it undergoes a single round of replication, and then the hemimethylated products accumulate, as described in **Figure 14.36**. So a hemimethylated origin cannot be used to initiate a replication cycle.

**Figure 14.36** Only fully methylated origins can initiate replication; hemimethylated daughter origins cannot be used again until they have been restored to the fully methylated state.

Two explanations suggest themselves. Initiation may require full methylation of the Dam target sites in the origin. Or initiation may be inhibited by hemimethylation of these sites. The latter seems to be the case, because an origin of nonmethylated DNA can function effectively.

So hemimethylated origins cannot initiate again until the Dam methylase has converted them into fully methylated origins. The GATC sites at the origin remain hemimethylated for ~13 minutes after replication (3111). This long period is unusual, because at typical GATC sites elsewhere in the genome, remethylation begins immediately (<1.5 min) following replication. One other region behaves like *oriC*; the promoter of the *dnaA* gene also shows a delay before remethylation begins.

While it is hemimethylated, the *dnaA* promoter is repressed, which causes a reduction in the level of DnaA protein. So the origin itself is inert, and production of the crucial initiator protein is repressed, during this period.

## DNA REPLICATION

### 4.14.19 Origins may be sequestered after replication

---

#### Key Concepts

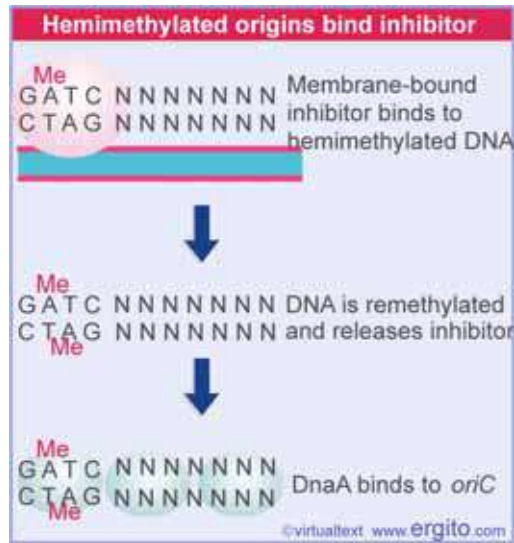

- SeqA binds to hemimethylated DNA and is required for delaying rereplication.
  - SeqA may interact with DnaA.
  - While the origins are hemimethylated, they bind to the cell membrane, and may be unavailable to methylases.
  - The nature of the connection between the origin and the membrane is still unclear.
- 

What is responsible for the delay in remethylation at *oriC* and *dnaA*? The most likely explanation is that these regions are sequestered in a form in which they are inaccessible to the Dam methylase.

A circuit responsible for controlling reuse of origins is identified by mutations in the gene *seqA*. The mutants reduce the delay in remethylation at both *oriC* and *dnaA*. As a result, they initiate DNA replication too soon, thereby accumulating an excessive number of origins (3108). This suggests that *seqA* is part of a negative regulatory circuit that prevents origins from being remethylated (3110). SeqA binds to hemimethylated DNA more strongly than to fully methylated DNA. It may initiate binding when the DNA becomes hemimethylated, and then its continued presence prevents formation of an open complex at the origin. SeqA does not have specificity for the *oriC* sequence, and it seems likely that this is conferred by DnaA protein, which would explain genetic interactions between *seqA* and *dnaA* (3109).

Hemimethylation of the GATC sequences in the origin is required for its association with the cell membrane *in vitro*. Hemimethylated *oriC* DNA binds to the membranes, but DNA that is fully methylated does not bind. One possibility is that membrane association is involved in controlling the activity of the origin. This function could be separate from any role that the membrane plays in segregation (see **Figure 13.26**). Association with the membrane could prevent reinitiation from occurring prematurely, either indirectly because the origins are sequestered or directly because some component at the membrane inhibits the reaction.

The properties of the membrane fraction suggest that it includes components that regulate replication. An inhibitor is found in this fraction that competes with DnaA protein. This inhibitor can prevent initiation of replication only if it is added to an *in vitro* system before DnaA protein. This suggests the model of **Figure 14.37**, in which the inhibitor specifically recognizes hemimethylated DNA and prevents DnaA from binding. When the DNA is remethylated, the inhibitor is released, and DnaA now is free to initiate replication. If the inhibitor is associated with the membrane, then association and dissociation of DNA with the membrane may be involved in the control of replication.

**Figure 14.37** A membrane-bound inhibitor binds to hemimethylated DNA at the origin, and may function by preventing the binding of DnaA. It is released when the DNA is remethylated.

The full scope of the system used to control reinitiation is not clear, but several mechanisms may be involved: physical sequestration of the origin; delay in remethylation; inhibition of DnaA binding; repression of *dnaA* transcription. It is not immediately obvious which of these events cause the others, and whether their effects on initiation are direct or indirect.

We still have to come to grips with the central issue of which feature has the basic responsibility for timing. One possibility is that attachment to the membrane occurs at initiation, and that assembly of some large structure is required to release the DNA. The period of sequestration appears to increase with the length of the cell cycle, which suggests that it directly reflects the clock that controls reinitiation.

As the only member of the replication apparatus uniquely required at the origin, DnaA has attracted much attention. DnaA is a target for several regulatory systems. It may be that no one of these systems by itself is adequate to control frequency of initiation, but the combination achieves the desired result. Some mutations in *dnaA* render replication asynchronous, suggesting that DnaA could be the "titrator" or "clock" that measures the number of origins relative to cell mass. Overproduction of DnaA yields conflicting results, varying from no effect to causing initiation to take place at reduced mass.

It has been difficult to identify the protein component(s) that mediate membrane-attachment. A hint that this is a function of DnaA is provided by its response to phospholipids. Phospholipids promote the exchange of ATP with ADP bound to DnaA. We do not know what role this plays in controlling the activity of DnaA (which requires ATP), but the reaction implies that DnaA is likely to interact with the membrane. This would imply that more than one event is involved in associating with the membrane. Perhaps a hemimethylated origin is bound by the membrane-associated inhibitor, but when the origin becomes fully methylated, the inhibitor is displaced by DnaA associated with the membrane.

If DnaA is the initiator that triggers a replication cycle, the key event will be its accumulation at the origin to a critical level. There are no cyclic variations in the overall concentration or expression of DnaA, which suggests that local events must be responsible. To be active in initiating replication, DnaA must be in the ATP-bound form. DnaA has a weak intrinsic activity that converts the ATP to ADP. This activity is enhanced by the  $\beta$  subunit of DNA polymerase III. When the replicase is incorporated into the replication complex, this interaction causes hydrolysis of the ATP bound to DnaA, thereby inactivating DnaA, and preventing it from starting another replication cycle (3112; 3113). This reaction has been called *RIDA* (regulatory inactivation of DnaA). It is enhanced by a protein called Hda (3114). We do not yet know what controls the timing of the reactivation of DnaA.

Another factor that controls availability of DnaA at the origin is the competition for binding it to other sites on DNA. In particular, a locus called *dat* has a large concentration of DnaA-binding sites. It binds about 8 $\times$  more DnaA than the origin. Deletion of *dat* causes initiation to occur more frequently (3115). This significantly reduces the amount of DnaA available to the origin, but we do not yet understand exactly what role this may play in controlling the timing of initiation.

## DNA REPLICATION

### 4.14.20 Licensing factor controls eukaryotic rereplication

---

#### Key Terms

A **licensing factor** is something in the nucleus that is necessary for replication, and is inactivated or destroyed after one round of replication. New licensing factors must be provided for further rounds of replication to occur.

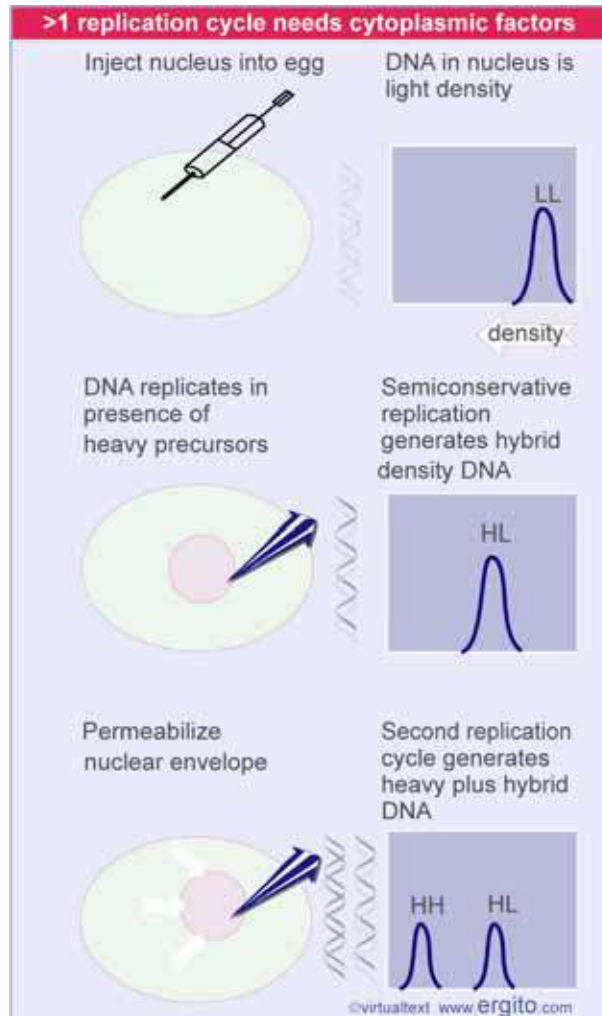

#### Key Concepts

- Licensing factor is necessary for initiation of replication at each origin.
- It is present in the nucleus prior to replication, but is inactivated or destroyed by replication.
- Initiation of another replication cycle becomes possible only after licensing factor reenters the nucleus after mitosis.

---

A eukaryotic genome is divided into multiple replicons, and the origin in each replicon is activated once and only once in a single division cycle. This could be achieved by providing some rate-limiting component that functions only once at an origin or by the presence of a repressor that prevents rereplication at origins that have been used. The critical questions about the nature of this regulatory system are how the system determines whether any particular origin has been replicated, and what protein components are involved.

Insights into the nature of the protein components have been provided by using a system in which a substrate DNA undergoes only one cycle of replication. *Xenopus* eggs have all the components needed to replicate DNA – in the first few hours after fertilization they undertake 11 division cycles without new gene expression – and they can replicate the DNA in a nucleus that is injected into the egg. **Figure 14.38** summarizes the features of this system.

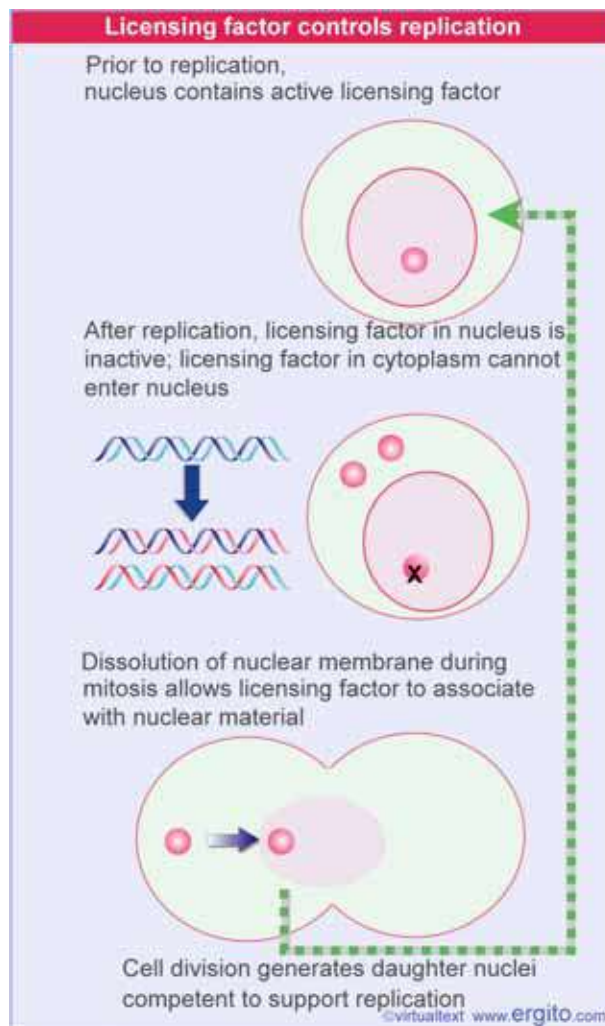

**Figure 14.38** A nucleus injected into a *Xenopus* egg can replicate only once unless the nuclear membrane is permeabilized to allow subsequent replication cycles.

When a sperm or interphase nucleus is injected into the egg, its DNA is replicated only once (this can be followed by use of a density label, just like the original experiment that characterized semiconservative replication, shown previously in **Figure 1.12**). If protein synthesis is blocked in the egg, the membrane around the injected material remains intact, and the DNA cannot replicate again. However, in the presence of protein synthesis, the nuclear membrane breaks down just as it would for a normal cell division, and in this case subsequent replication cycles can occur. The same result can be achieved by using agents that permeabilize the nuclear membrane. This suggests that the nucleus contains a protein(s) needed for replication that is used up in some way by a replication cycle; although more of the protein is present in the egg cytoplasm, it can only enter the nucleus if the nuclear membrane breaks down. The system can in principle be taken further by developing an *in vitro* extract that supports nuclear replication, thus allowing the components of the extract to be isolated, and the relevant factors identified.

**Figure 14.39** explains the control of reinitiation by proposing that this protein is a

**licensing factor** (3116). It is present in the nucleus prior to replication. One round of replication either inactivates or destroys the factor, and another round cannot occur until further factor is provided. Factor in the cytoplasm can gain access to the nuclear material only at the subsequent mitosis when the nuclear envelope breaks down. This regulatory system achieves two purposes. By removing a necessary component after replication, it prevents more than one cycle of replication from occurring. And it provides a feedback loop that makes the initiation of replication dependent on passing through cell division.

**Figure 14.39** Licensing factor in the nucleus is inactivated after replication. A new supply of licensing factor can enter only when the nuclear membrane breaks down at mitosis.

---

## DNA REPLICATION

### 4.14.21 Licensing factor consists of MCM proteins

---

#### Key Terms

The **prereplication complex** is a protein-DNA complex at the origin in *S. cerevisiae* that is required for DNA replication. The complex contains the ORC complex, Cdc6, and the MCM proteins.

The **postreplication complex** is a protein-DNA complex in *S. cerevisiae* that consists of the ORC complex bound to the origin.

#### Key Concepts

- The ORC is a protein complex that is associated with yeast origins throughout the cell cycle.
  - Cdc6 protein is an unstable protein that is synthesized only in G1.
  - Cdc6 binds to ORC and allows MCM proteins to bind.
  - When replication is initiated, Cdc6 and MCM proteins are displaced. The degradation of Cdc6 prevents reinitiation.
  - Some MCM proteins are in the nucleus throughout the cycle, but others may enter only after mitosis.
- 

The key event in controlling replication is the behavior of the ORC complex at the origin (for review see 2503; 3119; 3089). Recall that ORC is a 400 kD complex that binds to the *S. cerevisiae* ARS sequence (see *Molecular Biology 4.13.6 Replication origins can be isolated in yeast*). The origin (ARS) consists of the A consensus sequence and three B elements (see **Figure 13.10**). The ORC complex of 6 proteins (all of which are coded by essential genes) binds to the A and adjacent B1 element. ATP is required for the binding, but is not hydrolyzed until some later stage. The transcription factor ABF1 binds to the B3 element; this assists initiation, but it is the events that occur at the A and B1 elements that actually cause initiation. Most origins are localized in regions between genes, which suggests that it may be important for the local chromatin structure to be in a nontranscribed condition.

The striking feature is that ORC remains bound at the origin through the entire cell cycle. However, changes occur in the pattern of protection of DNA as a result of the binding of other proteins to the ORC-origin complex (2502; 2501; 3118). **Figure 14.40** summarizes the cycle of events at the origin.

**Figure 14.40** Proteins at the origin control susceptibility to initiation.

At the end of the cell cycle, ORC is bound to A/B1, and generates a pattern of protection *in vivo* that is similar to that found when it binds to free DNA *in vitro*. Basically the region across A-B1 is protected against DNAase, but there is a hypersensitive site in the center of B1.

During G1, this pattern changes, most strikingly by the loss of the hypersensitive site. This is due to the binding of Cdc6 protein to the ORC. In yeast, Cdc6 is a highly unstable protein (half-life <5 minutes). It is synthesized during G1, and typically binds to the ORC between the exit from mitosis and late G1. Its rapid degradation means that no protein is available later in the cycle. In mammalian cells it is controlled differently; it is phosphorylated during S phase, and as a result is exported from the nucleus. Cdc6 provides the connection between ORC and a complex of proteins that is involved in licensing and initiation. Cdc6 has an ATPase activity that is required for it to support initiation (3090).

An insight into the system that controls availability of licensing factor is provided by certain mutants in yeast. Mutations in the licensing factor itself could prevent initiation of replication. This is how mutations behave in *MCM2*, *3*, *5*. Mutations in

the system that inactivates licensing factor after the start of replication should allow the accumulation of excess quantities of DNA, because the continued presence of licensing factor allows rereplication to occur. Such mutations are found in genes that code for components of the ubiquitination system that is responsible for degrading certain proteins. This suggests that licensing factor may be destroyed after the start of a replication cycle.

The proteins MCM2, 3, 5 are required for replication and enter the nucleus only during mitosis. Homologues are found in animal cells, where MCM3 is bound to chromosomal material before replication, but is released after replication. The animal cell MCM2,3,5 complex remains in the nucleus throughout the cell cycle, suggesting that it may be one component of the licensing factor. Another component, able to enter only at mitosis, may be necessary for MCM2,3,5 to associate with chromosomal material.

In yeast, the presence of Cdc6 at the origin allows MCM proteins to bind to the complex. Their presence is necessary for initiation to occur at the origin. The origin therefore enters S phase in the condition of a **prereplication complex**, containing ORC, Cdc6, and MCM proteins. When initiation occurs, Cdc6 and MCM are displaced, returning the origin to the state of the **postreplication complex**, which contains only ORC. Because Cdc6 is rapidly degraded during S phase, it is not available to support reloading of MCM proteins, and so the origin cannot be used for a second cycle of initiation during the S phase.

If Cdc6 is made available to bind to the origin during G2 (by ectopic expression), MCM proteins do not bind until the following G1, suggesting that there is a secondary mechanism to ensure that they associate with origins only at the right time. This could be another part of licensing control. At least in *S. cerevisiae*, this control does not seem to be exercised at the level of nuclear entry, but this could be a difference between yeasts and animal cells. We discuss how the cell cycle control system regulates initiation (and reinitiation) of replication in *Molecular Biology 6.29 Cell cycle and growth regulation*.

The MCM2-7 proteins form a 6-member ring-shaped complex around DNA (2504). Some of the ORC proteins have similarities to replication proteins that load DNA polymerase on to DNA. It is possible that ORC uses hydrolysis of ATP to load the MCM ring on to DNA. In *Xenopus* extracts, replication can be initiated if ORC is removed after it has loaded Cdc6 and MCM proteins (2505). This shows that the major role of ORC is to identify the origin to the Cdc6 and MCM proteins that control initiation and licensing.

The MCM proteins are required for elongation as well as for initiation, and continue to function at the replication fork. Their exact role in elongation is not clear, but one possibility is that they contribute to the helicase activity that unwinds DNA. Another possibility is that they act as an advance guard that acts on chromatin in order to allow a helicase to act on DNA.

## DNA REPLICATION

### 4.14.22 Summary

DNA synthesis occurs by semidiscontinuous replication, in which the leading strand of DNA growing 5'–3' is extended continuously, but the lagging strand that grows overall in the opposite 3'–5' direction is made as short Okazaki fragments, each synthesized 5'–3'. The leading strand and each Okazaki fragment of the lagging strand initiate with an RNA primer that is extended by DNA polymerase. Bacteria and eukaryotes each possess more than one DNA polymerase activity. DNA polymerase III synthesizes both lagging and leading strands in *E. coli*. Many proteins are required for DNA polymerase III action and several constitute part of the replisome within which it functions.

The replisome contains an asymmetric dimer of DNA polymerase III; each new DNA strand is synthesized by a different core complex containing a catalytic ( $\alpha$ ) subunit. Processivity of the core complex is maintained by the  $\beta$  clamp, which forms a ring around DNA. The clamp is loaded on to DNA by the clamp loader complex. Clamp/clamp loader pairs with similar structural features are widely found in both prokaryotic and eukaryotic replication systems.

The looping model for the replication fork proposes that, as one half of the dimer advances to synthesize the leading strand, the other half of the dimer pulls DNA through as a single loop that provides the template for the lagging strand. The transition from completion of one Okazaki fragment to the start of the next requires the lagging strand catalytic subunit to dissociate from DNA and then to reattach to a  $\beta$  clamp at the priming site for the next Okazaki fragment.

DnaB provides the helicase activity at a replication fork; this depends on ATP cleavage. DnaB may function by itself in *oriC* replicons to provide primosome activity by interacting periodically with DnaG, which provides the primase that synthesizes RNA.

Phage T4 codes for a replication apparatus consisting of 7 proteins: DNA polymerase, helicase, single-strand binding protein, priming activities, and accessory proteins. Similar functions are required in other replication systems, including a HeLa cell system that replicates SV40 DNA. Different enzymes, DNA polymerase  $\alpha$  and DNA polymerase  $\delta$ , initiate and elongate the new strands of DNA.

The  $\phi$ X priming event also requires DnaB, DnaC, and DnaT. PriA is the component that defines the primosome assembly site (*pas*) for  $\phi$ X replicons; it displaces SSB from DNA in an action that involves cleavage of ATP. PriB and PriC are additional components of the primosome. The importance of the primosome for the bacterial cell is that it is used to restart replication at forks that stall when they encounter damaged DNA.

The common mode of origin activation involves an initial limited melting of the double helix, followed by more general unwinding to create single strands. Several proteins act sequentially at the *E. coli* origin. Replication is initiated at *oriC* in *E. coli*

when DnaA binds to a series of 9 bp repeats. This is followed by binding to a series of 13 bp repeats, where it uses hydrolysis of ATP to generate the energy to separate the DNA strands. The pre-priming complex of DnaC-DnaB displaces DnaA. DnaC is released in a reaction that depends on ATP hydrolysis; DnaB is joined by the replicase enzyme, and replication is initiated by two forks that set out in opposite directions. Similar events occur at the lambda origin, where phage proteins O and P are the counterparts of bacterial proteins DnaA and DnaC, respectively. In SV40 replication, several of these activities are combined in the functions of T antigen.

The availability of DnaA at the origin is an important component of the system that determines when replication cycles should initiate. Following initiation of replication, DnaA hydrolyzes its ATP under the stimulus of the  $\beta$  sliding clamp, generating an inactive form of the protein. Also, *oriC* must compete with the *dat* site for binding DnaA.

Several sites that are methylated by the Dam methylase are present in the *E. coli* origin, including those of the 13-mer binding sites for DnaA. The origin remains hemimethylated and is in a sequestered state for ~10 minutes following initiation of a replication cycle. During this period it is associated with the membrane, and reinitiation of replication is repressed. The protein SeqA is involved in sequestration and may interact with DnaA.

After cell division, nuclei of eukaryotic cells have a licensing factor that is needed to initiate replication. Its destruction after initiation of replication prevents further replication cycles from occurring in yeast. Licensing factor cannot be imported into the nucleus from the cytoplasm, and can be replaced only when the nuclear membrane breaks down during mitosis.

The origin is recognized by the ORC proteins, which in yeast remain bound throughout the cell cycle. The protein Cdc6 is available only at S phase. In yeast it is synthesized during S phase and rapidly degraded. In animal cells it is synthesized continuously, but is exported from the nucleus during S phase. The presence of Cdc6 allows the MCM proteins to bind to the origin. The MCM proteins are required for initiation. The action of Cdc6 and the MCM proteins provides the licensing function.

## RECOMBINATION AND REPAIR

### 4.15.1 Introduction

---

#### Key Terms

**Homologous recombination (generalized recombination)** involves a reciprocal exchange of sequences of DNA, e.g. between two chromosomes that carry the same genetic loci.

**Site-specific recombination (Specialized recombination)** occurs between two specific sequences, as in phage integration/excision or resolution of cointegrate structures during transposition.

**Transposition** refers to the movement of a transposon to a new site in the genome.

**Copy choice** is a type of recombination used by RNA viruses, in which the RNA polymerase switches from one template to another during synthesis.

---

Evolution could not happen without genetic recombination. If it were not possible to exchange material between (homologous) chromosomes, the content of each individual chromosome would be irretrievably fixed in its particular alleles. When mutations occurred, it would not be possible to separate favorable and unfavorable changes. The length of the target for mutation damage would effectively be increased from the gene to the chromosome. Ultimately a chromosome would accumulate so many deleterious mutations that it would fail to function.

By shuffling the genes, recombination allows favorable and unfavorable mutations to be separated and tested as individual units in new assortments. It provides a means of escape and spreading for favorable alleles, and a means to eliminate an unfavorable allele without bringing down all the other genes with which this allele is associated. This is the basis for natural selection.

Recombination occurs between precisely corresponding sequences, so that not a single base pair is added to or lost from the recombinant chromosomes. Three types of recombination share the feature that the process involves physical exchange of material between duplex DNAs:

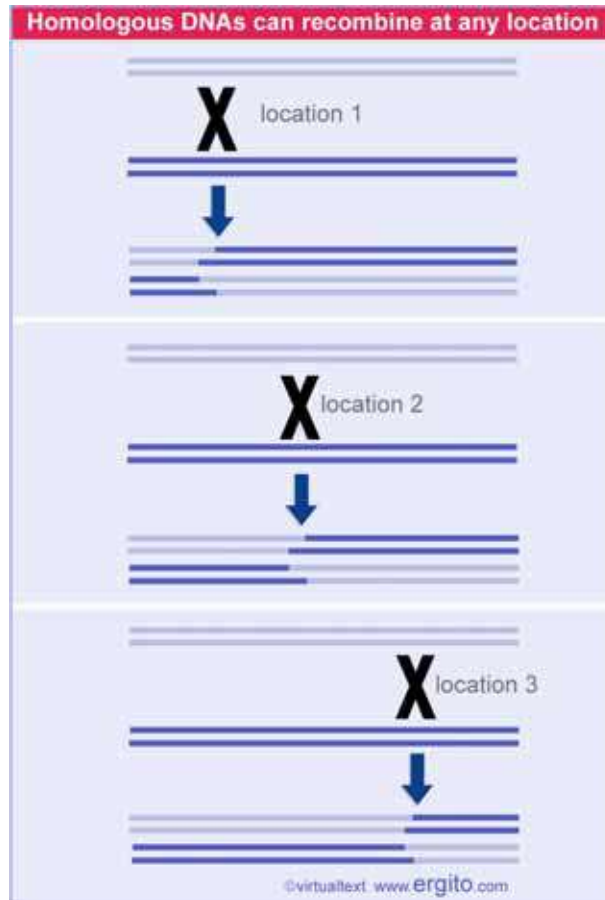

- Recombination involving reaction between homologous sequences of DNA is called *generalized* or **homologous recombination**. In eukaryotes, it occurs at meiosis, usually both in males (during spermatogenesis) and females (during oogenesis). We recall that it happens at the "four strand" stage of meiosis, and involves only two of the four strands (see *Molecular Biology 1.1.20 Recombination occurs by physical exchange of DNA*).
- Another type of event sponsors recombination between specific pairs of sequences. This was first characterized in prokaryotes where **specialized recombination**, also known as **site-specific recombination**, is responsible for the integration of phage genomes into the bacterial chromosome. The recombination event involves specific sequences of the phage DNA and bacterial

DNA, which include a short stretch of homology. The enzymes involved in this event act only on the particular pair of target sequences in an intermolecular reaction. Some related intramolecular reactions are responsible during bacterial division for regenerating two monomeric circular chromosomes when a dimer has been generated by generalized recombination. Also in this latter class are recombination events that invert specific regions of the bacterial chromosome.

- A different type of event allows one DNA sequence to be inserted into another without relying on sequence homology. **Transposition** provides a means by which certain elements move from one chromosomal location to another. The mechanisms involved in transposition depend upon breakage and reunion of DNA strands, and thus are related to the processes of recombination (see *Molecular Biology 4.16 Transposons* and *Molecular Biology 4.17 Retroviruses and retroposons*).
- Another type of recombination is used by RNA viruses, in which the polymerase switches from one template to another while it is synthesizing RNA. As a result, the newly synthesized molecule joins sequence information from two different parents. This type of mechanism for recombination is called **copy choice**, and is discussed briefly in *Molecular Biology 4.17.4 Viral DNA is generated by reverse transcription*.

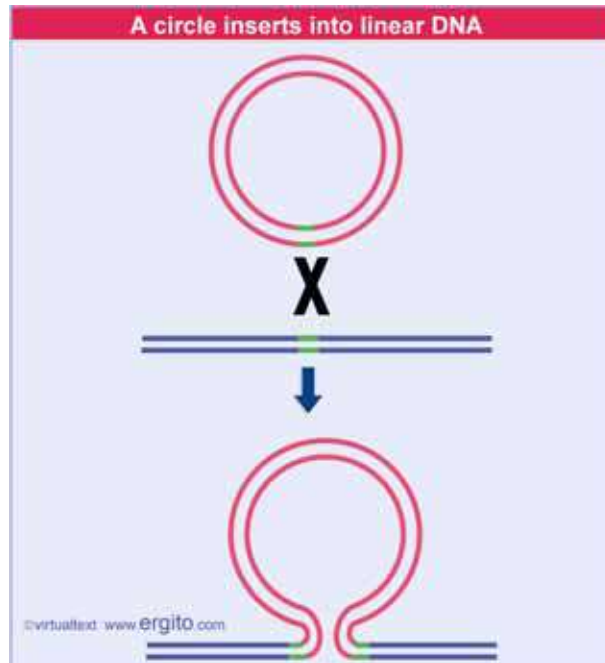

Let's consider the nature and consequences of the generalized and specialized recombination reactions.

**Figure 15.1** makes the point that generalized recombination occurs between two homologous DNA duplexes, and can occur at any point along their length. The two chromosomes are cut at equivalent points, and then each is joined to the other to generate reciprocal recombinants. The crossover (marked by the X) is the point at which each becomes joined to the other. There is no change in the overall organization of DNA; the products have the same structure as the parents, and both parents and products are homologous.

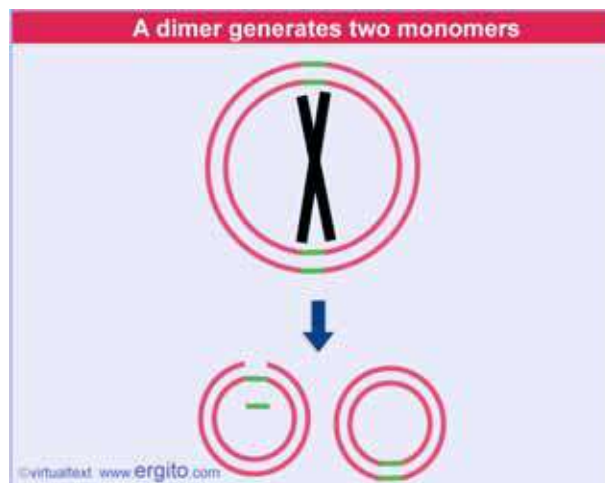

**Figure 15.1** Generalized recombination can occur at any point along the lengths of two homologous DNAs.

Specialized recombination occurs only between specific sites. The results depend on the locations of the two recombining sites. **Figure 15.2** shows that an intermolecular recombination between a circular DNA and a linear DNA inserts the circular DNA into the linear DNA. **Figure 15.3** shows that an intramolecular recombination between two sites on a circular DNA releases two smaller circular DNAs. Specialized recombination is often used to make changes such as these in the organization of DNA. The change in organization is a consequence of the locations of the recombining sites. We have a large amount of information about the enzymes that undertake specialized recombination, which are related to the topoisomerases that act to change the supercoiling of DNA in space.

**Figure 15.2** Site-specific recombination occurs between two specific sequences (identified in green). The other sequences in the two recombining DNAs are not homologous.

**Figure 15.3** Site-specific recombination can be used to generate two monomeric circles from a dimeric circle.

## RECOMBINATION AND REPAIR

### 4.15.2 Homologous recombination occurs between synapsed chromosomes

---

#### Key Terms

A **bivalent** is the structure containing all four chromatids (two representing each homologue) at the start of meiosis.

**Synapsis** describes the association of the two pairs of sister chromatids (representing homologous chromosomes) that occurs at the start of meiosis; the resulting structure is called a bivalent.

**Chromosome pairing** is the coupling of the homologous chromosomes at the start of meiosis.

The **synaptonemal complex** describes the morphological structure of synapsed chromosomes.

**Breakage and reunion** describes the mode of genetic recombination, in which two DNA duplex molecules are broken at corresponding points and then rejoined crosswise (involving formation of a length of heteroduplex DNA around the site of joining).

A **chiasma** (*pl.* chiasmata) is a site at which two homologous chromosomes appear to have exchanged material during meiosis.

#### Key Concepts

- Chromosomes must synapse (pair) in order for chiasmata to form where crossing-over occurs.
- We can correlate the stages of meiosis with the molecular events that happen to DNA.

---

Homologous recombination is a reaction between two duplexes of DNA. Its critical feature is that the enzymes responsible can use any pair of homologous sequences as substrates (although some types of sequences may be favored over others). The frequency of recombination is not constant throughout the genome, but is influenced by both global and local effects. The overall frequency may be different in oocytes and in sperm; recombination occurs twice as frequently in female as in male humans. And within the genome its frequency depends upon chromosome structure; for example, crossing-over is suppressed in the vicinity of the condensed and inactive regions of heterochromatin.

Recombination occurs during the protracted prophase of meiosis. **Figure 15.4** compares the visible progress of chromosomes through the five stages of meiotic prophase with the molecular interactions that are involved in exchanging material between duplexes of DNA.

**Figure 15.4** Recombination occurs during the first meiotic prophase. The stages of prophase are defined by the appearance of the chromosomes, each of which consists of two replicas (sister chromatids), although the duplicated state becomes visible only at the end. The molecular interactions of any individual crossing-over event involve two of the four duplex DNAs.

The beginning of meiosis is marked by the point at which individual chromosomes become visible. Each of these chromosomes has replicated previously, and consists of two sister chromatids, each of which contains a duplex DNA. The homologous chromosomes approach one another and begin to pair in one or more regions, forming **bivalents**. Pairing extends until the entire length of each chromosome is apposed with its homolog. The process is called **synapsis** or **chromosome pairing**.

When the process is completed, the chromosomes are laterally associated in the form of a **synaptonemal complex**, which has a characteristic structure in each species, although there is wide variation in the details between species.

Recombination between chromosomes involves a physical exchange of parts, usually represented as a **breakage and reunion**, in which two nonsister chromatids (each containing a duplex of DNA) have been broken and then linked each with the other. When the chromosomes begin to separate, they can be seen to be held together at discrete sites, the **chiasmata**. The number and distribution of chiasmata parallel the features of genetic crossing-over. Traditional analysis holds that a chiasma represents the crossing-over event (see **Figure 1.32**). The chiasmata remain visible when the chromosomes condense and all four chromatids become evident.

What is the molecular basis for these events? Each sister chromatid contains a single DNA duplex, so each bivalent contains 4 duplex molecules of DNA. Recombination requires a mechanism that allows the duplex DNA of one sister chromatid to interact with the duplex DNA of a sister chromatid from the other chromosome. It must be possible for this reaction to occur between any pair of corresponding sequences in the two molecules in a highly specific manner that allows material to be exchanged with precision at the level of the individual base pair.

We know of only one mechanism for nucleic acids to recognize one another on the basis of sequence: complementarity between single strands. The figure shows a general model for the involvement of single strands in recombination. The first step in providing single strands is to make a break in each DNA duplex. Then one or both of the strands of that duplex can be released. If (at least) one strand displaces the corresponding strand in the other duplex, the two duplex molecules will be specifically connected at corresponding sequences. If the strand exchange is extended, there can be more extensive connection between the duplex. And by exchanging both strands and later cutting them, it is possible to connect the parental duplex molecules by means of a crossover that corresponds to the demands of a breakage and reunion.

We cannot at this juncture relate these molecular events rigorously with the changes that are observed at the level of the chromosomes. There is no detailed information about the molecular events involved in recombination in higher eukaryotic cells (in which meiosis has been most closely observed). However, recently the isolation of mutants in yeast has made it possible to correlate some of the molecular steps with approximate stages of meiosis. Detailed information about the recombination process is available in bacteria, in which molecular activities are known that cause genetic exchange between duplex molecules. However, the bacterial reaction involves interaction between restricted regions of the genome, rather than an entire pairing of genomes. The synapsis of eukaryotic chromosomes remains the most difficult stage to explain at the molecular level.

---

## RECOMBINATION AND REPAIR

### 4.15.3 Breakage and reunion involves heteroduplex DNA

---

#### Key Terms

A **joint molecule** is a pair of DNA duplexes that are connected together through a reciprocal exchange of genetic material.

A **recombinant joint** is the point at which two recombining molecules of duplex DNA are connected (the edge of the heteroduplex region).

**Heteroduplex DNA (Hybrid DNA)** is generated by base pairing between complementary single strands derived from the different parental duplex molecules; it occurs during genetic recombination.

**Branch migration** describes the ability of a DNA strand partially paired with its complement in a duplex to extend its pairing by displacing the resident strand with which it is homologous.

**Resolution** occurs by a homologous recombination reaction between the two copies of the transposon in a cointegrate. The reaction generates the donor and target replicons, each with a copy of the transposon.

A **Holliday** structure is an intermediate structure in homologous recombination, where the two duplexes of DNA are connected by the genetic material exchanged between two of the four strands, one from each duplex. A joint molecule is said to be resolved when nicks in the structure restore two separate DNA duplexes.

**Splice recombinant** DNA results from a Holliday junction being resolved by cutting the non-exchanged strands. Both strands of DNA before the exchange point come from one chromosome; the DNA after the exchange point come from the homologous chromosome.

**Patch recombinant** DNA results from a Holliday junction being resolved by cutting the exchanged strands. The duplex is largely unchanged, except for a DNA sequence on one strand that came from the homologous chromosome.

#### Key Concepts

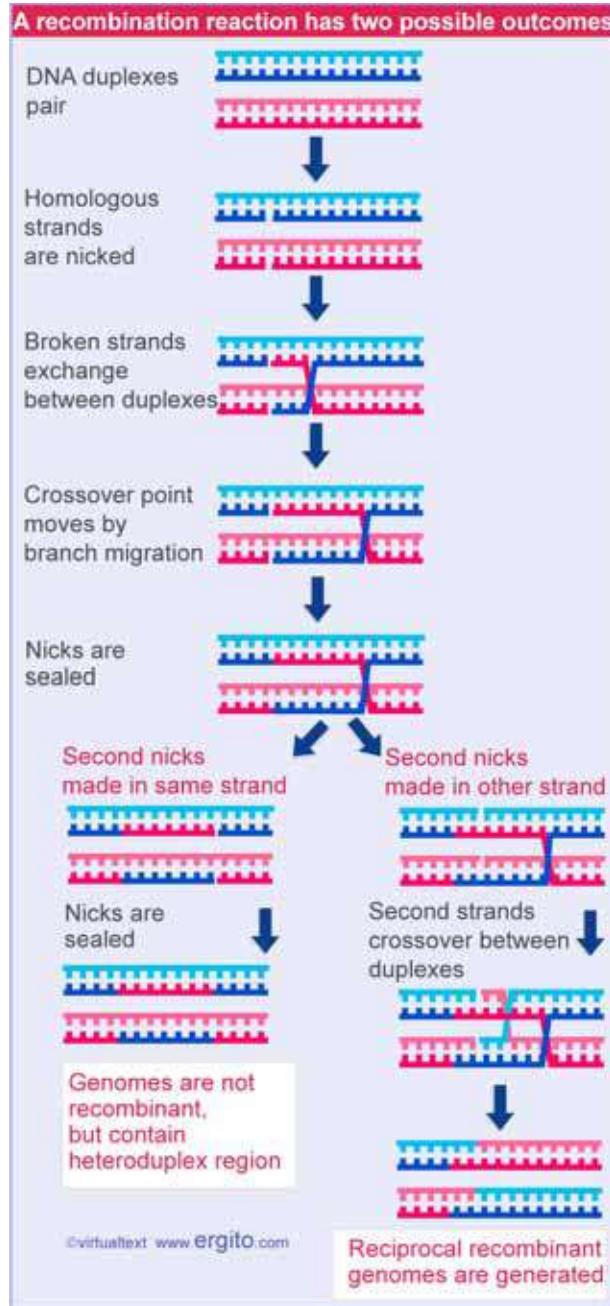

- The key event in recombination between two duplex DNA molecules is exchange of single strands.
- When a single strand from one duplex displaces its counterpart in the other duplex, it creates a branched structure.
- The exchange generates a stretch of heteroduplex DNA consisting of one strand from each parent.
- Two (reciprocal) exchanges are necessary to generate a joint molecule.
- The joint molecule is resolved into two separate duplex molecules by nicking two of the connecting strands.
- Whether recombinants are formed depends on whether the strands involved in the

original exchange or the other pair of strands are nicked during resolution.

-----

The act of connecting two duplex molecules of DNA is at the heart of the recombination process. Our molecular analysis of recombination therefore starts by expanding our view of the use of base pairing between complementary single strands in recombination. It is useful to imagine the recombination reaction in terms of single-strand exchanges (although we shall see that this is not necessarily how it is actually initiated), because the properties of the molecules created in this way are central to understanding the processes involved in recombination.

**Figure 15.5** illustrates a process that starts with breakage at the corresponding points of the homologous strands of two paired DNA duplexes. The breakage allows movement of the free ends created by the nicks. Each strand leaves its partner and crosses over to pair with its complement in the other duplex.

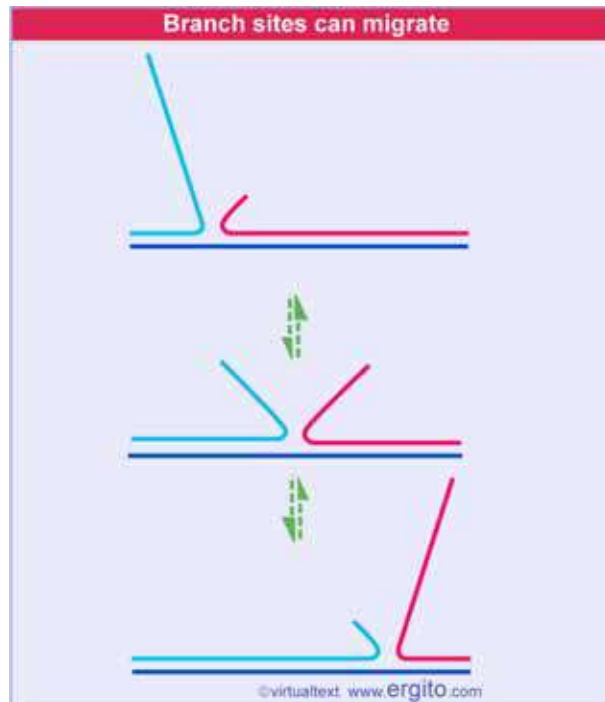

**Figure 15.5** Recombination between two paired duplex DNAs could involve reciprocal single-strand exchange, branch migration, and nicking.

The reciprocal exchange creates a connection between the two DNA duplexes. The connected pair of duplexes is called a **joint molecule**. The point at which an individual strand of DNA crosses from one duplex to the other is called the **recombinant joint**.

At the site of recombination, each duplex has a region consisting of one strand from each of the parental DNA molecules. This region is called **hybrid DNA** or

**heteroduplex DNA.**

An important feature of a recombinant joint is its ability to move along the duplex. Such mobility is called **branch migration**. **Figure 15.6** illustrates the migration of a single strand in a duplex. The branching point can migrate in either direction as one strand is displaced by the other.

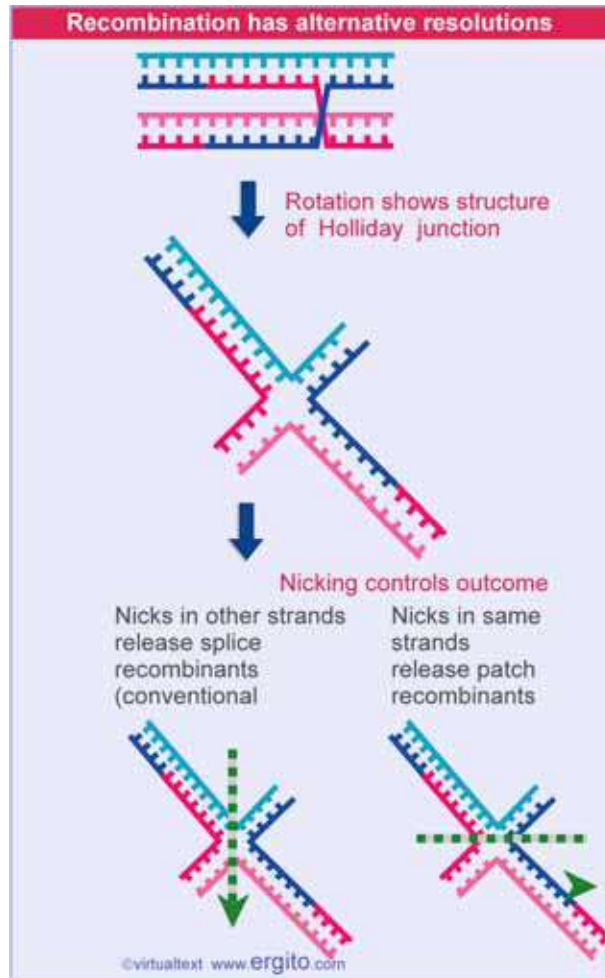

**Figure 15.6** Branch migration can occur in either direction when an unpaired single strand displaces a paired strand.

Branch migration is important for both theoretical and practical reasons. As a matter of principle, it confers a dynamic property on recombining structures. As a practical feature, its existence means that the point of branching cannot be established by examining a molecule *in vitro* (because the branch may have migrated since the molecule was isolated).

Branch migration could allow the point of crossover in the recombination intermediate to move in either direction. The rate of branch migration is uncertain, but as seen *in vitro* is probably inadequate to support the formation of extensive regions of heteroduplex DNA in natural conditions. Any extensive branch migration *in vivo* must therefore be catalyzed by a recombination enzyme.

The joint molecule formed by strand exchange must be *resolved* into two separate duplex molecules. **Resolution** requires a further pair of nicks. We can most easily visualize the outcome by viewing the joint molecule in one plane as a **Holliday** structure. This is illustrated in **Figure 15.7**, which represents the structure of **Figure 15.5** with one duplex rotated relative to the other. The outcome of the reaction depends on which pair of strands is nicked.

**Figure 15.7** Resolution of a Holliday junction can generate parental or recombinant duplexes, depending on which strands are nicked. Both types of product have a region of heteroduplex DNA.

If the nicks are made in the pair of strands that were not originally nicked (the pair that did not initiate the strand exchange), all four of the original strands have been nicked. This releases **splice recombinant** DNA molecules. The duplex of one DNA parent is covalently linked to the duplex of the other DNA parent, via a stretch of heteroduplex DNA. There has been a conventional recombination event between markers located on either side of the heteroduplex region.

If the same two strands involved in the original nicking are nicked again, the other two strands remain intact. The nicking releases the original parental duplexes, which remain intact except that each has a residuum of the event in the form of a length of heteroduplex DNA. These are called **patch recombinants**.

These alternative resolutions of the joint molecule establish the principle that *a strand exchange between duplex DNAs always leaves behind a region of heteroduplex DNA, but the exchange may or may not be accompanied by recombination of the flanking regions.*

What is the minimum length of the region required to establish the connection between the recombining duplexes? Experiments in which short homologous sequences carried by plasmids or phages are introduced into bacteria suggest that the rate of recombination is substantially reduced if the homologous region is <75 bp. This distance is appreciably longer than the ~10 bp required for association between complementary single-stranded regions, which suggests that recombination imposes demands beyond annealing of complements as such.

*This content is available online at <http://www.ergito.com/main.jsp?bcs=MBIO.4.15.3>*

---

## RECOMBINATION AND REPAIR

### 4.15.4 Double-strand breaks initiate recombination

---

#### Key Terms

A **double-strand break (DSB)** occurs when both strands of a DNA duplex are cleaved at the same site. Genetic recombination is initiated by double-strand breaks. The cell also has repair systems that act on double-strand breaks created at other times.

#### Key Concepts

- Recombination is initiated by making a double-strand break in one (recipient) DNA duplex.
- Exonuclease action generates 3' –single-stranded ends that invade the other (donor) duplex.
- New DNA synthesis replaces the material that has been degraded.
- This generates a recombinant joint molecule in which the two DNA duplexes are connected by heteroduplex DNA.

---

The general model of **Figure 15.4** shows that a break must be made in one duplex in order to generate a point from which single strands can unwind to participate in genetic exchange. Both strands of a duplex must be broken to accomplish a genetic exchange. **Figure 15.5** shows a model in which individual breaks in single strands occur successively. However, genetic exchange is actually initiated by a **double-strand break (DSB)**. The model is illustrated in **Figure 15.8** (3120; for review see 3121).

**Figure 15.8** Recombination is initiated by a double-strand break, followed by formation of single-stranded 3' ends, one of which migrates to a homologous duplex.

Recombination is initiated by an endonuclease that cleaves one of the partner DNA duplexes, the "recipient." The cut is enlarged to a gap by exonuclease action. The exonuclease(s) nibble away one strand on either side of the break, generating 3' single-stranded termini. One of the free 3' ends then invades a homologous region in the other, "donor" duplex. This is called single-strand invasion (1957). The formation of heteroduplex DNA generates a D loop, in which one strand of the donor duplex is displaced. The D loop is extended by repair DNA synthesis, using the free 3' end as a primer to generate double-stranded DNA.

Eventually the D loop becomes large enough to correspond to the entire length of the gap on the recipient chromatid. When the extruded single strand reaches the far side of the gap, the complementary single-stranded sequences anneal. Now there is heteroduplex DNA on either side of the gap, and the gap itself is represented by the single-stranded D loop.

The duplex integrity of the gapped region can be restored by repair synthesis using the 3' end on the left side of the gap as a primer. Overall, the gap has been repaired by two individual rounds of single-strand DNA synthesis.

Branch migration converts this structure into a molecule with two recombinant joints. The joints must be resolved by cutting.

If both joints are resolved in the same way, the original noncrossover molecules will be released, each with a region of altered genetic information that is a footprint of the exchange event. If the two joints are resolved in opposite ways a genetic crossover is produced.

The structure of the two-jointed molecule before it is resolved illustrates a critical difference between the double-strand break model and models that invoke only single-strand exchanges.

- Following the double-strand break, heteroduplex DNA has been formed at each end of the region involved in the exchange. Between the two heteroduplex segments is the region corresponding to the gap, which now has the sequence of the donor DNA in both molecules (**Figure 15.8**). So the arrangement of heteroduplex sequences is asymmetric, and part of one molecule has been converted to the sequence of the other (which is why the initiating chromatid is called the recipient).
- Following reciprocal single-strand exchange, each DNA duplex has heteroduplex material covering the region from the initial site of exchange to the migrating branch (**Figure 15.5**). In variants of the single-strand exchange model in which some DNA is degraded and resynthesized, the initiating chromatid is the donor of genetic information.

The double-strand break model does not reduce the importance of the formation of heteroduplex DNA, which remains the only plausible means by which two duplex molecules can interact. However, by shifting the responsibility for initiating recombination from single-strand to double-strand breaks, it influences our perspective about the ability of the cell to manipulate DNA.

The involvement of double-strand breaks seems surprising at first sight. Once a break has been made right across a DNA molecule, there is no going back. Compare the events of **Figure 15.5** and **Figure 15.8**. In the single-strand exchange model, at no point has any information been lost. But in the double-strand break model, the initial cleavage is immediately followed by loss of information. Any error in retrieving the information could be fatal. On the other hand, the very ability to retrieve lost information by resynthesizing it from another duplex provides a major safety net for the cell.

## RECOMBINATION AND REPAIR

### 4.15.5 Recombining chromosomes are connected by the synaptonemal complex

---

#### Key Terms

The **synaptonemal complex** describes the morphological structure of synapsed chromosomes.

An **axial element** is a proteinaceous structure around which the chromosomes condense at the start of synapsis.

A **lateral element** is a structure in the synaptonemal complex. It is an axial element that is aligned with the axial elements of other chromosomes.

The **central element** is a structure that lies in the middle of the synaptonemal complex, along which the lateral elements of homologous chromosomes align.

**Recombination nodules (Node)** are dense objects present on the synaptonemal complex; they may represent protein complexes involved in crossing-over.

#### Key Concepts

- During the early part of meiosis, homologous chromosomes are paired in the synaptonemal complex.
- The mass of chromatin of each homologue is separated from the other by a proteinaceous complex.

---

A basic paradox in recombination is that the parental chromosomes never seem to be in close enough contact for recombination of DNA to occur. The chromosomes enter meiosis in the form of replicated (sister chromatid) pairs, visible as a mass of chromatin. They pair to form the **synaptonemal complex**, and it has been assumed for many years that this represents some stage involved with recombination, possibly a necessary preliminary to exchange of DNA. A more recent view is that the synaptonemal complex is a consequence rather than a cause of recombination (for review see 3123). However, we have yet to define how the structure of the synaptonemal complex relates to molecular contacts between DNA molecules (for review see 985).

Synapsis begins when each chromosome (sister chromatid pair) condenses around a structure called the **axial element**, which is apparently proteinaceous. Then the axial elements of corresponding chromosomes become aligned, and the synaptonemal complex forms as a tripartite structure, in which the axial elements, now called **lateral elements**, are separated from each other by a **central element**. **Figure 15.9** shows an example.

**Figure 15.9** The synaptonemal complex brings chromosomes into juxtaposition. This example of *Neotellia* was kindly provided by M. Westergaard and D. Von Wettstein.

Each chromosome at this stage appears as a mass of chromatin bounded by a lateral element. The two lateral elements are separated from each other by a fine but dense central element. The triplet of parallel dense strands lies in a single plane that curves and twists along its axis. The distance between the homologous chromosomes is considerable in molecular terms, more than 200 nm (the diameter of DNA is 2 nm). So a major problem in understanding the role of the complex is that, although it aligns homologous chromosomes, it is far from bringing homologous DNA molecules into contact.

The only visible link between the two sides of the synaptonemal complex is provided by spherical or cylindrical structures observed in fungi and insects. They lie across the complex and are called **nodes** or **recombination nodules**; they occur with the same frequency and distribution as the chiasmata. Their name reflects the hope that they may prove to be the sites of recombination.

From mutations that affect synaptonemal complex formation, we can relate the types of proteins that are involved to its structure. **Figure 15.10** presents a molecular view of the synaptonemal complex. Its distinctive structural features are due to two groups of proteins:

**Figure 15.10** Each pair of sister chromatids has an axis made of cohesins. Loops of chromatin project from the axis. The synaptonemal complex is formed by linking together the axes via zip proteins.

- The cohesins form a single linear axis for each pair of sister chromatids from which loops of chromatin extend. This is equivalent to the lateral element of **Figure 15.9**. (The cohesins belong to a general group of proteins involved in connecting sister chromatids so they segregate properly at mitosis or meiosis; see *Molecular Biology* 6.29.19 *Cohesins hold sister chromatids together*).
- The lateral elements are connected by transverse filaments that are equivalent to the central element of **Figure 15.9**. These are formed from Zip proteins.

Mutations in proteins that are needed for lateral elements to form are found in the genes coding for cohesins. The cohesins that are used in meiosis include Smc3p (which is also used in mitosis) and Rec8p (which is specific to meiosis and is related to the mitotic cohesin Scc1p) (937). The cohesins appear to bind to specific sites along the chromosomes in both mitosis and meiosis (938). They are likely to play a structural role in chromosome segregation. At meiosis, the formation of the lateral elements may be necessary for the later stages of recombination, because although these mutations do not prevent the formation of double-strand breaks, they do block formation of recombinants.

The *zip1* mutation allows lateral elements to form and to become aligned, but they do not become closely synapsed (3136). The N-terminal domain of Zip1 protein is localized in the central element, but the C-terminal domain is localized in the lateral elements (3137). Two other proteins, Zip2 and Zip3 are also localized with Zip1. The group of Zip proteins form transverse filaments that connect the lateral elements of the sister chromatid pairs.

## RECOMBINATION AND REPAIR

### 4.15.6 The synaptonemal complex forms after double-strand breaks

---

#### Key Concepts

- Double-strand breaks that initiate recombination occur before the synaptonemal complex forms.
  - If recombination is blocked, the synaptonemal complex cannot form.
- 

There is good evidence in yeast that double strand breaks initiate recombination in both homologous and site-specific recombination. Double-strand breaks were initially implicated in the change of mating type, which involves the replacement of one sequence by another (see *Molecular Biology 4.18.8 Unidirectional transposition is initiated by the recipient MAT locus*). Double-strand breaks also occur early in meiosis at sites that provide hotspots for recombination. Their locations are not sequence-specific. They tend to occur in promoter regions and in general to coincide with more accessible regions of chromatin. The frequency of recombination declines in a gradient on one or both sides of the hotspot. The hotspot identifies the site at which recombination is initiated; and the gradient reflects the probability that the recombination events will spread from it (for review see 3122).

We may now interpret the role of double-strand breaks in molecular terms. The flush ends created by the double-strand break are rapidly converted on both sides into long 3' single-stranded ends, as shown in the model of **Figure 15.8**. A yeast mutation (*rad50*) that blocks the conversion of the flush end into the single-stranded protrusion is defective in recombination. This suggests that double-strand breaks are necessary for recombination. The gradient is determined by the declining probability that a single-stranded region will be generated as distance increases from the site of the double-strand break.

In *rad50* mutants, the 5' ends of the double-strand breaks are connected to the protein Spo11, which is homologous to the catalytic subunits of a family of type II topoisomerases. This suggests that Spo11 may be a topoisomerase-like enzyme that generates the double-strand breaks. The model for this reaction shown in **Figure 15.11** suggests that Spo11 interacts reversibly with DNA; the break is converted into a permanent structure by an interaction with another protein that dissociates the Spo11 complex. Then removal of Spo11 is followed by nuclease action. At least 9 other proteins are required to process the double-strand breaks. One group of proteins is required to convert the double-strand breaks into protruding 3' -OH single-stranded ends. Another group then enables the single-stranded ends to invade homologous duplex DNA

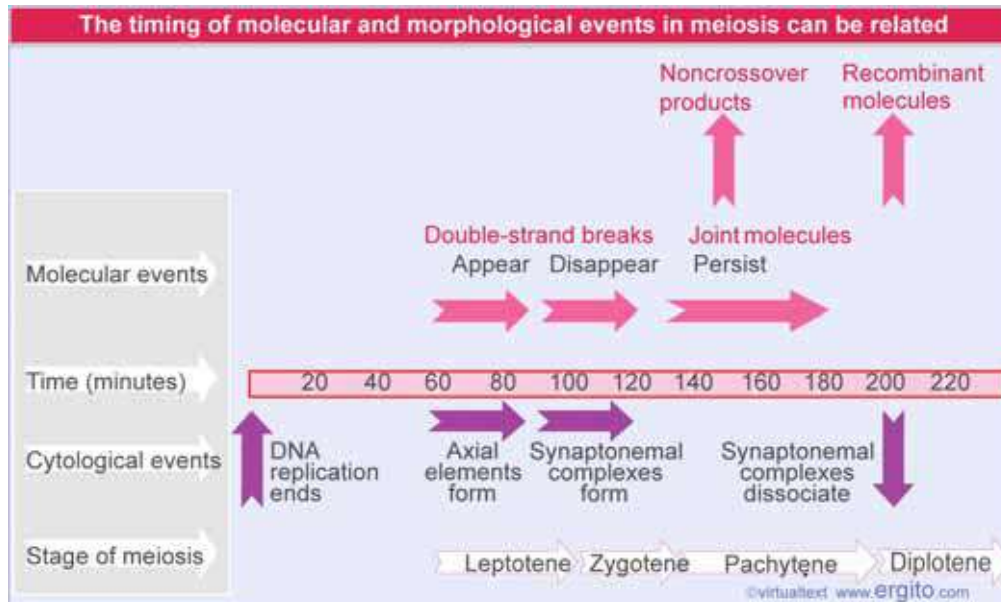

**Figure 15.11** Spo11 is covalently joined to the 5' ends of double-strand breaks.

The correlation between recombination and synaptonemal complex formation is well established, and recent work has shown that all mutations that abolish chromosome pairing in *Drosophila* or in yeast also prevent recombination (for review see 3236). The system for generating the double-strand breaks that initiate recombination is generally conserved. Spo11 homologues have been identified in several higher eukaryotes, and a mutation in the *Drosophila* gene blocks all meiotic recombination.

There are few systems in which it is possible to compare molecular and cytological events at recombination, but recently there has been progress in analyzing meiosis in *S. cerevisiae*. The relative timing of events is summarized in **Figure 15.12**.

**Figure 15.12** Double-strand breaks appear when axial elements form, and disappear during the extension of synaptonemal complexes. Joint molecules appear and persist until DNA recombinants are detected at the end of pachytene.

Double-strand breaks appear and then disappear over a 60 minute period. The first joint molecules, which are putative recombination intermediates, appear soon after the double-strand breaks disappear. The sequence of events suggests that double-strand breaks, individual pairing reactions, and formation of recombinant structures occur in succession at the same chromosomal site (3124).

Double-strand breaks appear during the period when axial elements form. They disappear during the conversion of the paired chromosomes into synaptonemal complexes. This relative timing of events suggests that formation of the synaptonemal complex results from the initiation of recombination via the introduction of double-strand breaks and their conversion into later intermediates of recombination. This idea is supported by the observation that the *rad50* mutant cannot convert axial elements into synaptonemal complexes. This refutes the traditional view of meiosis that the synaptonemal complex represents the need for chromosome pairing to precede the molecular events of recombination.

It has been difficult to determine whether recombination occurs at the stage of synapsis, because recombination is assessed by the appearance of recombinants after the completion of meiosis. However, by assessing the appearance of recombinants in yeast directly in terms of the production of DNA molecules containing diagnostic restriction sites, it has been possible to show that recombinants appear at the end of pachytene. This clearly places the completion of the recombination event after the formation of synaptonemal complexes.

So the synaptonemal complex forms after the double-strand breaks that initiate recombination, and it persists until the formation of recombinant molecules. It does not appear to be necessary for recombination as such, because some mutants that lack a normal synaptonemal complex can generate recombinants. Mutations that abolish recombination, however, also fail to develop a synaptonemal complex. This

suggests that the synaptonemal complex forms as a consequence of recombination, following chromosome pairing, and is required for later stages of meiosis.

Ever since the model for recombination via a Holliday structure was proposed, it has been assumed that the resolution of this structure gives rise to either noncrossover products (with a residual stretch of hybrid DNA) or to crossovers (recombinants), depending on which strands are involved in resolution (see **Figure 15.7**). However, recent measurements of the times of production of noncrossover and crossover molecules suggest that this may not be true (1956). Crossovers do not appear until well after the first appearance of joint molecules, but noncrossovers appear almost simultaneously with the joint molecules (see **Figure 15.12**). If both types of product were produced by the same resolution process, however, we would expect them to appear at the same time. The discrepancy in timing suggests that crossovers are produced as previously thought, by resolution of joint molecules, but that there may be some other route for the production of noncrossovers.

## RECOMBINATION AND REPAIR

### 4.15.7 Pairing and synaptonemal complex formation are independent

---

#### Key Terms

**Crossover control** limits the number of recombination events between meiotic chromosomes to 1-2 crossovers per pair of homologs.

#### Key Concepts

- Mutations can occur in either chromosome pairing or synaptonemal complex formation without affecting the other process.

---

We can distinguish the processes of pairing and synaptonemal complex formation by the effects of two mutations, each of which blocks one of the processes without affecting the other.

The *zip2* mutation allows chromosomes to pair, but they do not form synaptonemal complexes. So recognition between homologues is independent of recombination or synaptonemal complex formation.

The specificity of association between homologous chromosomes is controlled by the gene *hop2* in *S. cerevisiae*. In *hop2* mutants, normal amounts of synaptonemal complex form at meiosis, but the individual complexes contain nonhomologous chromosomes. This suggests that the formation of synaptonemal complexes as such is independent of homology (and therefore cannot be based on any extensive comparison of DNA sequences). The usual role of Hop2 is to prevent nonhomologous chromosomes from interacting.

Double-strand breaks form in the mispaired chromosomes in the synaptonemal complexes of *hop2* mutants, but they are not repaired. This suggests that, if formation of the synaptonemal complex requires double-strand breaks, it does not require any extensive reaction of these breaks with homologous DNA.

It is not clear what usually happens during pachytene, before DNA recombinants are observed. It may be that this period is occupied by the subsequent steps of recombination, involving the extension of strand exchange, DNA synthesis, and resolution.

At the next stage of meiosis (diplotene), the chromosomes shed the synaptonemal complex; then the chiasmata become visible as points at which the chromosomes are connected. This has been presumed to indicate the occurrence of a genetic exchange, but the molecular nature of a chiasma is unknown. It is possible that it represents the residuum of a completed exchange, or that it represents a connection between homologous chromosomes where a genetic exchange has not yet been resolved. Later in meiosis, the chiasmata move toward the ends of the chromosomes. This flexibility suggests that they represent some remnant of the recombination event,

rather than providing the actual intermediate.

Recombination events occur at discrete points on meiotic chromosomes, but we cannot as yet correlate their occurrence with the discrete structures that have been observed, that is, recombination nodules and chiasmata. However, insights into the molecular basis for the formation of discontinuous structures are provided by the identification of proteins involved in yeast recombination that can be localized to discrete sites. These include MSH4 (which is related to bacterial proteins involved in mismatch-repair), and Dmc1 and Rad51 (which are homologues of the *E. coli* RecA protein). The exact roles of these proteins in recombination remain to be established.

Recombination events are subject to a general control. Only a minority of interactions actually mature as crossovers, but these are distributed in such a way that typically each pair of homologues acquires only 1-2 crossovers, yet the probability of zero crossovers for a homologue pair is very low (<0.1%). This process is probably the result of a single **crossover control**, because the nonrandomness of crossovers is generally disrupted in certain mutants. Furthermore, the occurrence of recombination is necessary for progress through meiosis, and a "checkpoint" system (see *Molecular Biology 6.29 Cell cycle and growth regulation*) exists to block meiosis if recombination has not occurred. (The block is lifted when recombination has been successfully completed; this system provides a safeguard to ensure that cells do not try to segregate their chromosomes until recombination has occurred.)

---

**RECOMBINATION AND REPAIR****4.15.8 The bacterial RecBCD system is stimulated by *chi* sequences**

---

**Key Concepts**

- The RecBCD complex has nuclease and helicases activities.
  - It binds to DNA downstream of a *chi* sequence, unwinds the duplex, and degrades one strand from 3'–5' as it moves to the *chi* site.
  - The *chi* site triggers loss of the RecD subunit and nuclease activity.
- 

The nature of the events involved in exchange of sequences between DNA molecules was first described in bacterial systems. Here the recognition reaction is part and parcel of the recombination mechanism and involves restricted regions of DNA molecules rather than intact chromosomes. But the general order of molecular events is similar: a single strand from a broken molecule interacts with a partner duplex; the region of pairing is extended; and an endonuclease resolves the partner duplexes. Enzymes involved in each stage are known, although they probably represent only some of the components required for recombination.

Bacterial enzymes implicated in recombination have been identified by the occurrence of *rec*<sup>-</sup> mutations in their genes. The phenotype of *Rec*<sup>-</sup> mutants is the inability to undertake generalized recombination. Some 10-20 loci have been identified.

Bacteria do not usually exchange large amounts of duplex DNA, but there may be various routes to initiate recombination in prokaryotes. In some cases, DNA may be available with free single-stranded 3' ends: DNA may be provided in single-stranded form (as in conjugation; see *Molecular Biology 4.13.13 Conjugation transfers single-stranded DNA*); single-stranded gaps may be generated by irradiation damage; or single-stranded tails may be generated by phage genomes undergoing replication by a rolling circle. However, in circumstances involving two duplex molecules (as in recombination at meiosis in eukaryotes), single-stranded regions and 3' ends must be generated.

One mechanism for generating suitable ends has been discovered as a result of the existence of certain hotspots that stimulate recombination. They were discovered in phage lambda in the form of mutants, called *chi*, that have single base-pair changes creating sequences that stimulate recombination. These sites lead us to the role of other proteins involved in recombination.

These sites share a constant nonsymmetrical sequence of 8 bp:

5' GCTGGTGG 3'  
3' CGACCACC 5'

The *chi* sequence occurs naturally in *E. coli* DNA about once every 5-10 kb. Its absence from wild-type lambda DNA, and also from other genetic elements, shows that it is not essential for recombination.

A *chi* sequence stimulates recombination in its general vicinity, say within a distance of up to 10 kb from the site. A *chi* site can be activated by a double-strand break made several kb away on one particular side (to the right of the sequence as written above). This dependence on orientation suggests that the recombination apparatus must associate with DNA at a broken end, and then can move along the duplex only in one direction.

*chi* sites are targets for the action of an enzyme coded by the genes *recBCD*. This complex exercises several activities. It is a potent nuclease that degrades DNA, originally identified as the activity exonuclease V. It has helicase activities that can unwind duplex DNA in the presence of SSB; and it has an ATPase activity. Its role in recombination may be to provide a single-stranded region with a free 3' end.

**Figure 15.13** shows how these reactions are coordinated on a substrate DNA that has a *chi* site. RecBCD binds to DNA at a double-stranded end. Two of its subunits have helicase activities: RecD functions with 5' -3' polarity; and RecB functions with 3' -5' polarity (4182, 4183). Translocation along DNA and unwinding the double helix is initially driven by the RecD subunit. As RecBCD advances, it degrades the released single strand with the 3' end. When it reaches the *chi* site, it recognizes the top strand of the *chi* site in single-stranded form. This causes the enzyme to pause. It then cleaves the top strand of the DNA at a position between 4 and 6 bases to the right of *chi*. Recognition of the *chi* site causes the RecD subunit to dissociate or become inactivated, as a result of which the enzyme loses its nuclease activity. However, it continues to function as a helicase, now using only the RecB subunit to drive translocation, at about half the previous speed (4184). The overall result of this interaction is to generate single-stranded DNA with a 3' end at the *chi* sequence. This is a substrate for recombination.

**Figure 15.13** RecBCD nuclease approaches a *chi* sequence from one side, degrading DNA as it proceeds; at the *chi* site, it makes an endonucleolytic cut, loses RecD, and retains only the helicase activity.

## RECOMBINATION AND REPAIR

### 4.15.9 Strand-transfer proteins catalyze single-strand assimilation

---

#### Key Terms

**Single-strand assimilation (Single-strand uptake)** describes the ability of RecA protein to cause a single strand of DNA to displace its homologous strand in a duplex; that is, the single strand is assimilated into the duplex.

A **paranemic joint** describes a region in which two complementary sequences of DNA are associated side by side instead of being intertwined in a double helical structure.

A **plectonemic joint** is a region that consists of one molecule wound around another molecule, e.g. the DNA strands in a double helix.

#### Key Concepts

- RecA forms filaments with single-stranded or duplex DNA and catalyzes the ability of a single-stranded DNA with a free 3' to displace its counterpart in a DNA duplex.

---

The *E. coli* protein RecA was the first example to be discovered of a DNA strand-transfer protein. It is the paradigm for a group that includes several other bacterial and archaeal proteins, Rad51 in *S. cerevisiae*, and the higher eukaryotic protein Dmcl (for review see 3129; 3128; 3130). Analysis of yeast *rad51* mutants shows that this class of protein plays a central role in recombination. They accumulate double-strand breaks and fail to form normal synaptonemal complexes. This reinforces the idea that exchange of strands between DNA duplexes is involved in formation of the synaptonemal complex, and raises the possibility that chromosome synapsis is related to the bacterial strand assimilation reaction.

RecA in bacteria has two quite different types of activity: it can stimulate protease activity in the SOS response (see *Molecular Biology 4.15.27 RecA triggers the SOS system*); and can promote base pairing between a single strand of DNA and its complement in a duplex molecule. Both activities are activated by single-stranded DNA in the presence of ATP.

The DNA-handling activity of RecA enables a single strand to displace its homologue in a duplex in a reaction that is called **single-strand uptake** or **single-strand assimilation**. The displacement reaction can occur between DNA molecules in several configurations and has three general conditions:

- One of the DNA molecules must have a single-stranded region.
- One of the molecules must have a free 3' end.
- The single-stranded region and the 3' end must be located within a region that is

complementary between the molecules.

The reaction is illustrated in **Figure 15.14**. When a linear single strand invades a duplex, it displaces the original partner to its complement. The reaction can be followed most easily by making either the donor or recipient a circular molecule. The reaction proceeds 5'–3' along the strand whose partner is being displaced and replaced, that is, the reaction involves an exchange in which (at least) one of the exchanging strands has a free 3' end.

**Figure 15.14** RecA promotes the assimilation of invading single strands into duplex DNA so long as one of the reacting strands has a free end.

Single-strand assimilation is potentially related to the initiation of recombination. All models call for an intermediate in which one or both single strands cross over from one duplex to the other (see **Figure 15.5** and **Figure 15.8**). RecA could catalyze this stage of the reaction. In the bacterial context, RecA acts on substrates generated by RecBCD. RecBCD-mediated unwinding and cleavage can be used to generate ends that initiate the formation of heteroduplex joints. RecA can take the single strand with the 3' end that is released when RecBCD cuts at *chi*, and can use it to react with a homologous duplex sequence, thus creating a joint molecule.

All of the bacterial and archaeal proteins in the RecA family can aggregate into long filaments with single-stranded or duplex DNA. (Eukaryotic homologues of RecA do not form filaments, so the mechanics of the reaction are likely to be different in eukaryotes.) There are 6 RecA monomers per turn of the filament, which has a helical structure with a deep groove that contains the DNA. The stoichiometry of binding is 3 nucleotides (or base pairs) per RecA monomer. The DNA is held in a form that is extended 1.5 times relative to duplex B DNA, making a turn every 18.6 nucleotides (or base pairs). When duplex DNA is bound, it contacts RecA via its minor groove, leaving the major groove accessible for possible reaction with a second DNA molecule.

The interaction between two DNA molecules occurs within these filaments. When a single strand is assimilated into a duplex, the first step is for RecA to bind the single

strand into a filament. Then the duplex is incorporated, probably forming some sort of triple-stranded structure. In this system, synapsis precedes physical exchange of material, because the pairing reaction can take place even in the absence of free ends, when strand exchange is impossible. A free 3' end is required for strand exchange. The reaction occurs within the filament, and RecA remains bound to the strand that was originally single, so that at the end of the reaction RecA is bound to the duplex molecule.

All of the proteins in this family can promote the basic process of strand exchange without a requirement for energy input. However, RecA augments this activity by using ATP hydrolysis. Large amounts of ATP are hydrolyzed during the reaction. The ATP may act through an allosteric effect on RecA conformation. When bound to ATP, the DNA-binding site of RecA has a high affinity for DNA; this is needed to bind DNA and for the pairing reaction. Hydrolysis of ATP converts the binding site to low affinity, which is needed to release the heteroduplex DNA.

We can divide the reaction that RecA catalyzes between single-stranded and duplex DNA into three phases:

- a slow presynaptic phase in which RecA polymerizes on single-stranded DNA;
- a fast pairing reaction between the single-stranded DNA and its complement in the duplex to produce a heteroduplex joint;
- a slow displacement of one strand from the duplex to produce a long region of heteroduplex DNA.

The presence of SSB (single-strand binding protein) stimulates the reaction, by ensuring that the substrate lacks secondary structure. It is not clear yet how SSB and RecA both can act on the same stretch of DNA. Like SSB, RecA is required in stoichiometric amounts, which suggests that its action in strand assimilation involves binding cooperatively to DNA to form a structure related to the filament.

When a single-stranded molecule reacts with a duplex DNA, the duplex molecule becomes unwound in the region of the recombinant joint. The initial region of heteroduplex DNA may not even lie in the conventional double helical form, but could consist of the two strands associated side by side. A region of this type is called a **paranemic joint** (compared with the classical intertwined **plectonemic** relationship of strands in a double helix). A paranemic joint is unstable; further progress of the reaction requires its conversion to the double-helical form. This reaction is equivalent to removing negative supercoils and may require an enzyme that solves the unwinding/rewinding problem by making transient breaks that allow the strands to rotate about each other.

All of the reactions we have discussed so far represent only a part of the potential recombination event: the invasion of one duplex by a single strand. Two duplex molecules can interact with each other under the sponsorship of RecA, provided that one of them has a single-stranded region of at least 50 bases. The single-stranded region can take the form of a tail on a linear molecule or of a gap in a circular molecule.

The reaction between a partially duplex molecule and an entirely duplex molecule leads to the exchange of strands. An example is illustrated in **Figure 15.15**. Assimilation starts at one end of the linear molecule, where the invading single strand displaces its homologue in the duplex in the customary way. But when the reaction reaches the region that is duplex in both molecules, the invading strand unpairs from its partner, which then pairs with the other displaced strand.

**Figure 15.15** RecA-mediated strand exchange between partially duplex and entirely duplex DNA generates a joint molecule with the same structure as a recombination intermediate.

At this stage, the molecule has a structure indistinguishable from the recombinant joint in **Figure 15.7**. The reaction sponsored *in vitro* by RecA can generate Holliday junctions, which suggests that the enzyme can mediate reciprocal strand transfer. We know less about the geometry of four-strand intermediates bound by RecA, but presumably two duplex molecules can lie side by side in a way consistent with the requirements of the exchange reaction.

The biochemical reactions characterized *in vitro* leave open many possibilities for the

functions of strand-transfer proteins *in vivo*. Their involvement is triggered by the availability of a single-stranded 3' end. In bacteria, this is most likely generated when RecBCD processes a double-strand break to generate a single-stranded end. One of the main circumstances in which this is invoked may be when a replication fork stalls at a site of DNA damage (see *Molecular Biology 4.15.26 Recombination is an important mechanism to recover from replication errors*). The introduction of DNA during conjugation, when RecA is required for recombination with the host chromosome, is more closely related to conventional recombination. In yeast, double-strand breaks may be generated by DNA damage or as part of the normal process of recombination. In either case, processing of the break to generate a 3' single-stranded end is followed by loading the single strand into a filament with Rad51, followed by a search for matching duplex sequences. This can be used in both repair and recombination reactions.

**RECOMBINATION AND REPAIR****4.15.10 The Ruv system resolves Holliday junctions****Key Concepts**

- The Ruv complex acts on recombinant junctions.
- RuvA recognizes the structure of the junction and RuvB is a helicase that catalyzes branch migration.
- RuvC cleaves junctions to generate recombination intermediates.

One of the most critical steps in recombination is the resolution of the Holliday junction, which determines whether there is a reciprocal recombination or a reversal of the structure that leaves only a short stretch of hybrid DNA (see **Figure 15.5** and **Figure 15.7**). Branch migration from the exchange site (see **Figure 15.6**) determines the length of the region of hybrid DNA (with or without recombination). The proteins involved in stabilizing and resolving Holliday junctions have been identified as the products of the *Ruv* genes in *E. coli* (for review see 3131). RuvA and RuvB increase the formation of heteroduplex structures. RuvA recognizes the structure of the Holliday junction. RuvA binds to all four strands of DNA at the crossover point and forms two tetramers that sandwich the DNA. RuvB is a hexameric helicase with an ATPase activity that provides the motor for branch migration. Hexameric rings of RuvB bind around each duplex of DNA upstream of the crossover point. A diagram of the complex is shown in **Figure 15.16**.

**Figure 15.16** RuvAB is an asymmetric complex that promotes branch migration of a Holliday junction.

The RuvAB complex can cause the branch to migrate as fast as 10-20 bp/sec. A similar activity is provided by another helicase, RecG. RuvAB displaces RecA from DNA during its action. The RuvAB and RecG activities both can act on Holliday junctions, but if both are mutant, *E. coli* is completely defective in recombination activity.

The third gene, *ruvC*, codes for an endonuclease that specifically recognizes Holliday junctions. It can cleave the junctions *in vitro* to resolve recombination intermediates.

A common tetranucleotide sequence provides a hotspot for RuvC to resolve the Holliday junction. The tetranucleotide (ATTG) is asymmetric, and thus may direct resolution with regard to which pair of strands is nicked. This determines whether the outcome is patch recombinant formation (no overall recombination) or splice recombinant formation (recombination between flanking markers). Crystal structures of RuvC and other junction-resolving enzymes show that there is a little structural similarity among the group, in spite of their common function (for review see 3449).

All of this suggests that recombination uses a "resolvasome" complex that includes enzymes catalyzing branch migration as well as junction-resolving activity. It is possible that mammalian cells contain a similar complex (3460).

We may now account for the stages of recombination in *E. coli* in terms of individual proteins. **Figure 15.17** shows the events that are involved in using recombination to repair a gap in one duplex by retrieving material from the other duplex. The major caveat in applying these conclusions to recombination in eukaryotes is that bacterial recombination generally involves interaction between a fragment of DNA and a whole chromosome. It occurs as a repair reaction that is stimulated by damage to DNA, and this is not entirely equivalent to recombination between genomes at meiosis. Nonetheless, similar molecular activities are involved in manipulating DNA.

**Figure 15.17** Bacterial enzymes can catalyze all stages of recombination in the repair pathway following the production of suitable substrate DNA molecules.

Another system of resolvases has been characterized in yeast and mammals. Mutants in *S. cerevisiae mus81* are defective in recombination. Mus81 is a component of an endonuclease that resolves Holliday junctions into duplex structures (2930; 2931; 2932). The resolvase is important both in meiosis and for restarting stalled replication forks (see *Molecular Biology 4.15.26 Recombination is an important mechanism to recover from replication errors*).

## RECOMBINATION AND REPAIR

### 4.15.11 Gene conversion accounts for interallelic recombination

---

#### Key Terms

The **ascus** of a fungus contains a tetrad or octad of the (haploid) spores, representing the products of a single meiosis.

A **tetrad** describes the four (haploid) spores that result from a meiosis in yeast. (The term originally was used to describe the structure found at the beginning of meiosis, now known as a bivalent, that contains all four chromatids, produced by duplication of a homologous chromosome pair.)

**Postmeiotic segregation** describes the segregation of two strands of a duplex DNA that bear different information (created by heteroduplex formation during meiosis) when a subsequent replication allows the strands to separate.

**Gene conversion** is the alteration of one strand of a heteroduplex DNA to make it complementary with the other strand at any position(s) where there were mismatched bases.

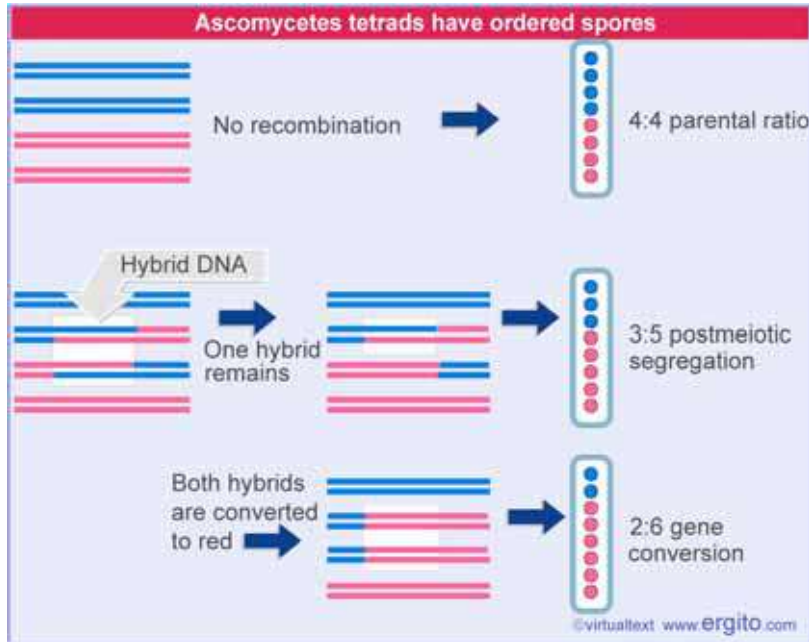

#### Key Concepts

- Heteroduplex DNA that is created by recombination can have mismatched sequences where the recombining alleles are not identical.
- Repair systems may remove mismatches by changing one of the strands so its sequence is complementary to the other.

---

The involvement of heteroduplex DNA explains the characteristics of recombination between alleles; indeed, allelic recombination provided the impetus for the development of the heteroduplex model. When recombination between alleles was discovered, the natural assumption was that it takes place by the same mechanism of reciprocal recombination that applies to more distant loci. That is to say that an individual breakage and reunion event occurs within the locus to generate a reciprocal pair of recombinant chromosomes. However, in the close quarters of a single gene, the formation of heteroduplex DNA itself is usually responsible for the recombination event.

Individual recombination events can be studied in the Ascomycetes fungi, because the products of a single meiosis are held together in a large cell, the **ascus**, also sometimes called the **tetrad** (see *Genetics 2.7.6 S. cerevisiae meiotic growth and tetrad analysis*). Even better, in some fungi, the four haploid nuclei produced by meiosis are arranged in a linear order. Actually, a mitosis occurs after the production of these four nuclei, giving a linear series of eight haploid nuclei. **Figure 15.18** shows that each of these nuclei effectively represents the genetic character of one of the eight strands of the four chromosomes produced by the meiosis.

**Figure 15.18** Spore formation in the *Ascomycetes* allows determination of the genetic constitution of each of the DNA strands involved in meiosis.

Meiosis in a heterozygote should generate four copies of each allele. This is seen in the majority of spores. But there are some spores with abnormal ratios. They are explained by the formation and correction of heteroduplex DNA in the region in which the alleles differ. The figure illustrates a recombination event in which a length of hybrid DNA occurs on one of the four meiotic chromosomes, a possible outcome of recombination initiated by a double-strand break.

Suppose that two alleles differ by a single point mutation. When a strand exchange occurs to generate heteroduplex DNA, the two strands of the heteroduplex will be mispaired at the site of mutation. So each strand of DNA carries different genetic information. If no change is made in the sequence, the strands separate at the ensuing replication, each giving rise to a duplex that perpetuates its information. This event is called **postmeiotic segregation**, because it reflects the separation of DNA strands after meiosis. Its importance is that it demonstrates directly the existence of heteroduplex DNA in recombining alleles.

Another effect is seen when examining recombination between alleles: the proportions of the alleles differ from the initial 4:4 ratio. This effect is called **gene conversion**. It describes a nonreciprocal transfer of information from one chromatid to another.

Gene conversion results from exchange of strands between DNA molecules, and the change in sequence may have either of two causes at the molecular level:

- As indicated by the double-strand break model in **Figure 15.8**, one DNA duplex may act as a donor of genetic information that directly replaces the corresponding sequences in the recipient duplex by a process of gap generation,

strand exchange, and gap filling.

- As part of the exchange process, heteroduplex DNA is generated when a single strand from one duplex pairs with its complement in the other duplex. Repair systems recognize mispaired bases in heteroduplex DNA, and may then excise and replace one of the strands to restore complementarity. Such an event converts the strand of DNA representing one allele into the sequence of the other allele.

Gene conversion does not depend on crossing-over, but is correlated with it. A large proportion of the aberrant asci show genetic recombination between two markers on either side of a site of interallelic gene conversion. This is exactly what would be predicted if the aberrant ratios result from initiation of the recombination process as shown in **Figure 15.5**, but with an approximately equal probability of resolving the structure with or without recombination (as indicated in **Figure 15.7**). The implication is that fungal chromosomes initiate crossing-over about twice as often as would be expected from the measured frequency of recombination between distant genes.

Various biases are seen when recombination is examined at the molecular level. Either direction of gene conversion may be equally likely, or allele-specific effects may create a preference for one direction. Gradients of recombination may fall away from hotspots. We now know that hotspots represent sites at which double-strand breaks are initiated, and the gradient is correlated with the extent to which the gap at the hotspot is enlarged and converted to long single-stranded ends (see *Molecular Biology 4.15.6 The synaptonemal complex forms after double-strand breaks*).

Some information about the extent of gene conversion is provided by the sequences of members of gene clusters. Usually, the products of a recombination event will separate and become unavailable for analysis at the level of DNA sequence. However, when a chromosome carries two (non-allelic) genes that are related, they may recombine by an "unequal crossing-over" event (see *Molecular Biology 1.4.7 Unequal crossing-over rearranges gene clusters*). All we need to note for now is that a heteroduplex may be formed between the two nonallelic genes. Gene conversion effectively converts one of the nonallelic genes to the sequence of the other.

The presence of more than one gene copy on the same chromosome provides a footprint to trace these events. For example, if heteroduplex formation and gene conversion occurred over part of one gene, this part may have a sequence identical with or very closely related to the other gene, while the remaining part shows more divergence. Available sequences suggest that gene conversion events may extend for considerable distances, up to a few thousand bases.

## RECOMBINATION AND REPAIR

### 4.15.12 Supercoiling affects the structure of DNA

---

#### Key Terms

**Supercoiling** describes the coiling of a closed duplex DNA in space so that it crosses over its own axis.

The **linking number** is the number of times the two strands of a closed DNA duplex cross over each other.

**Topological isomers** are molecules of DNA that are identical except for a difference in linking number.

The **twisting number** of a DNA is the number of base pairs divided by the number of base pairs per turn of the double helix.

The **writhing number** is the number of times a duplex axis crosses over itself in space.

#### Key Concepts

- Supercoiling occurs only in a closed DNA with no free ends.
- A closed DNA can be a circular DNA molecule or a linear molecule where both ends are anchored in a protein structure.
- Any closed DNA molecule has a linking number, which is the sum of the twisting number and writhing number.
- Turns can be repartitioned between the twisting number and writhing number, so that a change in the structure of the double helix can compensate for a change in its coiling in space.
- The linking number can be changed only by breaking and making bonds in DNA.

---

The winding of the two strands of DNA around each other in the double helical structure makes it possible to change the structure by influencing its conformation in space. If the two ends of a DNA molecule are fixed, the double helix can be wound around itself in space. This is called **supercoiling**. The effect can be imagined like a rubber band twisted around itself. The simplest example of a DNA with no fixed ends is a circular molecule. The effect of supercoiling can be seen by comparing the nonsupercoiled circular DNA lying flat in **Figure 15.19** with the supercoiled circular molecule that forms a twisted and therefore more condensed shape.

**Figure 15.19** Linear DNA is extended, a circular DNA remains extended if it is relaxed (nonsupercoiled), but a supercoiled DNA has a twisted and condensed form.

The consequences of supercoiling depend on whether the DNA is twisted around itself in the same sense as the two strands within the double helix (clockwise) or in the opposite sense. Twisting in the same sense produces *positive supercoiling*. This has the effect of causing the DNA strands to wound around one another more tightly, so that there are more base pairs per turn. Twisting in the opposite sense produces *negative supercoiling*. This causes the DNA strands to be twisted around one another less tightly, so there are fewer base pairs per turn. Negative supercoiling can be thought of as creating tension in the DNA that is relieved by unwinding the double helix. The ultimate effect of negative supercoiling is to generate a region in which the two strands of DNA have separated – formally there are zero base pairs per turn.

Topological manipulation of DNA is a central aspect of all its functional activities – recombination, replication, and transcription – as well as of the organization of higher-order structure. All synthetic activities involving double-stranded DNA require the strands to separate. However, the strands do not simply lie side by side; they are intertwined. Their separation therefore requires the strands to rotate about each other in space. Some possibilities for the unwinding reaction are illustrated in **Figure 15.20**.

**Figure 15.20** Separation of the strands of a DNA double helix could be achieved in several ways.

We might envisage the structure of DNA in terms of a free end that would allow the strands to rotate about the axis of the double helix for unwinding. Given the length of the double helix, however, this would involve the separating strands in a considerable amount of flailing about, which seems unlikely in the confines of the cell.

A similar result is achieved by placing an apparatus to control the rotation at the free end. However, the effect must be transmitted over a considerable distance, again involving the rotation of an unreasonable length of material.

Consider the effects of separating the two strands in a molecule whose ends are not free to rotate. When two intertwined strands are pulled apart from one end, the result is to increase their winding about each other farther along the molecule. The problem can be overcome by introducing a transient nick in one strand. An internal free end allows the nicked strand to rotate about the intact strand, after which the nick can be sealed. Each repetition of the nicking and sealing reaction releases one superhelical turn.

A closed molecule of DNA can be characterized by its **linking number**, the number

of times one strand crosses over the other in space. Closed DNA molecules of identical sequence may have different linking numbers, reflecting different degrees of supercoiling. Molecules of DNA that are the same except for their linking numbers are called **topological isomers**.

The linking number is made up of two components: the writhing number (W) and the twisting number (T).

The **twisting number**, T, is a property of the double helical structure itself, representing the rotation of one strand about the other. It represents the total number of turns of the duplex. It is determined by the number of base pairs per turn. For a relaxed closed circular DNA lying flat in a plane, the twist is the total number of base pairs divided by the number of base pairs per turn.

The **writhing number**, W, represents the turning of the axis of the duplex in space. It corresponds to the intuitive concept of supercoiling, but does not have exactly the same quantitative definition or measurement. For a relaxed molecule,  $W = 0$ , and the linking number equals the twist.

We are often concerned with the change in linking number,  $\Delta L$ , given by the equation

$$\Delta L = \Delta W + \Delta T$$

The equation states that any change in the total number of revolutions of one DNA strand about the other can be expressed as the sum of the changes of the coiling of the duplex axis in space ( $\Delta W$ ) and changes in the screwing of the double helix itself ( $\Delta T$ ). In a free DNA molecule, W and T are freely adjustable, and any  $\Delta L$  (change in linking number) is likely to be expressed by a change in W, that is, by a change in supercoiling.

A decrease in linking number, that is, a change of  $-\Delta L$ , corresponds to the introduction of some combination of negative supercoiling and/or underwinding. An increase in linking number, measured as a change of  $+\Delta L$ , corresponds to a decrease in negative supercoiling/underwinding.

We can describe the change in state of any DNA by the specific linking difference,  $\sigma = \Delta L/L_0$ , where  $L_0$  is the linking number when the DNA is relaxed. If all of the change in linking number is due to change in W (that is,  $\Delta T = 0$ ), the specific linking difference equals the supercoiling density. In effect,  $\sigma$  as defined in terms of  $\Delta L/L_0$  can be assumed to correspond to superhelix density so long as the structure of the double helix itself remains constant.

The critical feature about the use of the linking number is that this parameter is an invariant property of any individual closed DNA molecule. The linking number cannot be changed by any deformation short of one that involves the breaking and rejoining of strands. A circular molecule with a particular linking number can express it in terms of different combinations of T and W, but cannot change their sum so long as the strands are unbroken. (In fact, the partition of L between T and W prevents the assignment of fixed values for the latter parameters for a DNA molecule in solution.)

The linking number is related to the actual enzymatic events by which changes are made in the topology of DNA. The linking number of a particular closed molecule can be changed only by breaking a strand or strands, using the free end to rotate one strand about the other, and rejoining the broken ends. When an enzyme performs such an action, it must change the linking number by an integer; this value can be determined as a characteristic of the reaction. Then we can consider the effects of this change in terms of  $\Delta W$  and  $\Delta T$ .

*This content is available online at <http://www.ergito.com/main.jsp?bcs=MBIO.4.15.12>*

## RECOMBINATION AND REPAIR

### 4.15.13 Topoisomerases relax or introduce supercoils in DNA

---

#### Key Terms

A **type I topoisomerase** is an enzyme that changes the topology of DNA by nicking and resealing one strand of DNA.

A **type II topoisomerase** is an enzyme that changes the topology of DNA by nicking and resealing both strands of DNA.

#### Key Concepts

- Topoisomerases change the linking number by breaking bonds in DNA, changing the conformation of the double helix in space, and remaking the bonds.
- Type I enzymes act by breaking a single strand of DNA; type II enzymes act by making double-strand breaks.

---

Changes in the topology of DNA can be caused in several ways. **Figure 15.21** shows some examples. In order to start replication or transcription, the two strands of DNA must be unwound. In the case of replication, the two strands separate permanently, and each reforms a duplex with the newly-synthesized daughter strand. In the case of transcription, the movement of RNA polymerase creates a region of positive supercoiling in front and a region of negative supercoiling behind the enzyme. This must be resolved before the positive supercoils impede the movement of the enzyme (see *Molecular Biology 3.9.15 Supercoiling is an important feature of transcription*). When a circular DNA molecule is replicated, the circular products may be catenated, with one passed through the other. They must be separated in order for the daughter molecules to segregate to separate daughter cells. Yet another situation in which supercoiling is important is the folding of the DNA thread into a chain of nucleosomes in the eukaryotic nucleus (see *Molecular Biology 5.20.6 The periodicity of DNA changes on the nucleosome*). All of the situations are resolved by the actions of topoisomerases.

**Figure 15.21** The topological structure of DNA is changed during replication and transcription. Strand separation for replication (or transcription) requires a base turn of DNA to be unwound. Transcription creates positive supercoils ahead of the RNA polymerase. Replication of a circular template produces two catenated daughter templates.

**DNA topoisomerases** are enzymes that catalyze changes in the topology of DNA by transiently breaking one or both strands of DNA, passing the unbroken strand(s) through the gap, and then resealing the gap (for review see 2280). The ends that are generated by the break are never free, but are manipulated exclusively within the confines of the enzyme – in fact, they are covalently linked to the enzyme. Topoisomerases act on DNA irrespective of its sequence, but some enzymes involved in site-specific recombination function in the same way and also fit the definition of topoisomerases (see *Molecular Biology 4.15.18 Site-specific recombination resembles topoisomerase activity*).

Topoisomerases are divided into two classes, according to the nature of the mechanisms they employ (for review see 3434). **Type I topoisomerases** act by making a transient break in one strand of DNA. **Type II topoisomerases** act by introducing a transient double-strand break. Topoisomerases in general vary with regard to the types of topological change they introduce. Some topoisomerases can relax (remove) only negative supercoils from DNA; others can relax both negative and positive supercoils. Enzymes that can introduce negative supercoils are called gyrases; those that can introduce positive supercoils are called reverse gyrases.

There are four topoisomerase enzymes in *E. coli*, called topoisomerase I, III, IV and

DNA gyrase. DNA topoisomerase I and III are type I enzymes. Gyrase and DNA topoisomerase IV are type II enzymes. Each of the four enzymes is important in one or more of the situations described in **Figure 15.21**:

- The overall level of negative supercoiling in the bacterial nucleoid is the result of a balance between the introduction of supercoils by gyrase and their relaxation by topoisomerases I and IV. This is a crucial aspect of nucleoid structure (see *Molecular Biology 5.19.4 The bacterial genome is supercoiled*), and affects initiation of transcription at certain promoters (see *Molecular Biology 3.9.15 Supercoiling is an important feature of transcription*).
- The same enzymes are involved in resolving the problems created by transcription; gyrase converts the positive supercoils that are generated ahead of RNA polymerase into negative supercoils, and topoisomerases I and IV remove the negative supercoils that are left behind the enzyme. Similar, but more complicated, effects occur during replication, and the enzymes have similar roles in dealing with them.
- As replication proceeds, the daughter duplexes can become twisted around one another, in a stage known as precatenation. The precatenanes are removed by topoisomerase IV, which also decatenates any catenated genomes that are left at the end of replication. The functions of topoisomerase III partially overlap those of topoisomerase IV.

The enzymes in eukaryotes follow the same principles, although the detailed division of responsibilities may be different. They do not show sequence or structural similarity with the prokaryotic enzymes. Most eukaryotes contain a single topoisomerase I enzyme that is required both for replication fork movement and for relaxing supercoils generated by transcription. A topoisomerase II enzyme(s) is required to unlink chromosomes following replication. Other individual topoisomerases have been implicated in recombination and repair activities.

## RECOMBINATION AND REPAIR

### 4.15.14 Topoisomerases break and reseal strands

---

#### Key Terms

**Single-strand passage** is a reaction catalyzed by type I topoisomerase in which one section of single-stranded DNA is passed through another strand.

A **knot** in the DNA is an entangled region that cannot be resolved without cutting and rearranging the DNA.

To **catenate** is to link together two circular molecules as in a chain.

#### Key Concepts

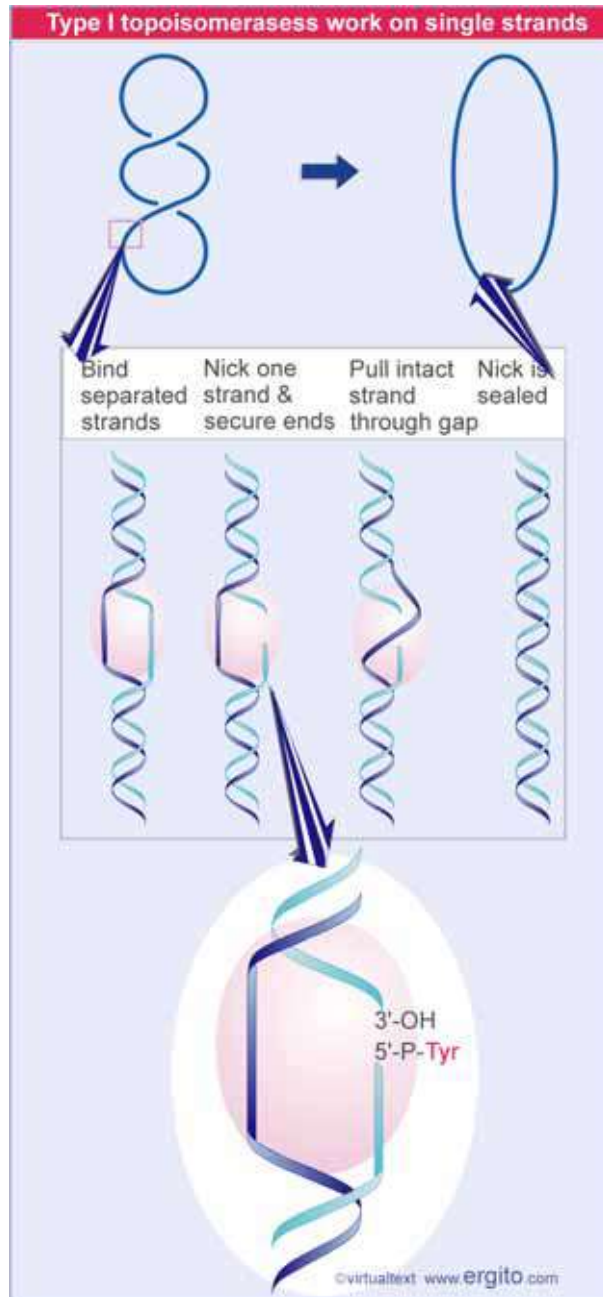

- Type I topoisomerases function by forming a covalent bond to one of the broken ends, moving one strand around the other, and then transferring the bound end to the other broken end. Because bonds are conserved, no input of energy is required.

---

The common action for all topoisomerases is to link one end of each broken strand to a tyrosine residue in the enzyme (for review see 2280). A type I enzyme links to the single broken strand; a type II enzyme links to one end of each broken strand. The topoisomerases are further divided into the A and B groups according to whether the linkage is to a 5' phosphate or 3' phosphate. The use of the transient phosphodiester-tyrosine bond suggests a mechanism for the action of the enzyme; it transfers a phosphodiester bond(s) in DNA to the protein, manipulates the structure of one or both DNA strands, and then rejoins the bond(s) in the original strand.

The *E. coli* enzymes are all of type A, using links to 5' phosphate. This is the general pattern for bacteria, where there are almost no type B topoisomerases. All four possible types of topoisomerase (IA, IB, IIA, IIB) are found in eukaryotes.

A model for the action of topoisomerase IA is illustrated in **Figure 15.22**. The enzyme binds to a region in which duplex DNA becomes separated into its single strands; then it breaks one strand, pulls the other strand through the gap, and finally seals the gap. The transfer of bonds from nucleic acid to protein explains how the enzyme can function without requiring any input of energy. There has been no irreversible hydrolysis of bonds; their energy has been conserved through the transfer reactions. The model is supported by the crystal structure of the enzyme (2460).

**Figure 15.22** Bacterial type I topoisomerases recognize partially unwound segments of DNA and pass one strand through a break made in the other.

The reaction changes the linking number in steps of 1. Each time one strand is passed through the break in the other, there is a  $\Delta L$  of +1. The figure illustrates the enzyme activity in terms of moving the individual strands. In a free supercoiled molecule, the interchangeability of W and T should let the change in linking number be taken up by a change of  $\Delta W = +1$ , that is, by one less turn of negative supercoiling.

The reaction is equivalent to the rotation illustrated in the bottom part of **Figure**

**15.20**, with the restriction that the enzyme limits the reaction to a single-strand passage per event. (By contrast, the introduction of a nick in a supercoiled molecule allows free strand rotation to relieve all the tension by multiple rotations.)

The type I topoisomerase also can pass one segment of a single-stranded DNA through another. This **single-strand passage** reaction can introduce **knots** in DNA and can **catenate** two circular molecules so that they are connected like links on a chain. We do not understand the uses (if any) to which these reactions are put *in vivo*.

Type II topoisomerases generally relax both negative and positive supercoils. The reaction requires ATP, with one ATP hydrolyzed for each catalytic event. As illustrated in **Figure 15.23**, the reaction is mediated by making a double-stranded break in one DNA duplex. The double-strand is cleaved with a 4-base stagger between the ends, and each subunit of the dimeric enzyme attaches to a protruding broken end. Then another duplex region is passed through the break. The ATP is used in the following religation/release step, when the ends are rejoined and the DNA duplexes are released. This is why inhibiting the ATPase activity of the enzyme results in a "cleavable complex" that contains broken DNA.

**Figure 15.23** Type II topoisomerases can pass a duplex DNA through a double-strand break in another duplex.

A formal consequence of two-strand transfer is that the linking number is always changed in multiples of two. The topoisomerase II activity can be used also to introduce or resolve catenated duplex circles and knotted molecules.

The reaction probably represents a nonspecific recognition of duplex DNA in which the enzyme binds any two double-stranded segments that cross each other. The hydrolysis of ATP may be used to drive the enzyme through conformational changes that provide the force needed to push one DNA duplex through the break made in the other. Because of the topology of supercoiled DNA, the relationship of the crossing segments allows supercoils to be removed from either positively or negatively supercoiled circles.

## RECOMBINATION AND REPAIR

### 4.15.15 Gyrase functions by coil inversion

---

#### Key Terms

The **sign inversion** model describes the mechanism of DNA gyrase. DNA gyrase binds a positive supercoil (inducing a compensatory negative supercoil elsewhere on the closed circular DNA), breaks both strands in one duplex, passes the other duplex through, and reseals the strands.

**Enzyme turnover** is the process through which the enzyme returns to its original shape, enabling the enzyme to catalyze another reaction.

#### Key Concepts

- *E. coli* gyrase is a type II topoisomerase that used hydrolysis of ATP to provide energy to introduce negative supercoils into DNA.

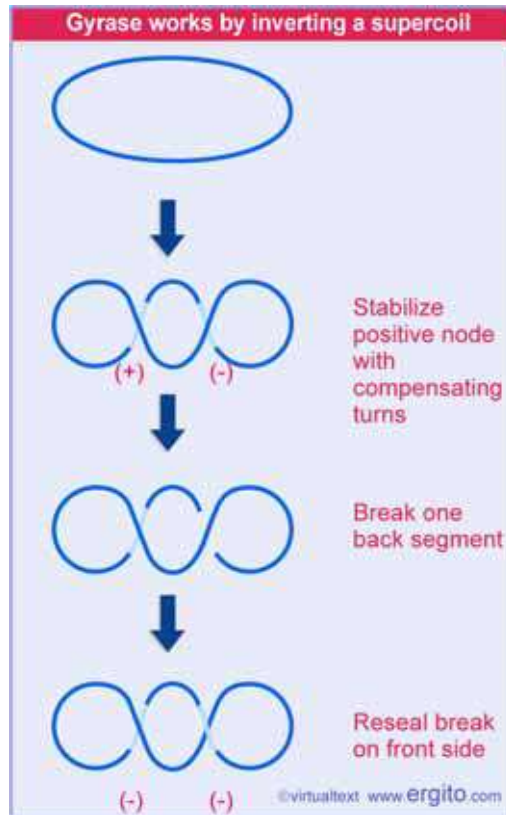

---

Bacterial DNA gyrase is a topoisomerase of type II that is able to introduce negative supercoils into a relaxed closed circular molecule. DNA gyrase binds to a circular DNA duplex and supercoils it processively and catalytically: it continues to introduce supercoils into the same DNA molecule. One molecule of DNA gyrase can introduce ~100 supercoils per minute.

The supercoiled form of DNA has a higher free energy than the relaxed form, and the energy needed to accomplish the conversion is supplied by the hydrolysis of ATP. In the absence of ATP, the gyrase can relax negative but not positive supercoils, although the rate is more than 10× slower than the rate of introducing supercoils.

The *E. coli* DNA gyrase is a tetramer consisting of two types of subunit, each of which is a target for antibiotics (the most often used being nalidixic acid which acts on GyrA, and novobiocin which acts on GyrB). The drugs inhibit replication, which suggests that DNA gyrase is necessary for DNA synthesis to proceed. Mutations that confer resistance to the antibiotics identify the loci that code for the subunits.

Gyrase binds its DNA substrate around the outside of the protein tetramer. Gyrase protects ~140 bp of DNA from digestion by micrococcal nuclease. The **sign inversion** model for gyrase action is illustrated in **Figure 15.24**. The enzyme binds the DNA in a crossover configuration that is equivalent to a positive supercoil. This induces a compensating negative supercoil in the unbound DNA. Then the enzyme breaks the double strand at the crossover of the positive supercoil, passes the other duplex through, and seals the break.

**Figure 15.24** DNA gyrase may introduce negative supercoils in duplex DNA by inverting a positive supercoil.

The reaction directly inverts the sign of the supercoil: it has been converted from a +1 turn to a -1 turn. So the linking number has changed by  $\Delta L = -2$ , conforming with the demand that all events involving double-strand passage must change the linking number by a multiple of two.

Gyrase then releases one of the crossing segments of the (now negative) bound supercoil; this allows the negative turns to redistribute along DNA (as change in either T or W or both), and the cycle begins again. The same type of topological manipulation is responsible for catenation and knotting.

On releasing the inverted supercoil, the conformation of gyrase changes. For the enzyme to undertake another cycle of supercoiling, its original conformation must be restored. This process is called **enzyme turnover**. It is thought to be driven by the hydrolysis of ATP, since the replacement of ATP by an analog that cannot be hydrolyzed allows gyrase to introduce only one inversion (-2 supercoils) per substrate. So the enzyme does not need ATP for the supercoiling reaction, but does need it to undertake a second cycle. Novobiocin interferes with the ATP-dependent reactions of gyrase, by preventing ATP from binding to the B subunit.

The ATP-independent relaxation reaction is inhibited by nalidixic acid. This implicates the A subunit in the breakage and reunion reaction. Treating gyrase with nalidixic acid allows DNA to be recovered in the form of fragments generated by a

staggered cleavage across the duplex. The termini all possess a free 3' -OH group and a 4-base 5' single-strand extension covalently linked to the A subunit. The covalent linkage retains the energy of the phosphate bond; this can be used to drive the sealing reaction, explaining why gyrase can undertake relaxation without ATP. The sites of cleavage are fairly specific, occurring about once every 100 bp.

## RECOMBINATION AND REPAIR

### 4.15.16 Specialized recombination involves specific sites

---

#### Key Terms

**Site-specific recombination (Specialized recombination)** occurs between two specific sequences, as in phage integration/excision or resolution of cointegrate structures during transposition.

**Prophage** is a phage genome covalently integrated as a linear part of the bacterial chromosome.

**Integration** of viral or another DNA sequence describes its insertion into a host genome as a region covalently linked on either side to the host sequences.

The **excision** step in an excision-repair system consists of removing a single-stranded stretch of DNA by the action of a 5' -3' exonuclease.

A **secondary attachment site** is a locus on the bacterial chromosome into which phage lambda integrate inefficiently because the site resembles the *att* site.

The **core** sequence is the segment of DNA that is common to the attachment sites on both the phage lambda and bacterial genomes. It is the location of the recombination event that allows phage lambda to integrate.

The **arms** of a lambda phage attachment site are the sequences flanking the core region where the recombination event occurs.

#### Key Concepts

- Specialized recombination involves reaction between specific sites that are not necessarily homologous.
- Phage lambda integrates into the bacterial chromosome by recombination between a site on the phage and the *att* site on the *E. coli* chromosome.
- The phage is excised from the chromosome by recombination between the sites at the end of the linear prophage.
- Phage lambda *int* codes for an integrase that catalyzes the integration reaction.

---

Specialized recombination involves a reaction between two specific sites. The target sites are short, typically in a 14-50 bp length range. In some cases the two sites have the same sequence, but in other cases they are nonhomologous. The reaction is used to insert a free phage DNA into the bacterial chromosome or to excise an integrated phage DNA from the chromosome, and in this case the two recombining sequences are different from one another. It is also used before division to regenerate monomeric circular chromosomes from a dimer that has been created by a generalized recombination event (see *Molecular Biology 4.13.19 Chromosomal segregation may require site-specific recombination*). In this case the recombining sequences are identical.

The enzymes that catalyze site-specific recombination are generally called recombinases, and >100 of them are now known (2921). Those involved in phage integration or related to these enzymes are also known as the integrase family. Prominent members of the integrase family are the prototype Int from phage lambda, Cre from phage P1, and the yeast FLP enzyme (which catalyzes a chromosomal inversion) (for review see 2922).

The classic model for **site-specific recombination** is illustrated by phage lambda. The conversion of lambda DNA between its different life forms involves two types of event. The pattern of gene expression is regulated as described in *Molecular Biology 3.12 Phage strategies*. And the physical condition of the DNA is different in the lysogenic and lytic states:

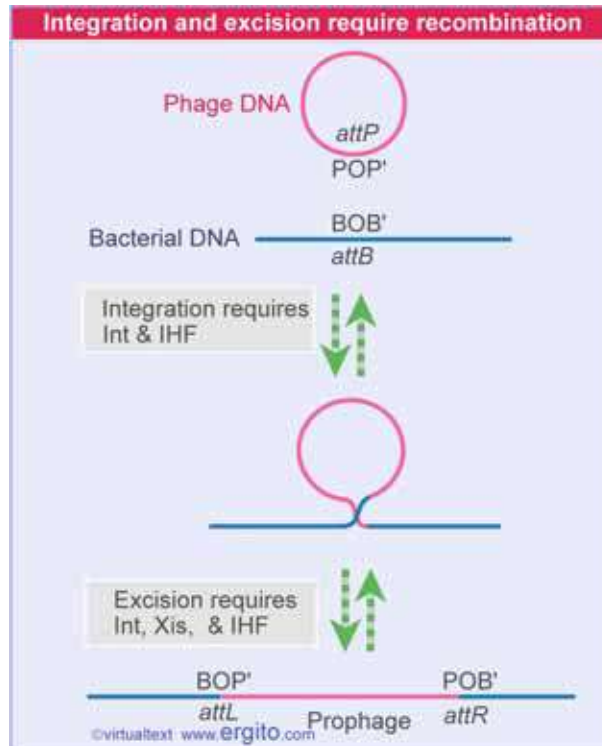

- In the lytic lifestyle, lambda DNA exists as an independent, circular molecule in the infected bacterium.
- In the lysogenic state, the phage DNA is an integral part of the bacterial chromosome (called **prophage**).

Transition between these states involves site-specific recombination:

- To enter the lysogenic condition, free lambda DNA must be inserted into the host DNA. This is called **integration**.
- To be released from lysogeny into the lytic cycle, prophage DNA must be released from the chromosome. This is called **excision**.

Integration and excision occur by recombination at specific loci on the bacterial and phage DNAs called attachment (**att**) sites. The attachment site on the bacterial chromosome is called  $att\lambda$  in bacterial genetics. The locus is defined by mutations that prevent integration of lambda; it is occupied by prophage  $\lambda$  in lysogenic strains. When the  $att\lambda$  site is deleted from the *E. coli* chromosome, an infecting lambda phage can establish lysogeny by integrating elsewhere, although the efficiency of the reaction is <0.1% of the frequency of integration at  $att\lambda$ . This inefficient integration occurs at **secondary attachment sites**, which resemble the authentic  $att$  sequences.

For describing the integration/excision reactions, the bacterial attachment site ( $att\lambda$ ) is called  $attB$ , consisting of the sequence components  $BOB'$ . The attachment site on the phage,  $attP$ , consists of the components  $POP'$ . **Figure 15.25** outlines the recombination reaction between these sites. The sequence O is common to  $attB$  and  $attP$ . It is called the **core** sequence; and the recombination event occurs within it. The flanking regions  $B$ ,  $B'$  and  $P$ ,  $P'$  are referred to as the **arms**; each is distinct in sequence. Because the phage DNA is circular, the recombination event inserts it into the bacterial chromosome as a linear sequence. The prophage is bounded by two new  $att$  sites, the products of the recombination, called  $attL$  and  $attR$ .

**Figure 15.25** Circular phage DNA is converted to an integrated prophage by a reciprocal recombination between *attP* and *attB*; the prophage is excised by reciprocal recombination between *attL* and *attR*.

An important consequence of the constitution of the *att* sites is that the integration and excision reactions do not involve the same pair of reacting sequences. Integration requires recognition between *attP* and *attB*; while excision requires recognition between *attL* and *attR*. The directional character of site-specific recombination is controlled by the identity of the recombining sites.

Although the recombination event is reversible, different conditions prevail for each direction of the reaction. This is an important feature in the life of the phage, since it offers a means to ensure that an integration event is not immediately reversed by an excision, and vice versa.

The difference in the pairs of sites reacting at integration and excision is reflected by a difference in the proteins that mediate the two reactions:

- Integration (*attB*×*attP*) requires the product of the phage gene *int*, which codes for an integrase enzyme, and a bacterial protein called integration host factor (IHF).
- Excision (*attL*×*attR*) requires the product of phage gene *xis*, in addition to Int and IHF.

So Int and IHF are required for both reactions. Xis plays an important role in

controlling the direction; it is required for excision, but inhibits integration.

A similar system, but with somewhat simpler requirements for both sequence and protein components, is found in the bacteriophage P1. The Cre recombinase coded by the phage catalyzes a recombination between two target sequences. Unlike phage lambda, where the recombining sequences are different, in phage P1 they are identical. Each consists of a 34 bp-long sequence called *loxP*. The Cre recombinase is sufficient for the reaction; no accessory proteins are required. Because of its simplicity and its efficiency, what is now known as the Cre/*lox* system has been adapted for use in eukaryotic cells, where it has become one of the standard techniques for undertaking site-specific recombination (2923).

## RECOMBINATION AND REPAIR

**4.15.17 Site-specific recombination involves breakage and reunion****Key Concepts**

- Cleavages staggered by 7 bp are made in both *attB* and *attP* and the ends are joined cross-wise.

The *att* sites have distinct sequence requirements, and *attP* is much larger than *attB*. The function of *attP* requires a stretch of 240 bp, but the function of *attB* can be exercised by the 23 bp fragment extending from -11 to +11, in which there are only 4 bp on either side of the core. The disparity in their sizes suggests that *attP* and *attB* play different roles in the recombination, with *attP* providing additional information necessary to distinguish it from *attB*.

Does the reaction proceed by a concerted mechanism in which the strands in *attP* and *attB* are cut simultaneously and exchanged? Or are the strands exchanged one pair at a time, the first exchange generating a Holliday junction, the second cycle of nicking and ligation occurring to release the structure? The alternatives are depicted in **Figure 15.26**.

**Figure 15.26** Does recombination between *attP* and *attB* proceed by sequential exchange or concerted cutting?

The recombination reaction has been halted at intermediate stages by the use of "suicide substrates," in which the core sequence is nicked. The presence of the nick interferes with the recombination process. This makes it possible to identify

molecules in which recombination has commenced but has not been completed. The structures of these intermediates suggest that exchanges of single strands take place sequentially.

The model illustrated in **Figure 15.27** shows that if *attP* and *attB* sites each suffer the same staggered cleavage, complementary single-stranded ends could be available for crosswise hybridization. The distance between the lambda crossover points is 7 bp, and the reaction generates 3' -phosphate and 5' -OH ends. The reaction is shown for simplicity as generating overlapping single-stranded ends that anneal, but actually occurs by a process akin to the recombination event of **Figure 15.5**. The corresponding strands on each duplex are cut at the same position, the free 3' ends exchange between duplexes, the branch migrates for a distance of 7 bp along the region of homology, and then the structure is resolved by cutting the other pair of corresponding strands.

**Figure 15.27** Staggered cleavages in the common core sequence of *attP* and *attB* allow crosswise reunion to generate reciprocal recombinant junctions.

## RECOMBINATION AND REPAIR

### 4.15.18 Site-specific recombination resembles topoisomerase activity

---

#### Key Concepts

- Integrases are related to topoisomerases, and the recombination reaction resembles topoisomerase action except that nicked strands from *different* duplexes are sealed together.
  - The reaction conserves energy by using a catalytic tyrosine in the enzyme to break a phosphodiester bond and link to the broken 3' end.
  - Two enzyme units bind to each recombination site and the two dimers synapse to form a complex in which the transfer reactions occur.
- 

Integrases use a mechanism similar to that of type I topoisomerases, in which a break is made in one DNA strand at a time. The difference is that a recombinase reconnects the ends cross-wise, whereas a topoisomerase makes a break, manipulates the ends, and then rejoins the original ends. The basic principle of the system is that four molecules of the recombinase are required, one to cut each of the four strands of the two duplexes that are recombining.

**Figure 15.28** shows the nature of the reaction catalyzed by an integrase. The enzyme is a monomeric protein that has an active site capable of cutting and ligating DNA. The reaction involves an attack by a tyrosine on a phosphodiester bond. The 3' end of the DNA chain is linked through a phosphodiester bond to a tyrosine in the enzyme. This releases a free 5' hydroxyl end.

**Figure 15.28** Integrases catalyze recombination by a mechanism similar to topoisomerases. Staggered cuts are made in DNA and the 3' -phosphate end is covalently linked to a tyrosine in the enzyme. Then the free hydroxyl group of each strand attacks the P-Tyr link of the other strand. The first exchange shown in the figure generates a Holliday structure. The structure is resolved by repeating the process with the other pair of strands.

Two enzyme units are bound to each of the recombination sites. At each site, only one of the enzyme active sites attacks the DNA. The symmetry of the system ensures that complementary strands are broken in each recombination site. Then the free 5' -OH end in each site attacks the 3' -phosphotyrosine link in the other site. This generates a Holliday junction.

The structure is resolved when the other two enzyme units (which had not been

involved in the first cycle of breakage and reunion) act on the other pair of complementary strands.

The successive interactions accomplish a conservative strand exchange, in which there are no deletions or additions of nucleotides at the exchange site, and there is no need for input of energy. The transient 3'–phospho-tyrosine link between protein and DNA conserves the energy of the cleaved phosphodiester bond.

**Figure 15.29** shows the reaction intermediate, based on the crystal structure (2924). (Trapping the intermediate was made possible by using a "suicide substrate", consisting of a synthetic DNA duplex with a missing phosphodiester bond, so that the attack by the enzyme does not generate a free 5'–OH end.) The structure of the Cre-*lox* complex shows two Cre molecules, each bound to a 15 bp length of DNA. The DNA is bent by  $\sim 100^\circ$  at the center of symmetry. Two of these complexes assemble in an anti-parallel way to form a tetrameric protein structure bound to two synapsed DNA molecules. Strand exchange takes place in a central cavity of the protein structure that contains the central 6 bases of the crossover region.

**Figure 15.29** A synapsed *loxA* recombination complex has a tetramer of Cre recombinases, with one enzyme monomer bound to each half site. Two of the four active sites are in use, acting on complementary strands of the two DNA sites.

The tyrosine that is responsible for cleaving DNA in any particular half site is provided by the enzyme subunit that is bound to that half site. This is called *cis* cleavage. This is true also for the Int integrase and XerD recombinase. However, the FLP recombinase cleaves in *trans*, involving a mechanism in which the enzyme subunit that provides the tyrosine is *not* the subunit bound to that half site, but is one of the other subunits.

## RECOMBINATION AND REPAIR

### 4.15.19 Lambda recombination occurs in an intasome

---

#### Key Terms

An **intasome** is a protein-DNA complex between the phage lambda integrase (Int) and the phage lambda attachment site (*attP*).

#### Key Concepts

- Lambda integration takes place in a large complex that also includes the host protein IHF.
- The excision reaction requires Int and Xis and recognizes the ends of the prophage DNA as substrates.

---

Unlike the Cre/*lox* recombination system, which requires only the enzyme and the two recombining sites, phage lambda recombination occurs in a large structure, and has different components for each direction of the reaction (integration versus excision).

A host protein called IHF is required for both integration and excision. IHF is a 20 kD protein of two different subunits, coded by the genes *himA* and *himD*. IHF is not an essential protein in *E. coli*, and is not required for homologous bacterial recombination. It is one of several proteins with the ability to wrap DNA on a surface. Mutations in the *him* genes prevent lambda site-specific recombination, and can be suppressed by mutations in  $\lambda$ *int*, which suggests that IHF and Int interact. Site-specific recombination can be performed *in vitro* by Int and IHF.

The *in vitro* reaction requires supercoiling in *attP*, but not in *attB*. When the reaction is performed *in vitro* between two supercoiled DNA molecules, almost all of the supercoiling is retained by the products. So there cannot be any free intermediates in which strand rotation could occur. This was one of the early hints that the reaction proceeds through a Holliday junction. We now know that the reaction proceeds by the mechanism typical of this class of enzymes, related to the topoisomerase I mechanism (see *Molecular Biology 4.15.18 Site-specific recombination resembles topoisomerase activity*).

Int has two different modes of binding. The C-terminal domain behaves like the Cre recombinase. It binds to inverted sites at the core sequence, positioning itself to make the cleavage and ligation reactions on each strand at the positions illustrated in **Figure 15.30**. The N-terminal domain binds to sites in the arms of *attP* that have a different consensus sequence. This binding is responsible for the aggregation of subunits into the intasome (2513). The two domains probably bind DNA simultaneously, thus bringing the arms of *attP* close to the core.

**Figure 15.30** Int and IHF bind to different sites in *attP*. The Int recognition sequences in the core region include the sites of cutting.

IHF binds to sequences of ~20 bp in *attP*. The IHF binding sites are approximately adjacent to sites where Int binds. Xis binds to two sites located close to one another in *attP*, so that the protected region extends over 30-40 bp. Together, Int, Xis, and IHF cover virtually all of *attP*. The binding of Xis changes the organization of the DNA so that it becomes inert as a substrate for the integration reaction.

When Int and IHF bind to *attP*, they generate a complex in which all the binding sites are pulled together on the surface of a protein. Supercoiling of *attP* is needed for the formation of this **intasome**. The only binding sites in *attB* are the two Int sites in the core. But Int does not bind directly to *attB* in the form of free DNA. The intasome is the intermediate that "captures" *attB*, as indicated schematically in **Figure 15.31**.

**Figure 15.31** Multiple copies of Int protein may organize *attP* into an intasome, which initiates site-specific recombination by recognizing *attB* on free DNA.

According to this model, the initial recognition between *attP* and *attB* does not depend directly on DNA homology, but instead is determined by the ability of Int proteins to recognize both *att* sequences. The two *att* sites then are brought together in an orientation predetermined by the structure of the intasome. Sequence homology becomes important at this stage, when it is required for the strand exchange reaction.

The asymmetry of the integration and excision reactions is shown by the fact that Int can form a similar complex with *attR* only if Xis is added. This complex can pair with a condensed complex that Int forms at *attL*. IHF is not needed for this reaction.

Much of the complexity of site-specific recombination may be caused by the need to regulate the reaction so that integration occurs preferentially when the virus is entering the lysogenic state, while excision is preferred when the prophage is entering the lytic cycle. By controlling the amounts of Int and Xis, the appropriate reaction will occur.

## RECOMBINATION AND REPAIR

### 4.15.20 Repair systems correct damage to DNA

---

#### Key Terms

A **structural distortion** is a change in the shape of a molecule.

A **pyrimidine dimer** is formed when ultraviolet irradiation generates a covalent link directly between two adjacent pyrimidine bases in DNA. It blocks DNA replication.

**Photoreactivation** uses a white-light-dependent enzyme to split cyclobutane pyrimidine dimers formed by ultraviolet light.

**Mismatch repair** corrects recently inserted bases that do not pair properly. The process preferentially corrects the sequence of the daughter strand by distinguishing the daughter strand and parental strand, sometimes on the basis of their states of methylation.

**Excision repair** describes a type of repair system in which one strand of DNA is directly excised and then replaced by resynthesis using the complementary strand as template.

**Recombination-repair** is a mode of filling a gap in one strand of duplex DNA by retrieving a homologous single strand from another duplex.

**Error-prone** synthesis occurs when DNA incorporates noncomplementary bases into the daughter strand.

#### Key Concepts

- Repair systems recognize DNA sequences that do not conform to standard base pairs.
  - Excision systems remove one strand of DNA at the site of damage and then replace it.
  - Recombination-repair systems use recombination to replace the double-stranded region that has been damaged.
  - All these systems are prone to introducing errors during the repair process.
  - Photoreactivation is a nonmutagenic repair system that acts specifically on pyrimidine dimers.
- 

Any event that introduces a deviation from the usual double-helical structure of DNA is a threat to the genetic constitution of the cell. We can divide such changes into two general classes:

- *Single base changes* affect the sequence but not the overall structure of DNA. They do not affect transcription or replication, when the strands of the DNA duplex are separated. So these changes exert their damaging effects on future

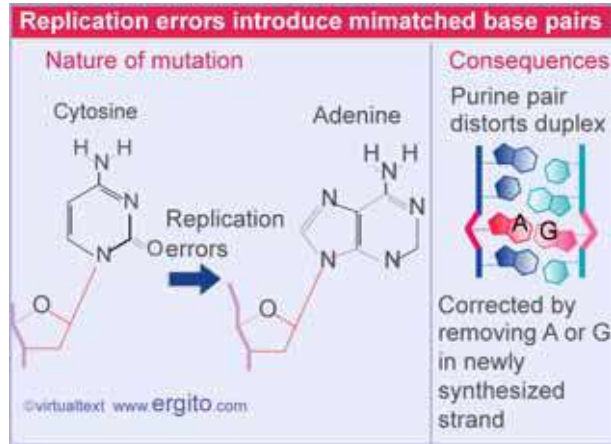

generations through the consequences of the change in DNA sequence. The cause of this type of effect is the conversion of one base into another that is not properly paired with the partner base. They may happen as the result of mutation of a base *in situ* or by replication errors. **Figure 15.32** shows that deamination of cytosine to uracil (spontaneously or by chemical mutagen) creates a mismatched U-G pair. **Figure 15.33** shows that a replication error might insert adenine instead of cytosine to create an A-G pair. Similar consequences could result from covalent addition of a small group to a base that modifies its ability to base pair. These changes may result in very minor structural distortion (as in the case of a U-G pair) or quite significant change (as in the case of an A-G pair), but the common feature is that the mismatch persists only until the next replication. So only limited time is available to repair the damage before it is fixed by replication.

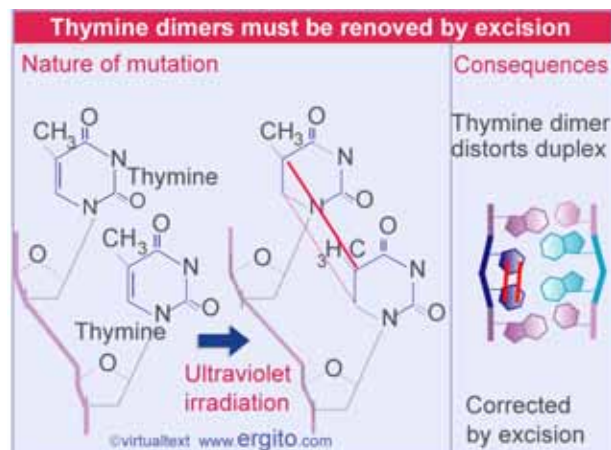

- **Structural distortions** may provide a physical impediment to replication or transcription. Introduction of covalent links between bases on one strand of DNA or between bases on opposite strands inhibits replication and transcription. **Figure 15.34** shows the example of ultraviolet irradiation, which introduces covalent bonds between two adjacent thymine bases, giving an intrastrand **pyrimidine dimer**. **Figure 15.35** shows that similar consequences could result from addition of a bulky adduct to a base that distorts the structure of the double helix. A single-strand nick or the removal of a base, as shown in **Figure 15.36**, prevents a strand from serving as a proper template for synthesis of RNA or DNA. The common feature in all these changes is that the damaged adduct remains in the DNA, continuing to cause structural problems and/or induce mutations, until it is removed.

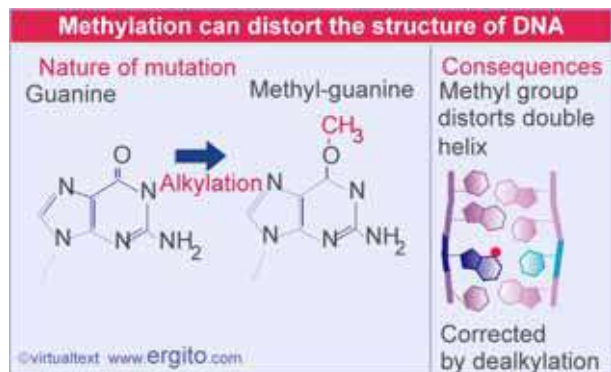

**Figure 15.32** Deamination of cytosine creates a U-G base pair. Uracil is preferentially removed from the mismatched pair.

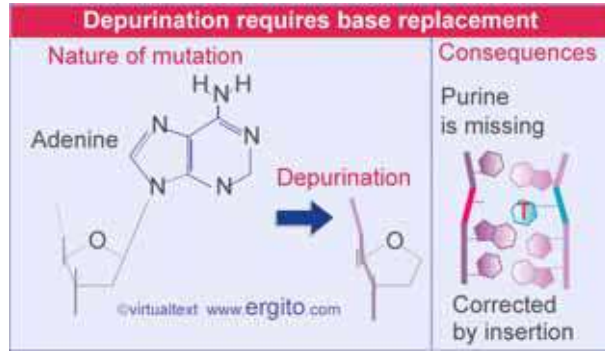

**Figure 15.33** A replication error creates a mismatched pair that may be corrected by replacing one base; if uncorrected, a mutation is fixed in one daughter duplex.

**Figure 15.34** Ultraviolet irradiation causes dimer formation between adjacent thymines. The dimer blocks replication and transcription.

**Figure 15.35** Methylation of a base distorts the double helix and causes mispairing at replication.

**Figure 15.36** Depurination removes a base from DNA, blocking replication and transcription.

Injury to DNA is minimized by systems that recognize and correct the damage. The repair systems are as complex as the replication apparatus itself, which indicates their importance for the survival of the cell. When a repair system reverses a change to DNA, there is no consequence. But a mutation may result when it fails to do so. The measured rate of mutation reflects a balance between the number of damaging events occurring in DNA and the number that have been corrected (or miscorrected).

Repair systems often can recognize a range of distortions in DNA as signals for action, and a cell is likely to have several systems able to deal with DNA damage. The importance of DNA repair in eukaryotes is indicated by the identification of >130 repair genes in the human genome (for review see 2398). We may divide them into several general types, as summarized in **Figure 15.37**:

**Figure 15.37** Repair genes can be classified into pathways that use different mechanisms to reverse or bypass damage to DNA.

- Some enzymes directly reverse specific sorts of damage to DNA.
- There are pathways for base excision repair, nucleotide excision repair, and mismatch repair, all of which function by removing and replacing material.
- There are systems that function by using recombination to retrieve an undamaged copy that is used to replace a damaged duplex sequence.
- The nonhomologous end-joining pathway rejoins broken double-stranded ends.
- Several different DNA polymerases that may be involved in resynthesizing stretches of replacement DNA.

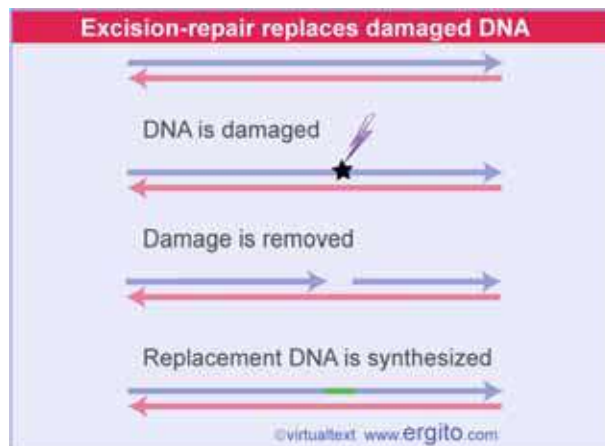

*Direct repair* is rare and involves the reversal or simple removal of the damage.

**Photoreactivation** of pyrimidine dimers, in which the offending covalent bonds are reversed by a light-dependent enzyme, is a good example. This system is widespread in nature, and appears to be especially important in plants. In *E. coli* it depends on the product of a single gene (*phr*) that codes for an enzyme called photolyase.

Mismatches between the strands of DNA are one of the major targets for repair systems. **Mismatch repair** is accomplished by scrutinizing DNA for apposed bases that do not pair properly. Mismatches that arise during replication are corrected by distinguishing between the "new" and "old" strands and preferentially correcting the sequence of the newly synthesized strand. Mismatches also occur when hybrid DNA is created during recombination, and their correction upsets the ratio of parental alleles (see **Figure 15.18**). Other systems deal with mismatches generated by base conversions, such as the result of deamination. The importance of these systems is emphasized by the fact that cancer is caused in human populations by mutation of genes related to those involved in mismatch repair in yeast.

Mismatches are usually corrected by **excision repair**, which is initiated by a recognition enzyme that sees an actual damaged base or a change in the spatial path of DNA. There are two types of excision repair system.

- *Base excision repair* systems directly remove the damaged base and replace it in DNA. A good example is DNA uracil glycolase, which removes uracils that are mispaired with guanines (see *Molecular Biology 4.15.22 Base flipping is used by methylases and glycosylases*).
- *Nucleotide excision repair* systems excise a sequence that includes the damaged base(s); then a new stretch of DNA is synthesized to replace the excised material. **Figure 15.38** summarizes the main events in the operation of such a system. Such systems are common. Some recognize general damage to DNA. Others act upon specific types of base damage. There are often multiple excision repair systems in a single cell type.

**Figure 15.38** Excision-repair directly replaces damaged DNA and then resynthesizes a replacement stretch for the damaged strand.

**Recombination-repair** systems handle situations in which damage remains in a daughter molecule, and replication has been forced to bypass the site, typically creating a gap in the daughter strand. A retrieval system uses recombination to obtain another copy of the sequence from an undamaged source; the copy is then used to repair the gap.

A major feature in recombination and repair is the need to handle double-strand breaks. DSBs initiate crossovers in homologous recombination. They can also be created by problems in replication, when they may trigger the use of recombination-repair systems. When DSBs are created by environmental damage (for example, by radiation damage) or because of the shortening of telomeres (see *Molecular Biology 6.30.28 Genetic instability is a key event in cancer*), they can cause mutations. One system for handling DSBs can join together nonhomologous DNA ends.

Mutations that affect the ability of *E. coli* cells to engage in DNA repair fall into groups, which correspond to several repair pathways (not necessarily all independent). The major known pathways are the *uvr* excision repair system, the methyl-directed mismatch-repair system, and the *recB* and *recF* recombination and recombination-repair pathways. The enzyme activities associated with these systems are endonucleases and exonucleases (important in removing damaged DNA), resolvases (endonucleases that act specifically on recombinant junctions), helicases to unwind DNA, and DNA polymerases to synthesize new DNA. Some of these enzyme activities are unique to particular repair pathways, but others participate in multiple pathways.

The replication apparatus devotes a lot of attention to quality control. DNA polymerases use proofreading to check the daughter strand sequence and to remove errors. Some of the repair systems are less accurate when they synthesize DNA to replace damaged material. For this reason, these systems have been known historically as **error-prone** systems.

When the repair systems are eliminated, cells become exceedingly sensitive to ultraviolet irradiation. The introduction of UV-induced damage has been a major test for repair systems, and so in assessing their activities and relative efficiencies, we should remember that the emphasis might be different if another damaged adduct were studied.

## RECOMBINATION AND REPAIR

### 4.15.21 Excision repair systems in *E. coli*

---

#### Key Terms

**Incision** is a step in a mismatch excision repair system. An endonuclease recognizes the damaged area in the DNA, and isolates it by cutting the DNA strand on both sides of the damage.

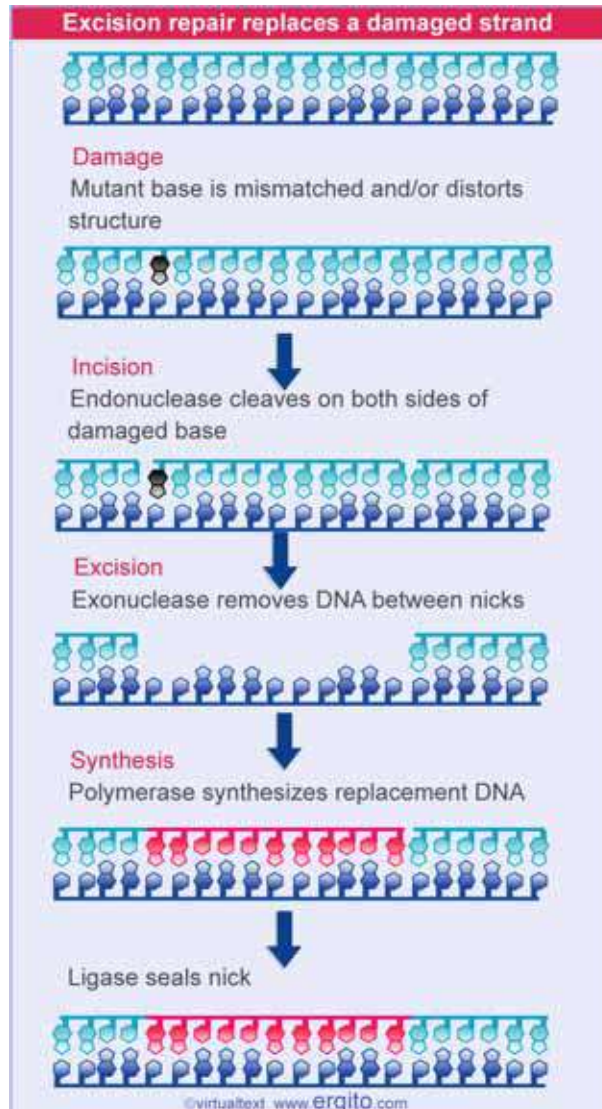

The **excision** step in an excision-repair system consists of removing a single-stranded stretch of DNA by the action of a 5' -3' exonuclease.

#### Key Concepts

- The Uvr system makes incisions ~12 bases apart on both sides of damaged DNA, removes the DNA between them, and resynthesizes new DNA.
- 

Excision repair systems vary in their specificity, but share the same general features. Each system removes mispaired or damaged bases from DNA and then synthesizes a new stretch of DNA to replace them. The main type of pathway for excision repair is illustrated in **Figure 15.39**.

**Figure 15.39** Excision-repair removes and replaces a stretch of DNA that includes the damaged base(s).

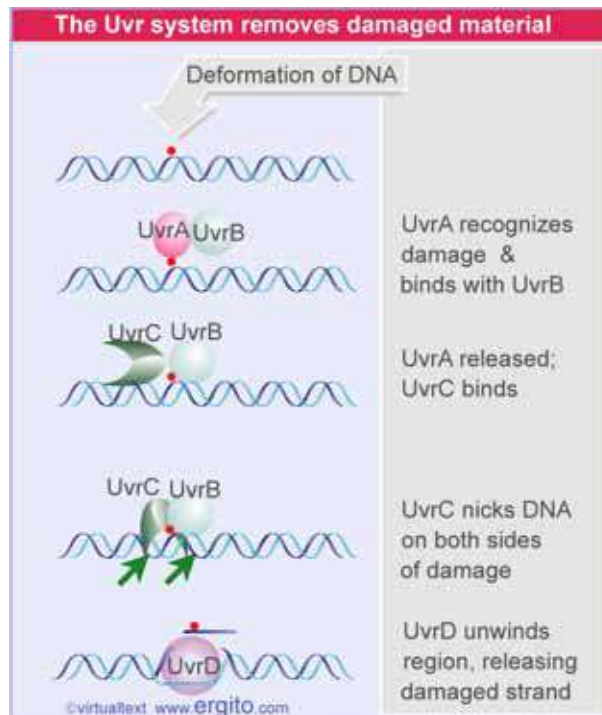

In the **incision** step, the damaged structure is recognized by an endonuclease that cleaves the DNA strand on both sides of the damage.

In the **excision** step, a 5'–3' exonuclease removes a stretch of the damaged strand.

In the **synthesis** step, the resulting single-stranded region serves as a template for a DNA polymerase to synthesize a replacement for the excised sequence. (Synthesis of the new strand could be associated with removal of the old strand, in one coordinated action.) Finally, DNA ligase covalently links the 3' end of the new material to the old material.

The *uvr* system of excision repair includes three genes, *uvrA*, *B*, *C*, that code for the components of a repair endonuclease. It functions in the stages indicated in **Figure 15.40**. First, a UvrAB combination recognizes pyrimidine dimers and other bulky

lesions. Then UvrA dissociates (this requires ATP), and UvrC joins UvrB. The UvrBC combination makes an incision on each side, one 7 nucleotides from the 5' side of the damaged site, and the other 3-4 nucleotides away from the 3' side. This also requires ATP. UvrD is a helicase that helps to unwind the DNA to allow release of the single strand between the two cuts. The enzyme that excises the damaged strand is DNA polymerase I. The enzyme involved in the repair synthesis probably also is DNA polymerase I (although DNA polymerases II and III can substitute for it). The events are basically the same, although their order is different, in the eukaryotic repair pathway shown in **Figure 15.53**.

**Figure 15.40** The Uvr system operates in stages in which UvrAB recognizes damage, UvrBC nicks the DNA, and UvrD unwinds the marked region.

This is a static version of an interactive figure; see <http://www.ergito.com/main.jsp?bcs=MBIO.4.15.21> to view properly.

UvrABC repair accounts for virtually all of the excision repair events in *E. coli*. In almost all (99%) of cases, the average length of replaced DNA is ~12 nucleotides. (For this reason, this is sometimes described as short-patch repair). The remaining 1% involve the replacement of stretches of DNA mostly ~1500 nucleotides long, but extending up to >9000 nucleotides (sometimes called long-patch repair). We do not know why some events trigger the long-patch rather than short-patch mode.

The Uvr complex can be directed to damaged sites by other proteins. Damage to DNA may prevent transcription, but the situation is handled by a protein called Mfd that displaces the RNA polymerase and recruits the Uvr complex (see **Figure 21.19** in *Molecular Biology 5.21.12 A connection between transcription and repair*).

## RECOMBINATION AND REPAIR

**4.15.22 Base flipping is used by methylases and glycosylases****Key Concepts**

- Uracil and alkylated bases are recognized by glycosylases and removed directly from DNA.
- Pyrimidine dimers are reversed by breaking the covalent bonds between them.
- Methylases add a methyl group to cytosine.
- All these types of enzyme act by flipping the base out of the double helix, where, depending on the reaction, it is either removed or is modified and returned to the helix.

As an alternative to the conventional removal of part of a polynucleotide chain by nuclease activity, glycosylases and lyases can remove bases from the chain. **Figure 15.41** shows that a glycosylase cleaves the bond between the damaged or mismatched base and the deoxyribose. **Figure 15.42** shows that some glycosylases are also lyases that can take the reaction a stage further by using an amino ( $\text{NH}_2$ ) group to attack the deoxyribose ring. Although the results of the glycosylase and lyase reaction appear different, the basic mechanisms of their attack on the DNA are similar (for review see 987).

**Figure 15.41** A glycosylase removes a base from DNA by cleaving the bond to the deoxyribose.

**Figure 15.42** A glycosylase hydrolyzes the bond between base and deoxyribose (using H<sub>2</sub>O), but a lyase takes the reaction further by opening the sugar ring (using NH<sub>2</sub>).

The interaction of these enzymes with DNA is remarkable. It follows the model first demonstrated for methyltransferases – enzymes that add a methyl group to cytosine in DNA. The methylase flips the target cytosine completely out of the helix (988). **Figure 15.43** shows that it enters a cavity in the enzyme where it is modified. Then it is returned to its normal position in the helix. All this occurs without input of an external energy source.

**Figure 15.43** A methylase "flips" the target cytosine out of the double helix in order to modify it. Photograph kindly provided by Rich Roberts.

One of the most common reactions in which a base is directly removed from DNA is

catalyzed by uracil-DNA glycosylase. Uracil occurs in DNA most typically because of a (spontaneous) deamination of cytosine. It is recognized by the glycosylase and removed. The reaction is similar to that of the methylase: the uracil is flipped out of the helix and into the active site in the glycosylase (990; 991).

Alkylated bases (typically in which a methyl group has been added to a base) are removed by a similar mechanism (2937; 2938). A single human enzyme, alkyladenine DNA glycosylase (AAG) recognizes and removes a variety of alkylated substrates, including 3-methyladenine, 7-methylguanine, and hypoxanthine.

By contrast with this mechanism, 1-methyl-adenine is corrected by an enzyme that uses an oxygenating mechanism (coded in *E. coli* by the gene *alkB* which has homologues widely spread through nature, including three genes in Man). The methyl group is oxidized to a CH<sub>2</sub>OH group, and then the release of the HCHO moiety [formaldehyde] restores the structure of adenine (2934; 2935). A very interesting development is the discovery that the bacterial enzyme, and one of the human enzymes, can also repair the same damaged base in RNA (3644). In the case of the human enzyme, the main target may be ribosomal RNA. This is the first known repair event with RNA as a target.

Another enzyme to use base flipping is the photolyase that reverses the bonds between pyrimidine dimers (see **Figure 15.34**). The pyrimidine dimer is flipped into a cavity in the enzyme (2939). Close to this cavity is an active site that contains an electron donor, which provides the electrons to break the bonds. Energy for the reaction is provided by light in the visible wavelength.

The common feature of these enzymes is the flipping of the target base into the enzyme structure. A variation on this theme is used by T4 endonuclease V, now renamed T4-pdg (pyrimidine dimer glycosylase) to reflect its mode of action. It flips out the adenine base that is *complementary* to the thymine on the 5' side of the pyrimidine dimer (989). So in this case, the target for the catalytic action of the enzyme remains in the DNA duplex, and the enzyme uses flipping as an indirect mechanism to get access to its target.

When a base is removed from DNA, the reaction is followed by excision of the phosphodiester backbone by an endonuclease, DNA synthesis by a DNA polymerase to fill the gap, and ligation by a ligase to restore the integrity of the polynucleotide chain.

## RECOMBINATION AND REPAIR

### 4.15.23 Error-prone repair and mutator phenotypes

---

#### Key Terms

**Error-prone** synthesis occurs when DNA incorporates noncomplementary bases into the daughter strand.

#### Key Concepts

- Damaged DNA that has not been repaired causes DNA polymerase III to stall during replication.
- DNA polymerase V (coded by *umuCD*), or DNA polymerase IV (coded by *dinB*) can synthesize a complement to the damaged strand.
- The DNA synthesized by the repair DNA polymerase often has errors in its sequence.
- Proteins that affect the fidelity of replication may be identified by mutator genes, in which mutation causes an increased rate of spontaneous mutation.

---

The existence of repair systems that engage in DNA synthesis raises the question of whether their quality control is comparable with that of DNA replication. So far as we know, most systems, including *uvr*-controlled excision repair, do not differ significantly from DNA replication in the frequency of mistakes. However, **error-prone** synthesis of DNA occurs in *E. coli* under certain circumstances.

The error-prone feature was first observed when it was found that the repair of damaged  $\lambda$  phage DNA is accompanied by the induction of mutations if the phage is introduced into cells that had previously been irradiated with UV. This suggests that the UV irradiation of the host has activated functions that generate mutations. The mutagenic response also operates on the bacterial host DNA.

What is the actual error-prone activity? It is a DNA polymerase that inserts incorrect bases, which represent mutations, when it passes any site at which it cannot insert complementary base pairs in the daughter strand. Functions involved in this error-prone pathway are identified by mutations in the genes *umuD* and *umuC*, which abolish UV-induced mutagenesis. This implies that the UmuC and UmuD proteins cause mutations to occur after UV irradiation. The genes constitute the *umuDC* operon, whose expression is induced by DNA damage. Their products form a complex UmuD<sub>2</sub>C, consisting of two subunits of a truncated UmuD protein and one subunit of UmuC. UmuD is cleaved by RecA, which is activated by DNA damage (see *Molecular Biology 4.15.27 RecA triggers the SOS system*).

The UmuD<sub>2</sub>C complex has DNA polymerase activity. It is called DNA polymerase V, and is responsible for synthesizing new DNA to replace sequences that have been damaged by UV (1159). This is the only enzyme in *E. coli* that can bypass the classic pyrimidine dimers produced by UV (or other bulky adducts). The polymerase

activity is "error-prone". Mutation of *umuC* or *umuD* inactivate the enzyme, which makes UV irradiation lethal. Some plasmids carry genes called *mucA* and *mucB*, which are homologues of *umuD* and *umuC*, and whose introduction into a bacterium increases resistance to UV killing and susceptibility to mutagenesis (1564).

How does an alternative DNA polymerase get access to the DNA? When the replicase (DNA polymerase III) encounters a block, such as a thymidine dimer, it stalls. Then it is displaced from the replication fork and replaced by DNA polymerase V. In fact, DNA polymerase V uses some of the same ancillary proteins as DNA polymerase III. The same situation is true for DNA polymerase IV, the product of *dinB*, which is another enzyme that acts on damaged DNA (1166). DNA polymerases IV and V are part of a larger family, including eukaryotic DNA polymerases, that are involved in repairing damaged DNA (see *Molecular Biology 4.15.28 Eukaryotic cells have conserved repair systems*) (for review see 1164).

## RECOMBINATION AND REPAIR

### 4.15.24 Controlling the direction of mismatch repair

---

#### Key Terms

A **mutator** is a mutation or a mutated gene that increases the basal level of mutation. Such genes often code for proteins that are involved in repairing damaged DNA.

#### Key Concepts

- The *mut* genes code for a mismatch repair system that deals with mismatched base pairs.
- There is a bias in the selection of which strand to replace at mismatches.
- The strand lacking methylation at a hemimethylated is usually replaced.
- This is used to remove errors in a newly synthesized strand of DNA. At G·T and C·T mismatches, the T is preferentially removed.

---

Genes whose products are involved in controlling the fidelity of DNA synthesis during either replication or repair may be identified by mutations that have a **mutator** phenotype. A mutator mutant has an increased frequency of spontaneous mutation. If identified originally by the mutator phenotype, a gene is described as *mut*; but often a *mut* gene is later found to be equivalent with a known replication or repair activity.

The general types of activities are identified by *mut* genes fall into two groups.

- The major group consists of components of mismatch-repair systems. Failure to remove a damaged or mispaired base before replication allows it to induce a mutation. Functions in this group include the *dam* methylase that identifies the target for repair, and enzymes that participate directly or indirectly in the removal of particular types of damage (*mutH,S,L,Y*).
- A smaller group, typified by *dnaQ* (which codes for a subunit of DNA polymerase III), is concerned with the accuracy of synthesizing new DNA.

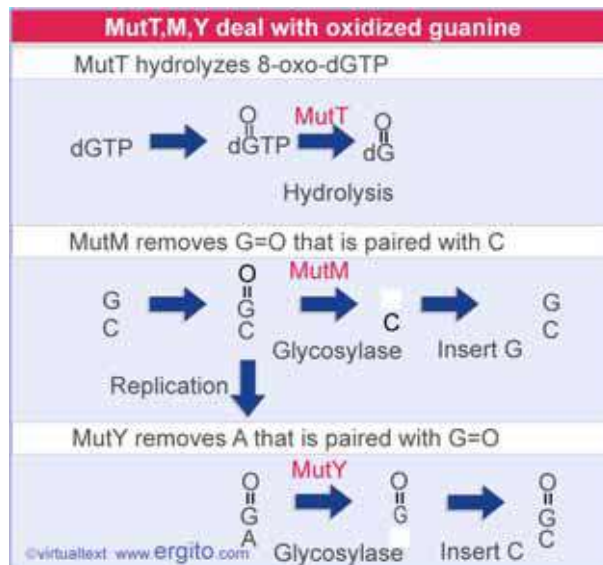

When a structural distortion is removed from DNA, the wild-type sequence is restored. In most cases, the distortion is due to the creation of a base that is not naturally found in DNA, and which is therefore recognized and removed by the repair system.

A problem arises if the target for repair is a mispaired partnership of (normal) bases created when one was mutated. The repair system has no intrinsic means of knowing which is the wild-type base and which is the mutant! All it sees are two improperly paired bases, either of which can provide the target for excision repair.

If the mutated base is excised, the wild-type sequence is restored. But if it happens to be the original (wild-type) base that is excised, the new (mutant) sequence becomes fixed. Often, however, the direction of excision repair is not random, but is biased in a way that is likely to lead to restoration of the wild-type sequence.

Some precautions are taken to direct repair in the right direction. For example, for cases such as the deamination of 5-methyl-cytosine to thymine, there is a special system to restore the proper sequence (see also *Molecular Biology 1.1.14 Many hotspots result from modified bases*). The deamination generates a G·T pair, and the system that acts on such pairs has a bias to correct them to G·C pairs (rather than to A·T pairs). The system that undertakes this reaction includes the *mutL,S* products that remove T from both G·T and C·T mismatches.

The *mutT,M,Y* system handles the consequences of oxidative damage. A major type of chemical damage is caused by oxidation of G to 8-oxo-G. **Figure 15.44** shows that the system operates at three levels. MutT hydrolyzes the damaged precursor (8-oxo-dGTP), which prevents it from being incorporated into DNA. When guanine is oxidized in DNA, its partner is cytosine; and MutM preferentially removes the C from 8-oxo-G·C pairs. Oxidized guanine mispairs with A, and so when 8-oxo-G survives and is replicated, it generates an 8-oxo-G·A pair. MutY removes A from these pairs. MutM and MutY are glycosylases that directly remove a base from DNA. This creates a apurinic site that is recognized by an endonuclease whose action triggers the involvement of the excision repair system.

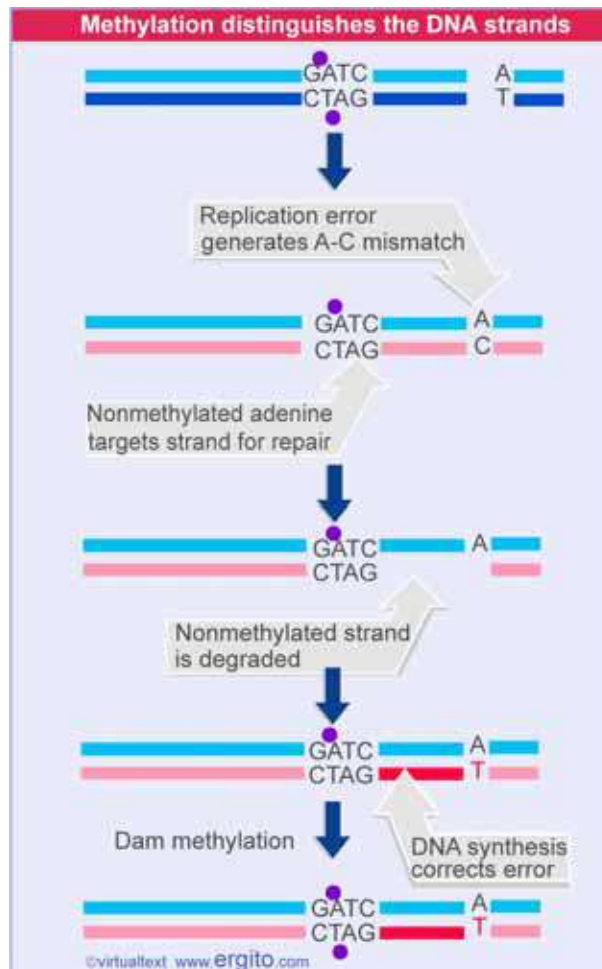

**Figure 15.44** Preferential removal of bases in pairs that have oxidized guanine is designed to minimize mutations.

When mismatch errors occur during replication in *E. coli*, it is possible to distinguish the original strand of DNA. Immediately after replication of methylated DNA, only the original parental strand carries the methyl groups. In the period while the newly synthesized strand awaits the introduction of methyl groups, the two strands can be distinguished.

This provides the basis for a system to correct replication errors. The *dam* gene codes

for a methylase whose target is the adenine in the sequence (see **Figure 14.35**). The hemimethylated state is used to distinguish replicated origins from nonreplicated origins. The same target sites are used by a replication-related repair system.

**Figure 15.45** shows that DNA containing mismatched base partners is repaired preferentially by excising the strand that lacks the methylation. The excision is quite extensive; mismatches can be repaired preferentially for >1 kb around a GATC site. The result is that the newly synthesized strand is corrected to the sequence of the parental strand.

**Figure 15.45** GATC sequences are targets for the Dam methylase after replication. During the period before this methylation occurs, the nonmethylated strand is the target for repair of mismatched bases.

*E. coli dam*<sup>-</sup> mutants show an increased rate of spontaneous mutation. This repair system therefore helps reduce the number of mutations caused by errors in replication. It consists of several proteins, coded by the *mut* genes. MutS binds to the mismatch and is joined by MutL. MutS can use two DNA-binding sites, as illustrated in **Figure 15.46**. The first specifically recognizes mismatches. The second is not specific for sequence or structure, and is used to translocate along DNA until a GATC sequence is encountered. Hydrolysis of ATP is used to drive the

translocation. Because MutS is bound to both the mismatch site and to DNA as it translocates, it creates a loop in the DNA.

**Figure 15.46** MutS recognizes a mismatch and translocates to a GATC site. MutH cleaves the unmethylated strand at the GATC. Endonucleases degrade the strand from the GATC to the mismatch site.

Recognition of the GATC sequence causes the MutH endonuclease to bind to MutSL. The endonuclease then cleaves the unmethylated strand. This strand is then excised from the GATC site to the mismatch site. The excision can occur in either the 5'–3' direction (using RecJ or exonuclease VII) or in the 3'–5' direction (using exonuclease I), assisted by the helicase UvrD. The new DNA strand is synthesized by DNA polymerase III.

The *msh* repair system of *S. cerevisiae* is homologous to the *E. coli mut* system. MSH2 provides a scaffold for the apparatus that recognizes mismatches. MSH3 and MSH6 provide specificity factors. The MSH2-MSH3 complex binds mismatched loops of 2-4 nucleotides, and the MSH2-MSH6 complex binds to single base mismatches or insertions or deletions. Other proteins are then required for the repair process itself.

homologues of the MutSL system also are found in higher eukaryotic cells. They are responsible for repairing mismatches that arise as the result of replication slippage (2255). In a region such as a microsatellite where a very short sequence is repeated several times, realignment between the newly synthesized daughter strand and its template can lead to a stuttering in which the DNA polymerase slips backward and synthesizes extra repeating units. These units in the daughter strand are extruded as a

single-stranded loop from the double helix (see **Figure 4.28**). They are repaired by homologues of the MutSL system as shown in **Figure 15.47**.

**Figure 15.47** The MutS/MutL system initiates repair of mismatches produced by replication slippage.

The importance of the MutSL system for mismatch repair is indicated by the high rate at which it is found to be defective in human cancers. Loss of this system leads to an increased mutation rate (see *Molecular Biology 6.30.29 Defects in repair systems cause mutations to accumulate in tumors*).

---

**RECOMBINATION AND REPAIR****4.15.25 Recombination-repair systems in *E. coli***

---

**Key Terms**

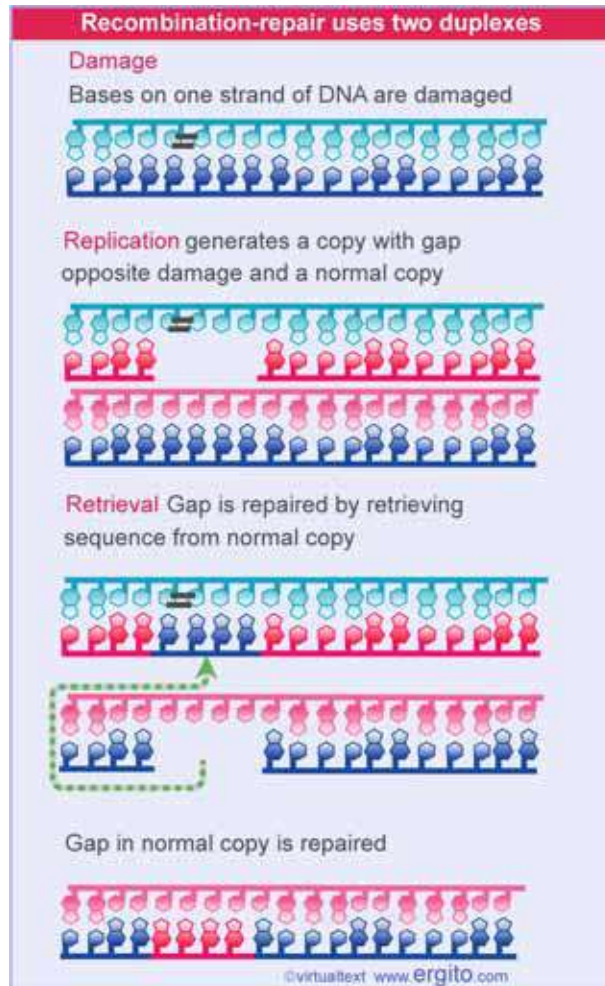

**Single-strand exchange** is a reaction in which one of the strands of a duplex of DNA leaves its former partner and instead pairs with the complementary strand in another molecule, displacing its homologue in the second duplex.

**Key Concepts**

- The *rec* genes of *E. coli* code for the principal retrieval system.
- It functions when replication leaves a gap in newly synthesized strand opposite a damaged sequence.
- The single strand of another duplex is used to replace the gap.
- Then the damaged sequence is removed and resynthesized.

---

Recombination-repair systems use activities that overlap with those involved in genetic recombination. They are also sometimes called "post-replication repair," because they function after replication. Such systems are effective in dealing with the defects produced in daughter duplexes by replication of a template that contains damaged bases. An example is illustrated in **Figure 15.48**. Restarting stalled replication forks could be the major role of the recombination-repair systems (see *Molecular Biology 4.14.17 The primosome is needed to restart replication*).

**Figure 15.48** An *E. coli* retrieval system uses a normal strand of DNA to replace the gap left in a newly synthesized strand opposite a site of unrepaired damage.

Consider a structural distortion, such as a pyrimidine dimer, on one strand of a double helix. When the DNA is replicated, the dimer prevents the damaged site from acting as a template. Replication is forced to skip past it.

DNA polymerase probably proceeds up to or close to the pyrimidine dimer. Then the polymerase ceases synthesis of the corresponding daughter strand. Replication restarts some distance farther along. A substantial gap is left in the newly synthesized strand.

The resulting daughter duplexes are different in nature. One has the parental strand containing the damaged adduct, facing a newly synthesized strand with a lengthy gap. The other duplicate has the undamaged parental strand, which has been copied into a normal complementary strand. The retrieval system takes advantage of the normal daughter.

The gap opposite the damaged site in the first duplex is filled by stealing the homologous single strand of DNA from the normal duplex. Following this

**single-strand exchange**, the recipient duplex has a parental (damaged) strand facing a wild-type strand. The donor duplex has a normal parental strand facing a gap; the gap can be filled by repair synthesis in the usual way, generating a normal duplex. So the damage is confined to the original distortion (although the same recombination-repair events must be repeated after every replication cycle unless and until the damage is removed by an excision repair system).

The principal pathway for recombination-repair in *E. coli* is identified by the *rec* genes (see **Figure 15.13**, **Figure 15.14**, **Figure 15.15**) (for review see 3131). In *E. coli* deficient in excision repair, mutation in the *recA* gene essentially abolishes all the remaining repair and recovery facilities. Attempts to replicate DNA in *uvr<sup>-</sup>recA<sup>-</sup>* cells produce fragments of DNA whose size corresponds with the expected distance between thymine dimers. This result implies that the dimers provide a lethal obstacle to replication in the absence of RecA function. It explains why the double mutant cannot tolerate >1-2 dimers in its genome (compared with the ability of a wild-type bacterium to handle as many as 50).

One *rec* pathway involves the *recBC* genes, and is well characterized; the other involves *recF*, and is not so well defined. They fulfill different functions *in vivo*. The RecBC pathway is involved in restarting stalled replication forks (see *Molecular Biology 4.15.26 Recombination is an important mechanism to recover from replication errors*). The RecF pathway is involved in repairing the gaps in a daughter strand that are left after replicating past a pyrimidine dimer.

The RecBC and RecF pathways both function prior to the action of RecA (although in different ways). They lead to the association of RecA with a single-stranded DNA. The ability of RecA to exchange single strands allows it to perform the retrieval step in **Figure 15.48**. Nuclease and polymerase activities then complete the repair action.

The RecF pathway contains a group of three genes: *recF*, *recO*, and *recR*. The proteins form two types of complex, RecOR and RecOF. They promote the formation of RecA filaments on single-stranded DNA. One of their functions is to make it possible for the filaments to assemble in spite of the presence of the SSB, which is inhibitory. Although they are thought to function at gaps, the reaction *in vitro* requires a free 5' end (3134).

The designations of repair and recombination genes are based on the phenotypes of the mutants; but sometimes a mutation isolated in one set of conditions and named as a *uvr* locus turns out to have been isolated in another set of conditions as a *rec* locus. This uncertainty makes an important point. We cannot yet define how many functions belong to each pathway or how the pathways interact. The *uvr* and *rec* pathways are not entirely independent, because *uvr* mutants show reduced efficiency in recombination-repair. We must expect to find a network of nuclease, polymerase, and other activities, constituting repair systems that are partially overlapping (or in which an enzyme usually used to provide some function can be substituted by another from a different pathway).

**RECOMBINATION AND REPAIR****4.15.26 Recombination is an important mechanism to recover from replication errors**

---

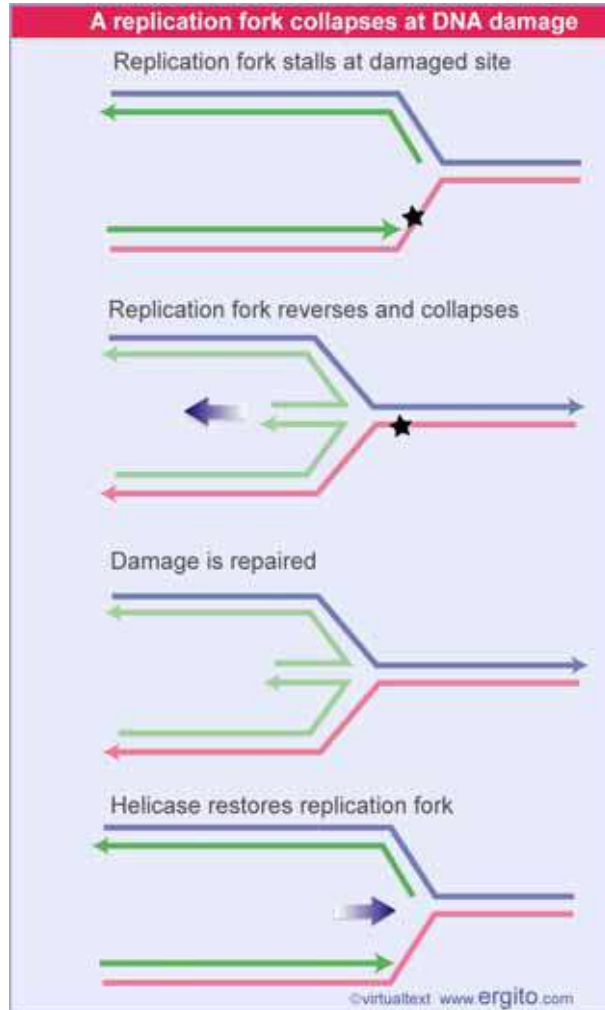

**Key Concepts**

- A replication fork may stall when it encounters a damaged site or a nick in DNA.
- A stalled fork may reverse by pairing between the two newly synthesized strands.
- A stalled fork may restart repairing the damage and using a helicase to move the fork forward.
- The structure of the stalled fork is the same as a Holliday junction and may be converted to a duplex and DSB by resolvases.

---

All cells have many pathways to repair damage in DNA. Which pathway is used will depend upon the type of damage and the situation. Excision-repair pathways can in principle be used at any time, but recombination-repair can be used only when there is a second duplex with a copy of the damaged sequence, that is, post-replication. A special situation is presented when damaged DNA is replicated, because the replication fork may stall at the site of damage. Recombination-repair pathways are involved in allowing the fork to be restored after the damage has been repaired or to allow it to bypass the damage.

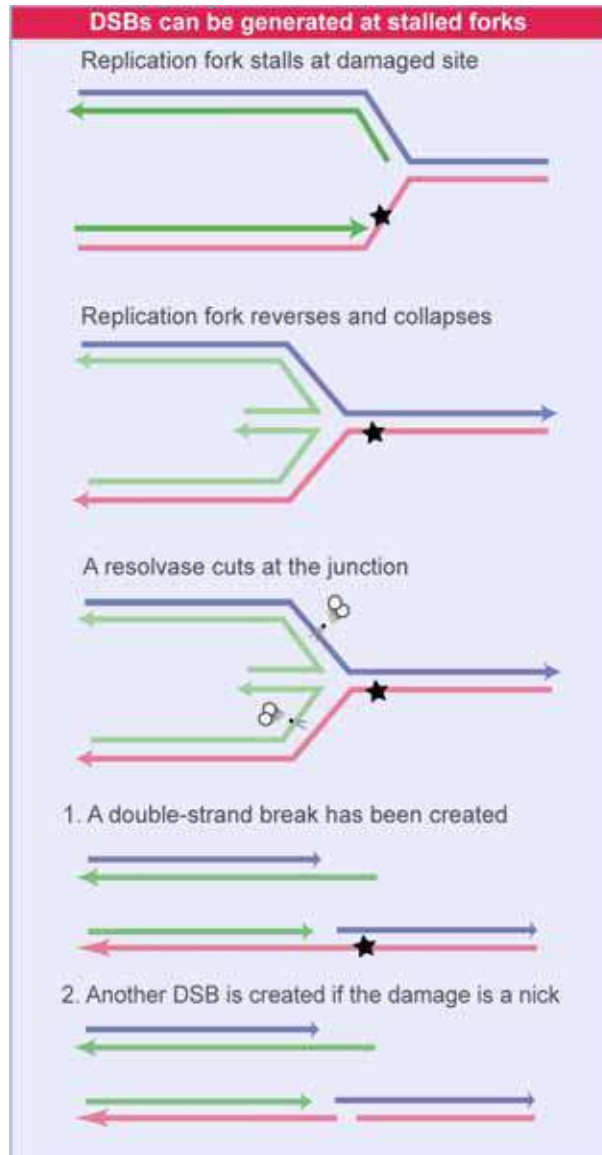

**Figure 15.49** shows one possible outcome when a replication fork stalls (for review see 956; 3442). The fork stops moving forward when it encounters the damage. The replication apparatus disassembles, at least partially. This allows branch migration to occur, when the fork effectively moves backward, and the new daughter strands pair to form a duplex structure. After the damage has been repaired, a helicase rolls the fork forward to restore its structure. Then the replication apparatus can reassemble, and replication is restarted (see *Molecular Biology 4.14.17 The primosome is needed to restart replication*). DNA polymerase II is required for the replication restart, and is later replaced by DNA polymerase III (4524).

**Figure 15.49** A replication fork stalls when it reaches a damaged site in DNA. Branch migration occurs to move the fork backward, and the two daughter strands pair to form a duplex. After the damage has been repaired, a helicase may cause forward branch migration to restore the structure of the fork. Arrowheads indicate 3' ends.

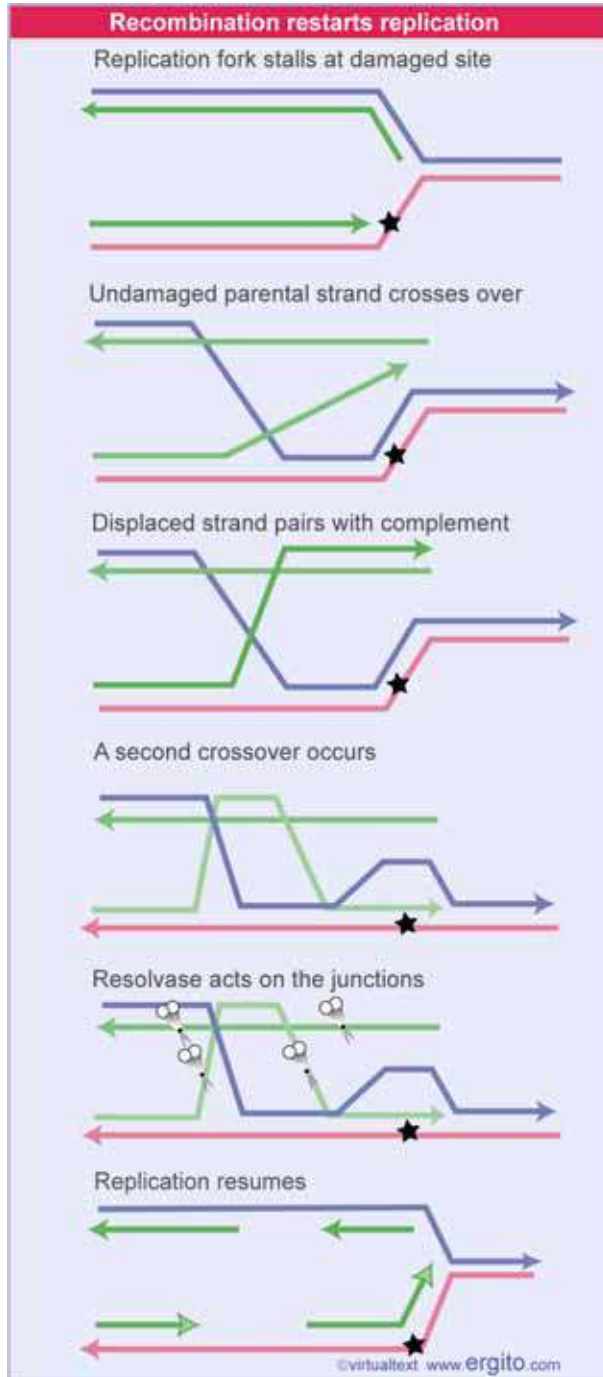

The pathway for handling a stalled replication fork requires repair enzymes. In *E. coli*, RecA and the RecBC system have an important role in this reaction (in fact, this may be their major function in the bacterium). One possible pathway is for RecA to bind to single-stranded DNA at the stalled replication fork, stabilizing it, and possibly acting as the sensor that detects the stalling event. RecBC is involved in excision-repair of the damage. After the damage has been repaired, replication can resume (for review see 4525).

Another pathway may use recombination-repair, possibly the strand-exchange reactions of RecA. **Figure 15.50** shows that the structure of the stalled fork is essentially the same as a Holliday junction created by recombination between two duplex DNAs. This makes it a target for resolvases. A double-strand break is generated if a resolvase cleaves either pair of complementary strands. In addition, if the damage is in fact a nick, another double-strand break is created at this site (2928).

**Figure 15.50** The structure of a stalled replication fork resembles a Holliday junction and can be resolved in the same way by resolvases. The results depend on whether the site of damage contains a nick. Result 1 shows that a double-strand break is generated by cutting a pair of strands at the junction. Result 2 shows a second DSB is generated at the site of damage if it contains a nick. Arrowheads indicate 3' ends.

Stalled replication forks can be rescued by recombination-repair (for review see 2929). We don't know the exact sequence of events, but one possible scenario is outlined in **Figure 15.51**. The principle is that a recombination event occurs on either side of the damaged site, allowing an undamaged single strand to pair with the damaged strand. This allows the replication fork to be reconstructed, so that replication can continue, effectively bypassing the damaged site.

**Figure 15.51** When a replication fork stalls, recombination-repair can place an undamaged strand opposite the damaged site. This allows replication to continue.

## RECOMBINATION AND REPAIR

### 4.15.27 RecA triggers the SOS system

---

#### Key Terms

An **SOS response** in *E. coli* describes the coordinate induction of many enzymes, including repair activities, in response to irradiation or other damage to DNA; results from activation of protease activity by RecA to cleave LexA repressor.

The **SOS box** is the DNA sequence (operator) of ~20 bp recognized by LexA repressor protein.

#### Key Concepts

- Damage to DNA causes RecA to trigger the SOS response, consisting of genes coding for many repair enzymes.
- RecA activates the autocleavage activity of LexA.
- LexA represses the SOS system; its autocleavage activates those genes.

---

The direct involvement of RecA protein in recombination-repair is only one of its activities. This extraordinary protein also has another, quite distinct function. It can be activated by many treatments that damage DNA or inhibit replication in *E. coli*. This causes it to trigger a complex series of phenotypic changes called the **SOS response**, which involves the expression of many genes whose products include repair functions. These dual activities of the RecA protein make it difficult to know whether a deficiency in repair in *recA* mutant cells is due to loss of the DNA strand-exchange function of RecA or to some other function whose induction depends on the protease activity.

The inducing damage can take the form of ultraviolet irradiation (the most studied case) or can be caused by crosslinking or alkylating agents. Inhibition of replication by any of several means, including deprivation of thymine, addition of drugs, or mutations in several of the *dna* genes, has the same effect.

The response takes the form of increased capacity to repair damaged DNA, achieved by inducing synthesis of the components of both the long-patch excision repair system and the Rec recombination-repair pathways. In addition, cell division is inhibited. Lysogenic prophages may be induced.

The initial event in the response is the activation of RecA by the damaging treatment. We do not know very much about the relationship between the damaging event and the sudden change in RecA activity. Because a variety of damaging events can induce the SOS response, current work focuses on the idea that RecA is activated by some common intermediate in DNA metabolism.

The inducing signal could consist of a small molecule released from DNA; or it might be some structure formed in the DNA itself. *In vitro*, the activation of RecA

requires the presence of single-stranded DNA and ATP. So the activating signal could be the presence of a single-stranded region at a site of damage. Whatever form the signal takes, its interaction with RecA is rapid: the SOS response occurs within a few minutes of the damaging treatment.

Activation of RecA causes proteolytic cleavage of the product of the *lexA* gene. LexA is a small (22 kD) protein that is relatively stable in untreated cells, where it functions as a repressor at many operons. The cleavage reaction is unusual; LexA has a latent protease activity that is activated by RecA. When RecA is activated, it causes LexA to undertake an autocatalytic cleavage; this inactivates the LexA repressor function, and coordinately induces all the operons to which it was bound. The pathway is illustrated in **Figure 15.52**.

**Figure 15.52** The LexA protein represses many genes, including repair functions, *recA* and *lexA*. Activation of RecA leads to proteolytic cleavage of LexA and induces all of these genes.

The target genes for LexA repression include many repair functions. Some of these SOS genes are active only in treated cells; others are active in untreated cells, but the level of expression is increased by cleavage of LexA. In the case of *uvrB*, which is a component of the excision repair system, the gene has two promoters; one functions independently of LexA, the other is subject to its control. So after cleavage of LexA, the gene can be expressed from the second promoter as well as from the first.

LexA represses its target genes by binding to a 20 bp stretch of DNA called an **SOS box**, which includes a consensus sequence with 8 absolutely conserved positions. Like other operators, the SOS boxes overlap with the respective promoters. At the *lexA* locus, the subject of autogenous repression, there are two adjacent SOS boxes.

RecA and LexA are mutual targets in the SOS circuit: RecA triggers cleavage of LexA, which represses *recA* and itself. The SOS response therefore causes amplification of both the RecA protein and the LexA repressor. The results are not so contradictory as might at first appear.

The increase in expression of RecA protein is necessary (presumably) for its direct role in the recombination-repair pathways. On induction, the level of RecA is increased from its basal level of ~1200 molecules/cell by up to 50×. The high level in induced cells means there is sufficient RecA to ensure that all the LexA protein is cleaved. This should prevent LexA from reestablishing repression of the target genes.

But the main importance of this circuit for the cell lies in the ability to return rapidly to normalcy. When the inducing signal is removed, the RecA protein loses the ability to destabilize LexA. At this moment, the *lexA* gene is being expressed at a high level; in the absence of activated RecA, the LexA protein rapidly accumulates in the uncleaved form and turns off the SOS genes. This explains why the SOS response is freely reversible.

RecA also triggers cleavage of other cellular targets, sometimes with more direct consequences. The UmuD protein is cleaved when RecA is activated; the cleavage event activates UmuD and the error-prone repair system. The current model for the reaction is that the UmuD<sub>2</sub>UmuC complex binds to a RecA filament near a site of damage, RecA activates the complex by cleaving UmuD to generate UmuD', and the complex then synthesizes a stretch of DNA to replace the damaged material (943).

Activation of RecA also causes cleavage of some other repressor proteins, including those of several prophages. Among these is the lambda repressor (with which the protease activity was discovered). This explains why lambda is induced by ultraviolet irradiation; the lysogenic repressor is cleaved, releasing the phage to enter the lytic cycle.

This reaction is not a cellular SOS response, but instead represents a recognition by the prophage that the cell is in trouble. Survival is then best assured by entering the lytic cycle to generate progeny phages. In this sense, prophage induction is piggybacking onto the cellular system by responding to the same indicator (activation of RecA).

The two activities of RecA are relatively independent. The *recA441* mutation allows the SOS response to occur without inducing treatment, probably because RecA remains spontaneously in the activated state. Other mutations abolish the ability to be activated. Neither type of mutation affects the ability of RecA to handle DNA. The reverse type of mutation, inactivating the recombination function but leaving intact the ability to induce the SOS response, would be useful in disentangling the direct and indirect effects of RecA in the repair pathways.

## RECOMBINATION AND REPAIR

### 4.15.28 Eukaryotic cells have conserved repair systems

---

#### Key Concepts

- The yeast *RAD* mutations, identified by radiation sensitive phenotypes, are in genes that code for repair systems.
- Xeroderma pigmentosum (XP) is a human disease caused by mutations in any one of several repair genes.
- A complex of proteins including XP products and the transcription factor TF<sub>III</sub> provides a human excision-repair mechanism.
- Transcriptionally active genes are preferentially repaired.

---

The types of repair functions recognized in *E. coli* are common to a wide range of organisms. The best characterized eukaryotic systems are in yeast, where Rad51 is the counterpart to RecA. In yeast, the main function of the strand-transfer protein is homologous recombination. Many of the repair systems found in yeast have direct counterparts in higher eukaryotic cells, and in several cases these systems are involved with human diseases (see also *Molecular Biology 6.30.29 Defects in repair systems cause mutations to accumulate in tumors*).

Genes involved in repair functions have been characterized genetically in yeast by virtue of their sensitivity to radiation. They are called *RAD* genes. There are three general groups of repair genes in the yeast *S. cerevisiae*, identified by the *RAD3* group (involved in excision repair), the *RAD6* group (required for post-replication repair), and the *RAD52* group (concerned with recombination-like mechanisms). The *RAD52* group is divided into two subgroups by a difference in mutant phenotypes. One subgroup affects homologous recombination, as seen by a reduction in mitotic recombination in *RAD50*, *RAD51*, *RAD54*, *RAD55*, and *RAD57*. These Rad proteins form a multiprotein complex at a double-strand break. After an exonuclease has acted on the free ends to generate single-stranded tails, Rad51 initiates the process by binding to the single-stranded DNA to form a nucleoprotein filament. Rad52, Rad55, and Rad54 then bind sequentially to the filament (4190). By contrast, recombination rates are increased in *RAD59*, *MRE11*, and *XRS2* mutants; this subgroup is not deficient in homologous recombination, but is deficient in nonhomologous DNA joining reactions.

A superfamily of DNA polymerases involved in synthesizing DNA to replace material at damaged sites is identified by the *dinB* and *umuCD* genes that code for DNA polymerases IV and V in *E. coli*, the *rad30* gene coding for DNA polymerase  $\eta$  of *S. cerevisiae*, and the gene *XPV* that codes for the human homolog. They are sometimes called translesion DNA polymerases (for review see 4523). A difference between the bacterial and eukaryotic enzymes is that the latter are not error-prone at thymine dimers: they accurately introduces an A-A pair opposite a T-T dimer (1167;

for review see 1164; 2940). When they replicate through other sites of damage, however, they are more prone to introduce errors.

An interesting feature of repair that has been best characterized in yeast is its connection with transcription. Transcriptionally active genes are preferentially repaired. The consequence is that the transcribed strand is preferentially repaired (removing the impediment to transcription). The cause appears to be a mechanistic connection between the repair apparatus and RNA polymerase. The RAD3 protein, which is a helicase required for the incision step, is a component of a transcription factor associated with RNA polymerase (see *Molecular Biology* 5.21.12 *A connection between transcription and repair*).

Mammalian cells show heterogeneity in the amount of DNA resynthesized at each lesion after damage. However, the patches are always relatively short, <10 bases.

An indication of the existence and importance of the mammalian repair systems is given by certain human hereditary disorders. The best investigated of these is xeroderma pigmentosum (XP), a recessive disease resulting in hypersensitivity to sunlight, in particular to ultraviolet. The deficiency results in skin disorders (and sometimes more severe defects).

The disease is caused by a deficiency in excision repair. Fibroblasts from XP patients cannot excise pyrimidine dimers and other bulky adducts. Mutations fall into 8 genes, called *XP-A* to *XP-G*. They have homologues in the *RAD* genes of yeast, showing that this pathway is a widely used in eukaryotes.

A protein complex that includes products of several of the *XP* genes is responsible for excision of thymine dimers. **Figure 15.53** shows its role in the repair pathway. The complex binds to DNA at a site of damage, perhaps by a mechanism involving the cooperative action of several of its components 4519. Then the strands of DNA are unwound for ~20 bp around the damaged site. This action is undertaken by the helicase activity of the transcription factor TF<sub>II</sub>H, itself a large complex, which includes the products of several *XP* genes, and which is involved with the repair of damaged DNA that is encountered by RNA polymerase during transcription. Then cleavages are made on either side of the lesion by endonucleases coded by *XP* genes. The single-stranded stretch including the damaged bases can then be replaced by synthesis of a replacement.

**Figure 15.53** A helicase unwinds DNA at a damaged site, endonucleases cut on either side of the lesion, and new DNA is synthesized to replace the excised stretch.

This is a static version of an interactive figure; see <http://www.ergito.com/main.jsp?bcs=MBIO.4.15.28> to view properly.

In cases where replication encounters a thymine dimer that has not been removed, replication requires the DNA polymerase  $\eta$  activity in order to proceed past the dimer. This is coded by the *XPV*. Skin cancers that occur in *XPV* mutants are presumably due to loss of the DNA polymerase.

## RECOMBINATION AND REPAIR

### 4.15.29 A common system repairs double-strand breaks

---

#### Key Terms

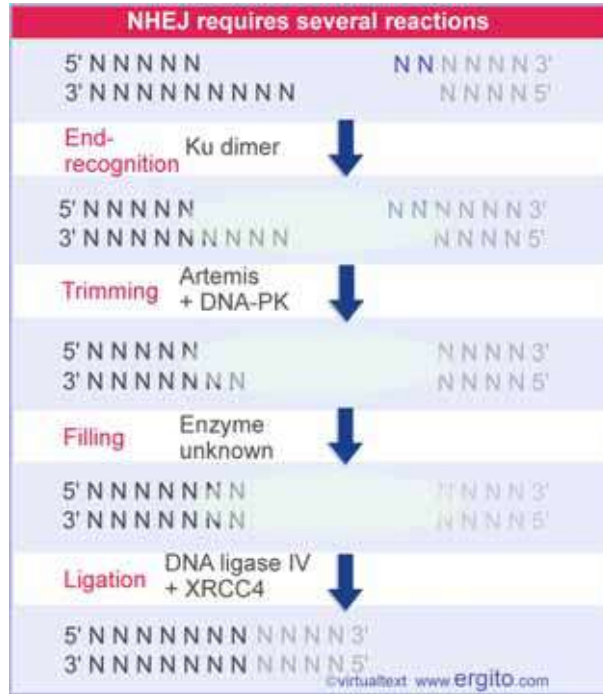

**Non-homologous end-joining (NHEJ)** ligates blunt ends. It is common to many repair pathways and to certain recombination pathways (such as immunoglobulin recombination).

#### Key Concepts

- The NHEJ pathway can ligate blunt ends of duplex DNA.
  - Mutations in the NHEJ pathway cause human diseases.
- 

Double-strand breaks occur in cells in various circumstances. They initiate the process of homologous recombination and are an intermediate in the recombination of immunoglobulin genes (see *Molecular Biology 5.25.9 The RAG proteins catalyze breakage and reunion*). They also occur as the result of damage to DNA, for example, by irradiation. The major mechanism to repair these breaks is called **non-homologous end-joining (NHEJ)**, and consists of ligating the blunt ends together.

The steps involved in NHEJ are summarized in **Figure 15.54**. The same enzyme complex undertakes the process in both NHEJ and immune recombination. The first stage is recognition of the broken ends by a heterodimer consisting of the proteins Ku70 and Ku80. They form a scaffold that holds the ends together and allows other enzymes to act on them. A key component is the DNA-dependent protein kinase (DNA-PKcs), which is activated by DNA to phosphorylate protein targets. One of these targets is the protein Artemis, which in its activated form has both exonuclease and endonuclease activities, and can both trim overhanging ends and cleave the hairpins generated by recombination of immunoglobulin genes (2397). The DNA polymerase activity that fills in any remaining single-stranded protrusions is not known. The actual joining of the double-stranded ends is undertaken by the DNA ligase IV, which functions in conjunction with the protein XRCC4. Mutations in any of these components may render eukaryotic cells more sensitive to radiation. Some of the genes for these proteins are mutated in patients who have diseases due to deficiencies in DNA repair.

**Figure 15.54** Nonhomologous end joining requires recognition of the broken ends, trimming of overhanging ends and/or filling, followed by ligation.

The Ku heterodimer is the sensor that detects DNA damage by binding to the broken ends. The crystal structure in **Figure 15.55** shows why it binds only to ends. The bulk of the protein extends for about two turns along one face of DNA (lower), but a narrow bridge between the subunits, located in the center of the structure, completely encircles DNA (2151). This means that the heterodimer needs to slip onto a free end.

**Figure 15.55** The Ku70-Ku80 heterodimer binds along two turns of the DNA double helix and surrounds the helix at the center of the binding site. Photograph kindly provided by Jonathan Goldberg (see 2151).

Ku can bring broken ends together by binding two DNA molecules (2152; 2153). The ability of Ku heterodimers to associate with one another suggests that the reaction might take place as illustrated in **Figure 15.56**. This would predict that the ligase would act by binding in the region between the bridges on the individual heterodimers. Presumably Ku must change its structure in order to be released from DNA.

**Figure 15.56** If two heterodimers of Ku bind to DNA, the distance between the two bridges that encircle DNA is ~12 bp.

Deficiency in DNA repair causes several human diseases. The common feature is

that an inability to repair double-strand breaks in DNA leads to chromosomal instability. The instability is revealed by chromosomal aberrations, which are associated with an increased rate of mutation, in turn leading to an increased susceptibility to cancer in patients with the disease. The basic cause can be mutation in pathways that control DNA repair or in the genes that code for enzymes of the repair complexes. The phenotypes can be very similar, as in the case of Ataxia telangiectasia (AT), which is caused by failure of a cell cycle checkpoint pathway, and Nijmegen breakage syndrome (NBS), which is caused by a mutation of a repair enzyme. One of the lessons that we learn from characterizing the repair pathways is that they are conserved in mammals, yeast, and bacteria.

The recessive human disorder of Bloom's syndrome is caused by mutations in a helicase gene (called *BLM*) that is homologous to *recQ* of *E. coli* (2927). The mutation results in an increased frequency of chromosomal breaks and sister chromatid exchanges. *BLM* associates with other repair proteins as part of a large complex. One of the proteins with which it interacts is hMLH1, a mismatch-repair protein that is the human homologue of bacterial *mutL*. The yeast homologues of these two proteins, Sgs1 and MLH1, also associate, identifying these genes as parts of a well-conserved repair pathway.

Nijmegen breakage syndrome results from mutations in a gene coding for a protein (variously called Nibrin, p95, or NBS1) that is a component of the Mre11/Rad50 repair complex (2925; 2926). Its involvement in repairing double-strand breaks is shown by the formation of foci containing the group of proteins when human cells are irradiated with agents that induce double-strand breaks. After irradiation, the kinase ATMP (coded by the *AT* gene) phosphorylates NBS1; this activates the complex, which localizes at sites of DNA damage. Subsequent steps involve triggering a checkpoint (a mechanism that prevents the cell cycle from proceeding until the damage is repaired; see *Molecular Biology 4.15.29 A common system repairs double-strand breaks*), and recruiting other proteins that are required to repair the damage (for review see 3431).

## RECOMBINATION AND REPAIR

### 4.15.30 Summary

---

Recombination involves the physical exchange of parts between corresponding DNA molecules. This results in a duplex DNA in which two regions of opposite parental origins are connected by a stretch of hybrid (heteroduplex) DNA in which one strand is derived from each parent. Correction events may occur at sites that are mismatched within the hybrid DNA. Hybrid DNA can also be formed without recombination occurring between markers on either side. Gene conversion occurs when an extensive region of hybrid DNA forms during normal recombination (or between nonallelic genes in an aberrant event) and is corrected to the sequence of only one parental strand; then one gene takes on the sequence of the other.

Recombination is initiated by a double-strand break in DNA. The break is enlarged to a gap with a single-stranded end; then the free single-stranded end forms a heteroduplex with the allelic sequence. The DNA in which the break occurs actually incorporates the sequence of the chromosome that it invades, so the initiating DNA is called the recipient. Hot spots for recombination are sites where double strand breaks are initiated. A gradient of gene conversion is determined by the likelihood that a sequence near the free end will be converted to a single strand; this decreases with distance from the break.

Recombination is initiated in yeast by Spo11, a topoisomerase-like enzyme that becomes linked to the free 5' ends of DNA. The DSB is then processed by generating single-stranded DNA that can anneal with its complement in the other chromosome. Yeast mutations that block synaptonemal complex formation show that recombination is required for its formation. Formation of the synaptonemal complex may be initiated by double-strand breaks, and it may persist until recombination is completed. Mutations in components of the synaptonemal complex block its formation but do not prevent chromosome pairing, so homologue recognition is independent of recombination and synaptonemal complex formation.

The full set of reactions required for recombination can be undertaken by the Rec and Ruv proteins of *E. coli*. A single stranded region with a free end is generated by the RecBCD nuclease. The enzyme binds to DNA on one side of a *chi* sequence, and then moves to the *chi* sequence, unwinding DNA as it progresses. A single-strand break is made at the *chi* sequence. *chi* sequences provide hotspots for recombination. The single-strand provides a substrate for RecA, which has the ability to synapse homologous DNA molecules by sponsoring a reaction in which a single strand from one molecule invades a duplex of the other molecule. Heteroduplex DNA is formed by displacing one of the original strands of the duplex. These actions create a recombination junction, which is resolved by the Ruv proteins. RuvA and RuvB act at a heteroduplex, and RuvC cleaves Holliday junctions.

Recombination, like replication and (probably) transcription, requires topological manipulation of DNA. Topoisomerases may relax (or introduce) supercoils in DNA, and are required to disentangle DNA molecules that have become catenated by recombination or by replication. Type I topoisomerases introduce a break in one strand of a DNA duplex; type II topoisomerases make double-stranded breaks. The

---

enzyme becomes linked to the DNA by a bond from tyrosine to either 5' phosphate (type A enzymes) or 3' phosphate (type B enzymes).

The enzymes involved in site-specific recombination have actions related to those of topoisomerases. Among this general class of recombinases, those concerned with phage integration form the subclass of integrases. The Cre-*lox* system uses two molecules of Cre to bind to each *lox* site, so that the recombining complex is a tetramer. This is one of the standard systems for inserting DNA into a foreign genome. Phage lambda integration requires the phage Int protein and host IHF protein and involves a precise breakage and reunion in the absence of any synthesis of DNA. The reaction involves wrapping of the *attP* sequence of phage DNA into the nucleoprotein structure of the intasome, which contains several copies of Int and IHF; then the host *attB* sequence is bound, and recombination occurs. Reaction in the reverse direction requires the phage protein Xis. Some integrases function by *cis*-cleavage, where the tyrosine that reacts with DNA in a half site is provided by the enzyme subunit bound to that half site; others function by *trans*-cleavage, where a different protein subunit provides the tyrosine.

Bacteria contain systems that maintain the integrity of their DNA sequences in the face of damage or errors of replication and that distinguish the DNA from sequences of a foreign source.

Repair systems can recognize mispaired, altered, or missing bases in DNA, or other structural distortions of the double helix. Excision repair systems cleave DNA near a site of damage, remove one strand, and synthesize a new sequence to replace the excised material. The Uvr system provides the main excision-repair pathway in *E. coli*. The *dam* system is involved in correcting mismatches generated by incorporation of incorrect bases during replication and functions by preferentially removing the base on the strand of DNA that is not methylated at the *dam* target sequence. Eukaryotic homologues of the *E. coli* MutSL system are involved in repairing mismatches that result from replication slippage; mutations in this pathway are common in certain types of cancer.

Recombination-repair systems retrieve information from a DNA duplex and use it to repair a sequence that has been damaged on both strands. The RecBC and RecF pathways both act prior to RecA, whose strand-transfer function is involved in all bacterial recombination. A major use of recombination-repair may be to recover from the situation created when a replication fork stalls.

The other capacity of recA is the ability to induce the SOS response. RecA is activated by damaged DNA in an unknown manner. It triggers cleavage of the LexA repressor protein, thus releasing repression of many loci, and inducing synthesis of the enzymes of both excision repair and recombination-repair pathways. Genes under LexA control possess an operator SOS box. RecA also directly activates some repair activities. Cleavage of repressors of lysogenic phages may induce the phages to enter the lytic cycle.

Repair systems can be connected with transcription in both prokaryotes and eukaryotes. Human diseases are caused by mutations in genes coding for repair activities that are associated with the transcription factor TFIIF. They have homologues in the *RAD* genes of yeast, suggesting that this repair system is

widespread.

Nonhomologous end joining (NHEJ) is a general reaction for repairing broken ends in (eukaryotic) DNA. The Ku heterodimer brings the broken ends together so they can be ligated. Several human diseases are caused by mutations in enzymes of this pathway.

## TRANSPOSONS

### 4.16.1 Introduction

---

#### Key Terms

A **transposon (transposable element)** is a DNA sequence able to insert itself (or a copy of itself) at a new location in the genome, without having any sequence relationship with the target locus.

---

Genomes evolve both by acquiring new sequences and by rearranging existing sequences.

The sudden introduction of new sequences results from the ability of vectors to carry information between genomes. Extrachromosomal elements move information horizontally by mediating the transfer of (usually rather short) lengths of genetic material. In bacteria, plasmids move by conjugation (see *Molecular Biology 4.13.13 Conjugation transfers single-stranded DNA*), while phages spread by infection (see *Molecular Biology 3.12 Phage strategies*). Both plasmids and phages occasionally transfer host genes along with their own replicon. Direct transfer of DNA occurs between some bacteria by means of transformation (see *Molecular Biology 1.1.2 DNA is the genetic material of bacteria*). In eukaryotes, some viruses, notably the retroviruses, can transfer genetic information during an infective cycle (see *Molecular Biology 4.17.6 Retroviruses may transduce cellular sequences*).

Rearrangements are sponsored by processes internal to the genome. Two of the major causes are summarized in **Figure 16.1**.

**Figure 16.1** A major cause of sequence change within a genome is the movement of a transposon to a new site. This may have direct consequences on gene expression. Unequal crossing-over between related sequences causes rearrangements. Copies of transposons can provide targets for such events.

Unequal recombination results from mispairing by the cellular systems for homologous recombination. Nonreciprocal recombination results in duplication or rearrangement of loci (see *Molecular Biology 1.4.7 Unequal crossing-over rearranges gene clusters*). Duplication of sequences within a genome provides a major source of new sequences. One copy of the sequence can retain its original function, while the other may evolve into a new function. Furthermore, significant differences between individual genomes are found at the molecular level because of polymorphic variations caused by recombination. We saw in *Molecular Biology 1.4.14 Minisatellites are useful for genetic mapping* that recombination between minisatellites adjusts their lengths so that every individual genome is distinct.

Another major cause of variation is provided by **transposable elements** or **transposons**: these are discrete sequences in the genome that are mobile – they are able to transport themselves to other locations within the genome. The mark of a transposon is that it does not utilize an independent form of the element (such as phage or plasmid DNA), but moves directly from one site in the genome to another. Unlike most other processes involved in genome restructuring, transposition does not rely on any relationship between the sequences at the donor and recipient sites. Transposons are restricted to moving themselves, and sometimes additional sequences, to new sites elsewhere within the same genome; they are therefore an internal counterpart to the vectors that can transport sequences from one genome to another. They may provide the major source of mutations in the genome.

Transposons fall into two general classes. The groups of transposons reviewed in this chapter exist as sequences of DNA coding for proteins that are able directly to manipulate DNA so as to propagate themselves within the genome. The transposons

reviewed in *Molecular Biology 4.17 Retroviruses and retroposons* are related to retroviruses, and the source of their mobility is the ability to make DNA copies of their RNA transcripts; the DNA copies then become integrated at new sites in the genome.

Transposons that mobilize via DNA are found in both prokaryotes and eukaryotes. Each bacterial transposon carries gene(s) that code for the enzyme activities required for its own transposition, although it may also require ancillary functions of the genome in which it resides (such as DNA polymerase or DNA gyrase). Comparable systems exist in eukaryotes, although their enzymatic functions are not so well characterized. A genome may contain both functional and nonfunctional (defective) elements. Often the majority of elements in a eukaryotic genome are defective, and have lost the ability to transpose independently, although they may still be recognized as substrates for transposition by the enzymes produced by functional transposons (for review see 164). A eukaryotic genome contains a large number and variety of transposons. The fly genome has >50 types of transposon, with a total of several hundred individual elements.

Transposable elements can promote rearrangements of the genome, directly or indirectly:

- The transposition event itself may cause deletions or inversions or lead to the movement of a host sequence to a new location.
- Transposons serve as substrates for cellular recombination systems by functioning as "portable regions of homology"; two copies of a transposon at different locations (even on different chromosomes) may provide sites for reciprocal recombination. Such exchanges result in deletions, insertions, inversions, or translocations.

The intermittent activities of a transposon seem to provide a somewhat nebulous target for natural selection. This concern has prompted suggestions that (at least some) transposable elements confer neither advantage nor disadvantage on the phenotype, but could constitute "selfish DNA," concerned only with their own propagation. Indeed, in considering transposition as an event that is distinct from other cellular recombination systems, we tacitly accept the view that the transposon is an independent entity that resides in the genome.

Such a relationship of the transposon to the genome would resemble that of a parasite with its host. Presumably the propagation of an element by transposition is balanced by the harm done if a transposition event inactivates a necessary gene, or if the number of transposons becomes a burden on cellular systems. Yet we must remember that any transposition event conferring a selective advantage – for example, a genetic rearrangement – will lead to preferential survival of the genome carrying the active transposon (for review see 146).

## TRANSPOSONS

### 4.16.2 Insertion sequences are simple transposition modules

---

#### Key Terms

An insertion sequence (IS) is a small bacterial transposon that carries only the genes needed for its own transposition.

Inverted terminal repeats are the short related or identical sequences present in reverse orientation at the ends of some transposons.

Direct repeats are identical (or closely related) sequences present in two or more copies in the same orientation in the same molecule of DNA; they are not necessarily adjacent.

A transposase is the enzyme activity involved in insertion of transposon at a new site.

#### Key Concepts

- An insertion sequence is a transposon that codes for the enzyme(s) needed for transposition flanked by short inverted terminal repeats.
- The target site at which a transposon is inserted is duplicated during the insertion process to form two repeats in direct orientation at the ends of the transposon.
- The length of the direct repeat is 5-9 bp and is characteristic for any particular transposon.

---

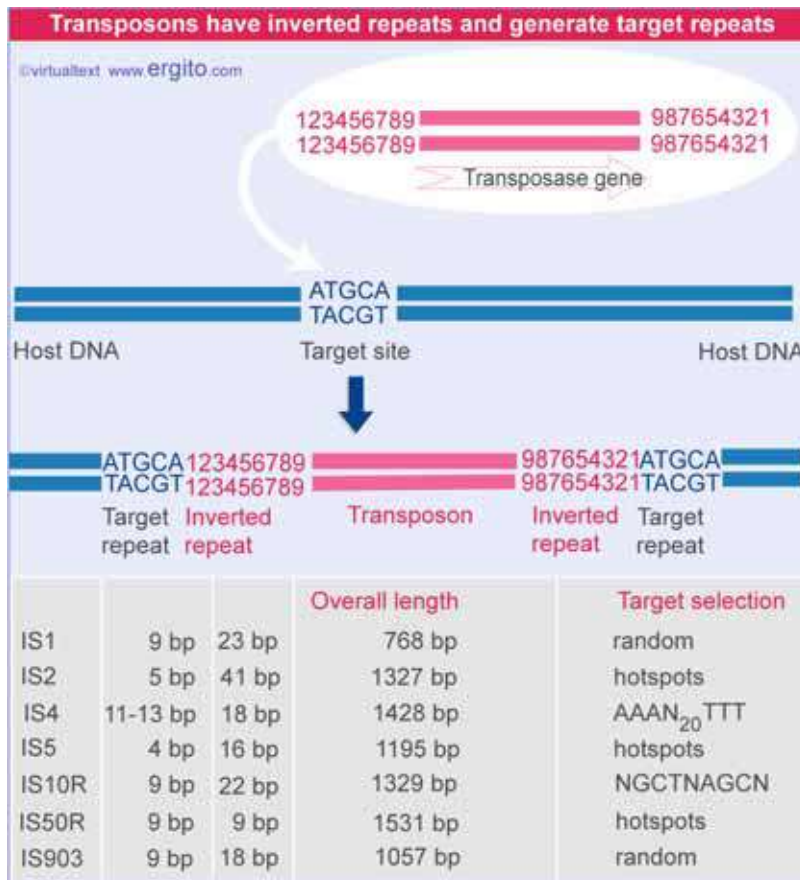

Transposable elements were first identified at the molecular level in the form of spontaneous insertions in bacterial operons. Such an insertion prevents transcription and/or translation of the gene in which it is inserted. Many different types of transposable elements have now been characterized (for review see 143; 144; 145; 149).

The simplest transposons are called insertion sequences (reflecting the way in which they were detected). Each type is given the prefix **IS**, followed by a number that identifies the type. (The original classes were numbered IS1-4; later classes have numbers reflecting the history of their isolation, but not corresponding to the total number of elements so far isolated!)

The IS elements are normal constituents of bacterial chromosomes and plasmids. A standard strain of *E. coli* is likely to contain several (<10) copies of any one of the more common IS elements. To describe an insertion into a particular site, a double colon is used; so  $\lambda::IS1$  describes an IS1 element inserted into phage lambda.

The IS elements are autonomous units, each of which codes only for the proteins needed to sponsor its own transposition. Each IS element is different in sequence, but there are some common features in organization. The structure of a generic

transposon before and after insertion at a target site is illustrated in **Figure 16.2**, which also summarizes the details of some common IS elements (for review see 153).

**Figure 16.2** Transposons have inverted terminal repeats and generate direct repeats of flanking DNA at the target site. In this example, the target is a 5 bp sequence. The ends of the transposon consist of inverted repeats of 9 bp, where the numbers 1 through 9 indicate a sequence of base pairs.

An IS element ends in short **inverted terminal repeats**; usually the two copies of the repeat are closely related rather than identical. As illustrated in the figure, the presence of the inverted terminal repeats means that the same sequence is encountered proceeding toward the element from the flanking DNA on either side of it.

When an IS element transposes, a sequence of host DNA at the site of insertion is duplicated. The nature of the duplication is revealed by comparing the sequence of the target site before and after an insertion has occurred. **Figure 16.2** shows that at the site of insertion, the IS DNA is always flanked by very short **direct repeats**. (In this context, "direct" indicates that two copies of a sequence are repeated in the same orientation, not that the repeats are adjacent.) But in the original gene (prior to insertion), the target site has the sequence of only one of these repeats. In the figure,

---

**ATGCA** . After transposition, one copy of this sequence is present on either side of  
**TACGT**  
the transposon (562; 563).

The sequence of the direct repeat varies among individual transposition events undertaken by a transposon, but the length is constant for any particular IS element (a reflection of the mechanism of transposition). The most common length for the direct repeats is 9 bp.

An IS element therefore displays a characteristic structure in which its ends are identified by the inverted terminal repeats, while the adjacent ends of the flanking host DNA are identified by the short direct repeats. When observed in a sequence of DNA, this type of organization is taken to be diagnostic of a transposon, and suggests that the sequence originated in a transposition event.

Most IS elements insert at a variety of sites within host DNA. However, some show (varying degrees of) preference for particular hotspots (for review see 163).

The inverted repeats define the ends of a transposon. Recognition of the ends is common to transposition events sponsored by all types of transposon. *Cis*-acting mutations that prevent transposition are located in the ends, which are recognized by a protein(s) responsible for transposition. The protein is called a **transposase**.

All the IS elements except IS1 contain a single long coding region, starting just inside the inverted repeat at one end, and terminating just before or within the inverted repeat at the other end. This codes for the transposase. IS1 has a more complex organization, with two separate reading frames; the transposase is produced by making a frameshift during translation to allow both reading frames to be used.

The frequency of transposition varies among different elements. The overall rate of transposition is  $\sim 10^{-3}$ – $10^{-4}$  per element per generation. Insertions in individual targets occur at a level comparable with the spontaneous mutation rate, usually  $\sim 10^{-5}$ – $10^{-7}$  per generation. Reversion (by precise excision of the IS element) is usually infrequent, with a range of rates of  $10^{-6}$  to  $10^{-10}$  per generation,  $\sim 10^3$  times less frequent than insertion.

## TRANSPOSONS

### 4.16.3 Composite transposons have IS modules

---

#### Key Terms

Bacterial transposons that contain markers that are not related to their function, e.g. drug resistance, are named as **Tn** followed by a number.

**Composite transposons (Composite element)** have a central region flanked on each side by insertion sequences, either or both of which may enable the entire element to transpose.

#### Key Concepts

- Transposons can carry other genes in addition to those coding for transposition.
- Composite transposons have a central region flanked by an IS element at each end.
- Either one or both of the IS elements of a composite transposon may be able to undertake transposition.
- A composite transposon may transpose as a unit, but an active IS element at either end may also transpose independently.

---

Some transposons carry drug resistance (or other) markers in addition to the functions concerned with transposition. These transposons are named **Tn** followed by a number. One class of larger transposons are called **composite elements**, because a central region carrying the drug marker(s) is flanked on either side by "arms" that consist of IS elements.

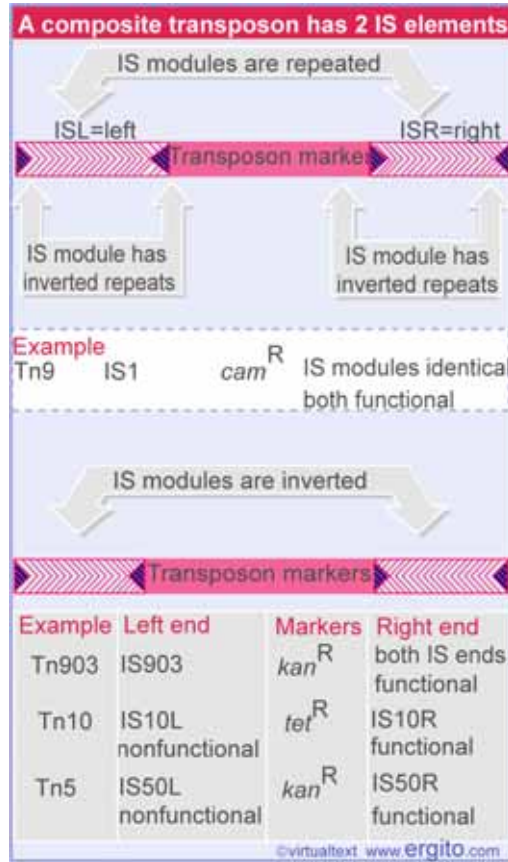

The arms may be in either the same or (more commonly) inverted orientation. So a composite transposon with arms that are direct repeats has the structure

If the arms are inverted repeats, the structure is

The arrows indicate the orientation of the arms, which are identified as L and R according to an (arbitrary) orientation of the genetic map of the transposon from left to right. The structure of a composite transposon is illustrated in more detail in **Figure 16.3**, which also summarizes the properties of some common composite transposons.

**Figure 16.3** A composite transposon has a central region carrying markers (such as drug resistance) flanked by IS modules. The modules have short inverted terminal repeats. If the modules themselves are in inverted orientation, the short inverted terminal repeats at the ends of the transposon are identical.

Since arms consist of IS modules, and each module has the usual structure ending in inverted repeats, the composite transposon also ends in the same short inverted repeats.

In some cases, the modules of a composite transposon are identical, such as Tn9 (direct repeats of IS1) or Tn903 (inverted repeats of IS903). In other cases, the modules are closely related, but not identical. So we can distinguish the L and R modules in Tn10 or in Tn5.

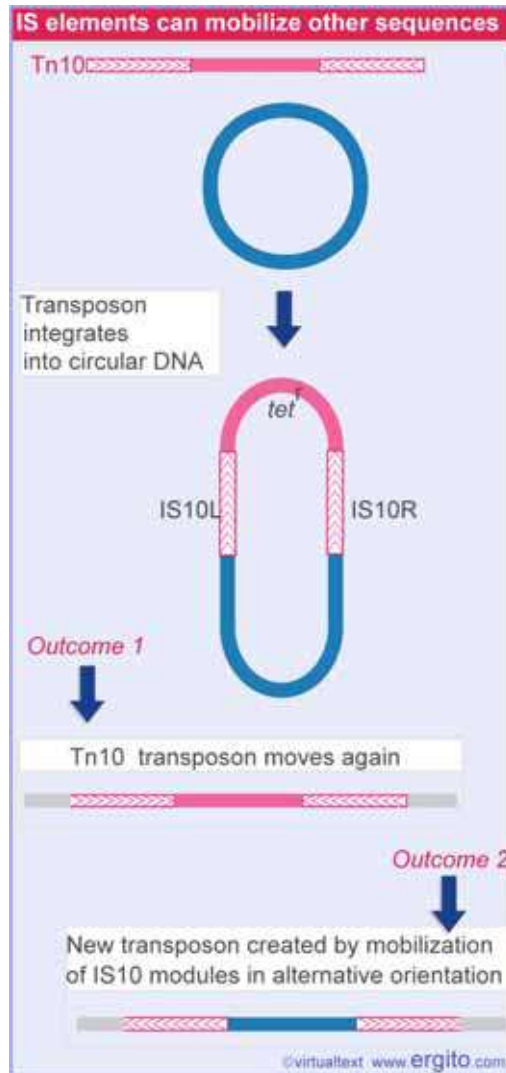

A functional IS module can transpose either itself or the entire transposon. When the modules of a composite transposon are identical, presumably either module can sponsor movement of the transposon, as in the case of Tn9 or Tn903. When the modules are different, they may differ in functional ability, so transposition can depend entirely or principally on one of the modules, as in the case of Tn10 or Tn5.

We assume that composite transposons evolved when two originally independent modules associated with the central region. Such a situation could arise when an IS element transposes to a recipient site close to the donor site. The two identical

modules may remain identical or diverge. The ability of a single module to transpose the entire composite element explains the lack of selective pressure for both modules to remain active.

What is responsible for transposing a composite transposon instead of just the individual module? This question is especially pressing in cases where both the modules are functional. In the example of Tn9, where the modules are IS1 elements, presumably each is active in its own right as well as on behalf of the composite transposon. Why is the transposon preserved as a whole, instead of each insertion sequence looking out for itself?

Two IS elements in fact can transpose any sequence residing between them, as well as themselves. **Figure 16.4** shows that if Tn10 resides on a circular replicon, its two modules can be considered to flank either the *tet<sup>R</sup>* gene of the original Tn10 or the sequence in the other part of the circle. So a transposition event can involve either the original Tn10 transposon (marked by the movement of *tet<sup>R</sup>*) or the creation of the new "inside-out" transposon with the alternative central region.

**Figure 16.4** Two IS10 modules create a composite transposon that can mobilize any region of DNA that lies between them. When Tn10 is part of a small circular molecule, the IS10 repeats can transpose either side of the circle.

Note that both the original and "inside-out" transposons have inverted modules, but these modules evidently can function in either orientation relative to the central region. The frequency of transposition for composite transposons declines with the distance between the modules. So length dependence is a factor in determining the sizes of the common composite transposons.

A major force supporting the transposition of composite transposons is selection for the marker(s) carried in the central region. An IS10 module is free to move around on its own, and mobilizes an order of magnitude more frequently than Tn10. But Tn10 is held together by selection for *tet<sup>R</sup>*; so that under selective conditions, the relative frequency of intact Tn10 transposition is much increased (for review see 154).

The IS elements code for transposase activities that are responsible both for creating a target site and for recognizing the ends of the transposon. Only the ends are needed for a transposon to serve as a substrate for transposition.

## TRANSPOSONS

### 4.16.4 Transposition occurs by both replicative and nonreplicative mechanisms

---

#### Key Terms

**Replicative transposition** describes the movement of a transposon by a mechanism in which first it is replicated, and then one copy is transferred to a new site.

A **transposase** is the enzyme activity involved in insertion of transposon at a new site.

**Resolvase** is the enzyme activity involved in site-specific recombination between two transposons present as direct repeats in a cointegrate structure.

**Nonreplicative transposition** describes the movement of a transposon that leaves a donor site (usually generating a double-strand break) and moves to a new site.

**Conservative transposition** refers to the movement of large elements, originally classified as transposons, but now considered to be episomes. The mechanism of movement resembles that of phage excision and integration.

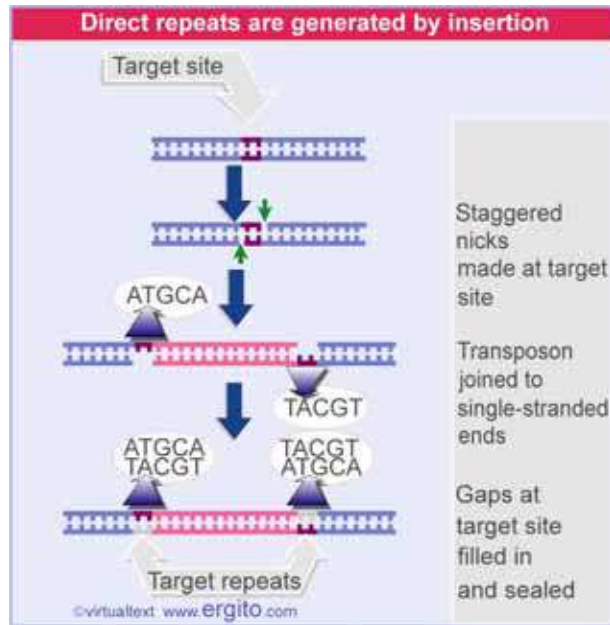

#### Key Concepts

- All transposons use a common mechanism in which staggered nicks are made in target DNA, the transposon is joined to the protruding ends, and the gaps are filled.
- The order of events and exact nature of the connections between transposon and target DNA determine whether transposition is replicative or nonreplicative.

---

The insertion of a transposon into a new site is illustrated in **Figure 16.5**. It consists of making staggered breaks in the target DNA, joining the transposon to the protruding single-stranded ends, and filling in the gaps. The generation and filling of the staggered ends explain the occurrence of the direct repeats of target DNA at the site of insertion. The stagger between the cuts on the two strands determines the length of the direct repeats; so the target repeat characteristic of each transposon reflects the geometry of the enzyme involved in cutting target DNA (for review see 148).

**Figure 16.5** The direct repeats of target DNA flanking a transposon are generated by the introduction of staggered cuts whose protruding ends are linked to the transposon.

The use of staggered ends is common to all means of transposition, but we can distinguish three different types of mechanism by which a transposon moves:

- In **replicative transposition**, the element is duplicated during the reaction, so that the transposing entity is a copy of the original element. **Figure 16.6** summarizes the results of such a transposition. The transposon is copied as part of its movement. One copy remains at the original site, while the other inserts at the new site. So transposition is accompanied by an increase in the number of copies of the transposon. Replicative transposition involves two types of enzymatic activity: a **transposase** that acts on the ends of the original transposon; and a **resolvase** that acts on the duplicated copies. A group of transposons related to TnA move only by replicative transposition (see *Molecular Biology 4.16.7 Replicative transposition proceeds through a cointegrate*).
- In **nonreplicative transposition**, the transposing element moves as a physical entity directly from one site to another, and is conserved. The insertion sequences and composite transposons **Tn10** and **Tn5** use the mechanism shown in Figure 16.7, which involves the release of the transposon from the flanking donor DNA during transfer. This type of mechanism requires only a transposase. Another mechanism utilizes the connection of donor and target DNA sequences and shares some steps with replicative transposition (see *Molecular Biology 4.16.6 Common intermediates for transposition*). Both mechanisms of nonreplicative transposition cause the element to be inserted at the target site and lost from the donor site. What happens to the donor molecule after a nonreplicative transposition? Its survival requires that host repair systems recognize the double-strand break and repair it.

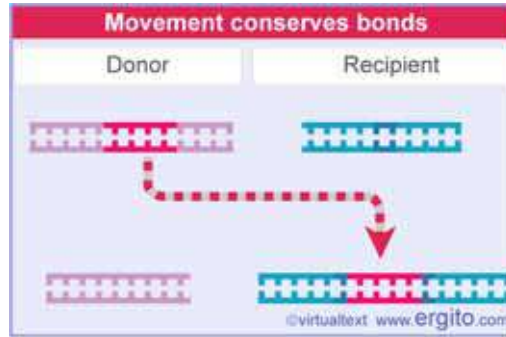

- **Conservative transposition** describes another sort of nonreplicative event, in which the element is excised from the donor site and inserted into a target site by a series of events in which every nucleotide bond is conserved. **Figure 16.8** summarizes the result of a conservative event. This exactly resembles the mechanism of lambda integration discussed in *Molecular Biology 4.15.17 Site-specific recombination involves breakage and reunion*, and the transposases of such elements are related to the  $\lambda$  integrase family. The elements that use this mechanism are large, and can mediate transfer not only of the element itself but also of donor DNA from one bacterium to another. Although originally classified as transposons, such elements may more properly be regarded as episomes (for review see 162).

**Figure 16.6** Replicative transposition creates a copy of the transposon, which inserts at a recipient site. The donor site remains unchanged, so both donor and recipient have a copy of the transposon.

**Figure 16.7** Nonreplicative transposition allows a transposon to move as a physical entity from a donor to a recipient site. This leaves a break at the donor site, which is lethal unless it can be repaired.

**Figure 16.8** Conservative transposition involves direct movement with no loss of nucleotide bonds; compare with lambda integration and excision.

Although some transposons use only one type of pathway for transposition, others may be able to use multiple pathways. The elements IS1 and IS903 use both nonreplicative and replicative pathways, and the ability of phage Mu to turn to either type of pathway from a common intermediate has been well characterized (see *Molecular Biology 4.16.6 Common intermediates for transposition*).

The same basic types of reaction are involved in all classes of transposition event (for review see 3142). The ends of the transposon are disconnected from the donor DNA by cleavage reactions that generate 3' -OH ends. Then the exposed ends are joined to the target DNA by transfer reactions, involving transesterification in which the 3' -OH end directly attacks the target DNA. These reactions take place within a nucleoprotein complex that contains the necessary enzymes and both ends of the transposon. Transposons differ as to whether the target DNA is recognized before or after the cleavage of the transposon itself.

The choice of target site is in effect made by the transposase. In some cases, the target is chosen virtually at random. In others, there is specificity for a consensus sequence or for some other feature in DNA (163). The feature can take the form of a structure in DNA, such as bent DNA, or for a protein-DNA complex. In the latter case, the nature of the target complex can cause the transposon to insert at specific promoters (such as Ty1 or Ty3 which select pol III promoters in yeast), inactive regions of the chromosome, or replicating DNA.

## TRANSPOSONS

### 4.16.5 Transposons cause rearrangement of DNA

---

#### Key Terms

A **deletion** is the removal of a sequence of DNA, the regions on either side being joined together except in the case of a terminal deletion at the end of a chromosome.

**Precise excision** describes the removal of a transposon plus one of the duplicated target sequences from the chromosome. Such an event can restore function at the site where the transposon inserted.

**Imprecise excision** occurs when the transposon removes itself from the original insertion site, but leaves behind some of its sequence.

#### Key Concepts

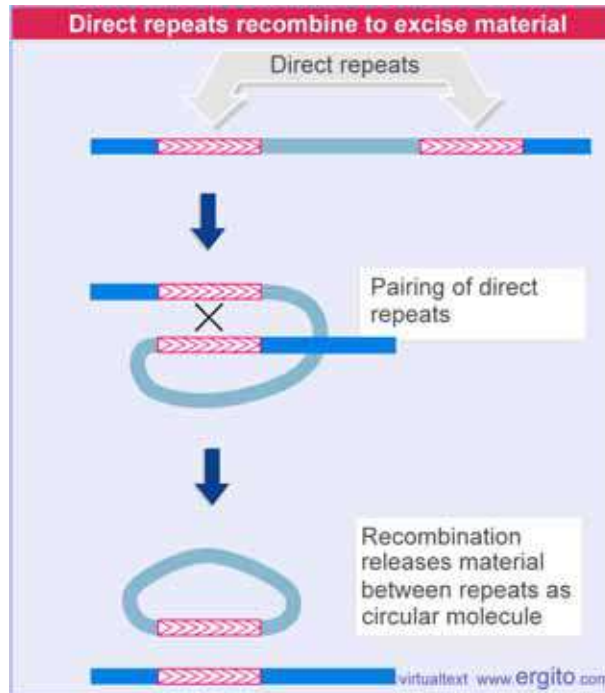

- Homologous recombination between multiple copies of a transposon causes rearrangement of host DNA.
- Homologous recombination between the repeats of a transposon may lead to precise or imprecise excision.

---

In addition to the "simple" intermolecular transposition that results in insertion at a new site, transposons promote other types of DNA rearrangements. Some of these events are consequences of the relationship between the multiple copies of the transposon. Others represent alternative outcomes of the transposition mechanism, and they leave clues about the nature of the underlying events.

Rearrangements of host DNA may result when a transposon inserts a copy at a second site near its original location. Host systems may undertake reciprocal recombination between the two copies of the transposon; the consequences are determined by whether the repeats are the same or in inverted orientation.

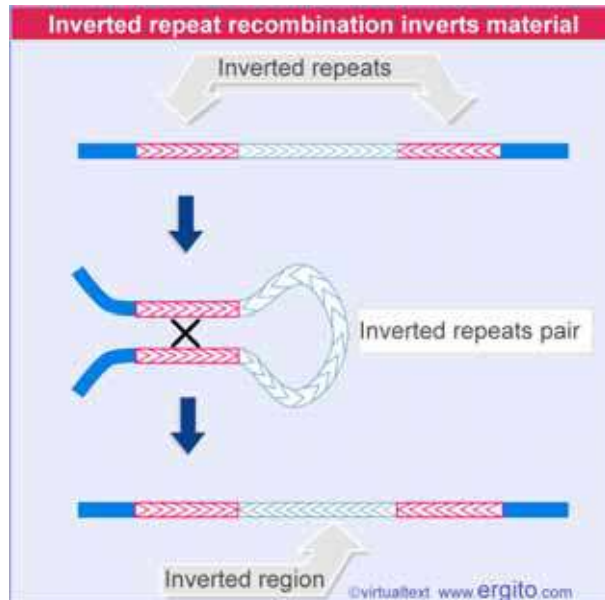

**Figure 16.9** illustrates the general rule that recombination between any pair of direct repeats will delete the material between them. The intervening region is excised as a circle of DNA (which is lost from the cell); the chromosome retains a single copy of the direct repeat. A recombination between the directly repeated IS1 modules of the composite transposon Tn9 would replace the transposon with a single IS1 module.

**Figure 16.9** Reciprocal recombination between direct repeats excises the material between them; each product of recombination has one copy of the direct repeat.

**Deletion** of sequences adjacent to a transposon could therefore result from a two-stage process; transposition generates a direct repeat of a transposon, and recombination occurs between the repeats. However, the majority of deletions that arise in the vicinity of transposons probably result from a variation in the pathway followed in the transposition event itself.

**Figure 16.10** depicts the consequences of a reciprocal recombination between a pair of inverted repeats. The region between the repeats becomes inverted; the repeats themselves remain available to sponsor further inversions. A composite transposon whose modules are inverted is a stable component of the genome, although the direction of the central region with regard to the modules could be inverted by recombination.

**Figure 16.10** Reciprocal recombination between inverted repeats inverts the region between them.

Excision is not supported by transposons themselves, but may occur when bacterial enzymes recognize homologous regions in the transposons. This is important because the loss of a transposon may restore function at the site of insertion. **Precise excision** requires removal of the transposon plus one copy of the duplicated sequence. This is rare; it occurs at a frequency of  $\sim 10^{-6}$  for Tn5 and  $\sim 10^{-9}$  for Tn10. It probably involves a recombination between the 9 bp duplicated target sites.

**Imprecise excision** leaves a remnant of the transposon. Although the remnant may be sufficient to prevent reactivation of the target gene, it may be insufficient to cause polar effects in adjacent genes, so that a change of phenotype occurs. Imprecise excision occurs at a frequency of  $\sim 10^{-6}$  for Tn10. It involves recombination between sequences of 24 bp in the IS10 modules; these sequences are inverted repeats, but since the IS10 modules themselves are inverted, they form direct repeats in Tn10.

The greater frequency of imprecise excision compared with precise excision probably reflects the increase in the length of the direct repeats (24 bp as opposed to 9 bp). Neither type of excision relies on transposon-coded functions, but the mechanism is not known. Excision is RecA-independent and could occur by some cellular mechanism that generates spontaneous deletions between closely spaced repeated sequences.

*This content is available online at <http://www.ergito.com/main.jsp?bcs=MBIO.4.16.5>*

## TRANSPOSONS

### 4.16.6 Common intermediates for transposition

---

#### Key Concepts

- Transposition starts by forming a strand transfer complex in which the transposon is connected to the target site through one strand at each end.
  - The Mu transposase forms the complex by synapsing the ends of Mu DNA, followed by nicking, and then a strand transfer reaction.
  - Replicative transposition follows if the complex is replicated and nonreplicative transposition follows if it is repaired.
- 

Many mobile DNA elements transpose from one chromosomal location to another by a fundamentally similar mechanism. They include IS elements, prokaryotic and eukaryotic transposons, and bacteriophage Mu. Insertion of the DNA copy of retroviral RNA uses a similar mechanism (see *Molecular Biology 4.17.2 The retrovirus life cycle involves transposition-like events*). The first stages of immunoglobulin recombination also are similar (see *Molecular Biology 5.25.9 The RAG proteins catalyze breakage and reunion*).

Transposition starts with a common mechanism for joining the transposon to its target. **Figure 16.11** shows that the transposon is nicked at both ends, and the target site is nicked on both strands. The nicked ends are joined crosswise to generate a covalent connection between the transposon and the target. The two ends of the transposon are brought together in this process; for simplicity in following the cleavages, the synapsis stage is shown after cleavage, but actually occurs previously.

**Figure 16.11** Transposition is initiated by nicking the transposon ends and target site and joining the nicked ends into a strand transfer complex.

Much of this pathway was first revealed with phage Mu, which uses the process of transposition in two ways. Upon infecting a host cell, Mu integrates into the genome by nonreplicative transposition; during the ensuing lytic cycle, the number of copies is amplified by replicative transposition. Both types of transposition involve the same type of reaction between the transposon and its target, but the subsequent reactions are different (for review see 157; 160).

The initial manipulations of the phage DNA are performed by the MuA transposase. Three MuA-binding sites with a 22 bp consensus are located at each end of Mu DNA. L1, L2, and L3 are at the left end; R1, R2, and R3 are at the right end. A monomer of MuA can bind to each site. MuA also binds to an internal site in the phage genome. Binding of MuA at both the left and right ends and the internal site forms a complex. The role of the internal site is not clear; it appears to be necessary for formation of the complex, but not for strand cleavage and subsequent steps.

Joining the Mu transposon DNA to a target site passes through the three stages illustrated in **Figure 16.12**. This involves only the two sites closest to each end of the transposon. MuA subunits bound to these sites form a tetramer. This achieves synapsis of the two ends of the transposon. The tetramer now functions in a way that ensures a coordinated reaction on both ends of Mu DNA. MuA has two sites for manipulating DNA, and their mode of action compels subunits of the transposase to act in *trans*. The consensus-binding site binds to the 22 bp sequences that constitute the L1, L2, R1, and R2 sites. The active site cleaves the Mu DNA strands at positions adjacent to the MuA-binding sites L1 and R1. But the active site cannot cleave the DNA sequence that is adjacent to the consensus sequence in the consensus-binding site. However, it can cleave the appropriate sequence on a different stretch of DNA.

**Figure 16.12** Mu transposition passes through three stable stages. MuA transposase forms a tetramer that synapses the ends of phage Mu. Transposase subunits act in *trans* to nick each end of the DNA; then a second *trans* action joins the nicked ends to the target DNA.

The ends of the transposon are thus cleaved by MuA subunits acting in *trans*. The *trans* mode of action means that the monomers actually bound to L1 and R1 do not cleave the adjacent sites. One of the monomers bound to the left end nicks the site at the right end, and vice versa. (We do not know which monomer is active at this stage)

of the reaction.) The strand transfer reaction also occurs in *trans*; the monomer at L1 transfers the strand at R1, and vice versa. It could be the case that different monomers catalyze the cleavage and strand transfer reactions for a given end (571; 572).

A second protein, MuB, assists the reaction. It has an influence on the choice of target sites. Mu has a preference for transposing to a target site >10-15 kb away from the original insertion. This is called "target immunity." It is demonstrated in an *in vitro* reaction containing donor (Mu-containing) and target (Mu-deficient) plasmids, MuA and MuB proteins, *E. coli* HU protein, and  $Mg^{2+}$  and ATP. The presence of MuB and ATP restricts transposition exclusively to the target plasmid. The reason is that when MuB binds to the MuA-Mu DNA complex, MuA causes MuB to hydrolyze ATP, after which MuB is released. However, MuB binds (nonspecifically) to the target DNA, where it stimulates the recombination activity of MuA when a transposition complex forms. In effect, the prior presence of MuA "clears" MuB from the donor, thus giving a preference for transposition to the target.

The product of these reactions is a strand transfer complex in which the transposon is connected to the target site through one strand at each end. The next step of the reaction differs and determines the type of transposition. We see in the next two sections how the common structure can be a substrate for replication (leading to replicative transposition) or used directly for breakage and reunion (leading to nonreplicative transposition).
