---

#### Key Terms

A **cointegrate structure** is produced by fusion of two replicons, one originally possessing a transposon, the other lacking it; the cointegrate has copies of the transposon present at both junctions of the replicons, oriented as direct repeats.

**Resolution** occurs by a homologous recombination reaction between the two copies of the transposon in a cointegrate. The reaction generates the donor and target replicons, each with a copy of the transposon.

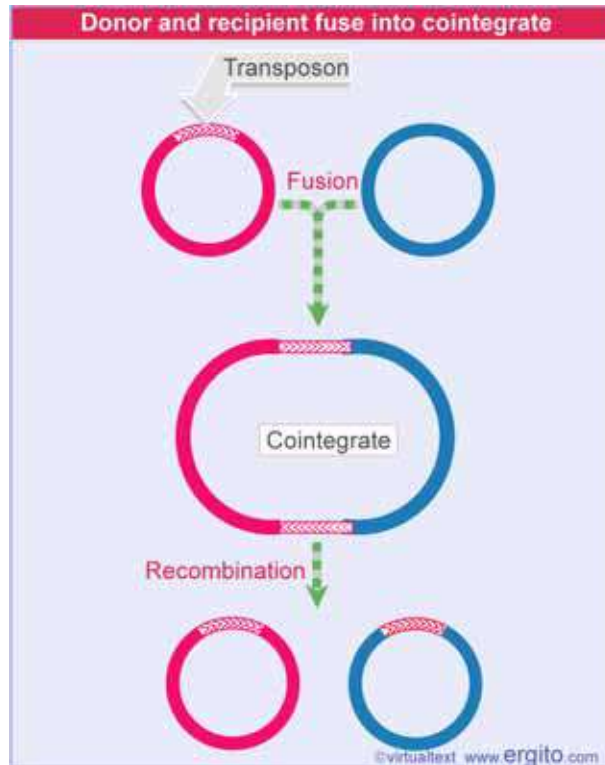

**Resolvase** is the enzyme activity involved in site-specific recombination between two transposons present as direct repeats in a cointegrate structure.

#### Key Concepts

- Replication of a strand transfer complex generates a cointegrate, which is a fusion of the donor and target replicons.
- The cointegrate has two copies of the transposon, which lie between the original replicons.
- Recombination between the transposon copies regenerates the original replicons, but the recipient has gained a copy of the transposon.
- The recombination reaction is catalyzed by a resolvase coded by the transposon.

---

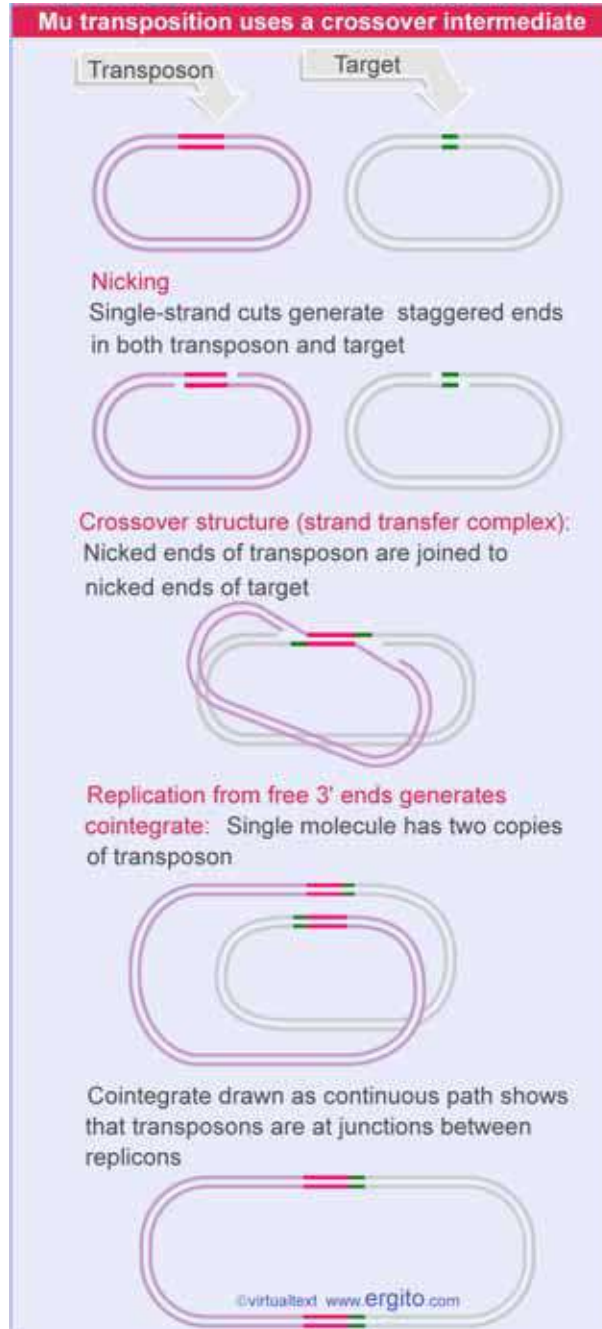

The basic structures involved in replicative transposition are illustrated in **Figure 16.13**:

**Figure 16.13** Transposition may fuse a donor and recipient replicon into a cointegrate. Resolution releases two replicons, each containing a copy of the transposon.

- The 3' ends of the strand transfer complex are used as primers for replication. This generates a structure called a **cointegrate**, which represents a fusion of the two original molecules. The cointegrate has two copies of the transposon, one at each junction between the original replicons, oriented as direct repeats. The crossover is formed by the transposase, as described in the previous section. Its conversion into the cointegrate requires host replication functions.
- A homologous recombination between the two copies of the transposon releases two individual replicons, each of which has a copy of the transposon. One of the replicons is the original donor replicon. The other is a target replicon that has gained a transposon flanked by short direct repeats of the host target sequence. The recombination reaction is called **resolution**; the enzyme activity responsible is called the **resolvase**.

The reactions involved in generating a cointegrate have been defined in detail for phage Mu, and are illustrated in **Figure 16.14**. The process starts with the formation of the strand transfer complex (sometimes also called a crossover complex). The donor and target strands are ligated so that each end of the transposon sequence is joined to one of the protruding single strands generated at the target site. The strand transfer complex generates a crossover-shaped structure held together at the duplex transposon. The fate of the crossover structure determines the mode of transposition.

**Figure 16.14** Mu transposition generates a crossover structure, which is converted by replication into a cointegrate.

The principle of replicative transposition is that replication through the transposon duplicates it, creating copies at both the target and donor sites. The product is a cointegrate.

The crossover structure contains a single-stranded region at each of the staggered ends. These regions are pseudoreplication forks that provide a template for DNA synthesis. (Use of the ends as primers for replication implies that the strand breakage

must occur with a polarity that generates a 3' –OH terminus at this point.)

If replication continues from both the pseudoreplication forks, it will proceed through the transposon, separating its strands, and terminating at its ends. Replication is probably accomplished by host-coded functions. At this juncture, the structure has become a cointegrate, possessing direct repeats of the transposon at the junctions between the replicons (as can be seen by tracing the path around the cointegrate).

*This content is available online at <http://www.ergito.com/main.jsp?bcs=MBIO.4.16.7>*

**TRANSPOSONS****4.16.8 Nonreplicative transposition proceeds by breakage and reunion****Key Concepts**

- Nonreplicative transposition results if a crossover structure is nicked on the unbroken pair of donor strands, and the target strands on either side of the transposon are ligated.
- Two pathways for nonreplicative transposition differ according to whether the first pair of transposon strands are joined to the target before the second pair are cut (Tn5), or whether all four strands are cut before joining to the target (Tn10).

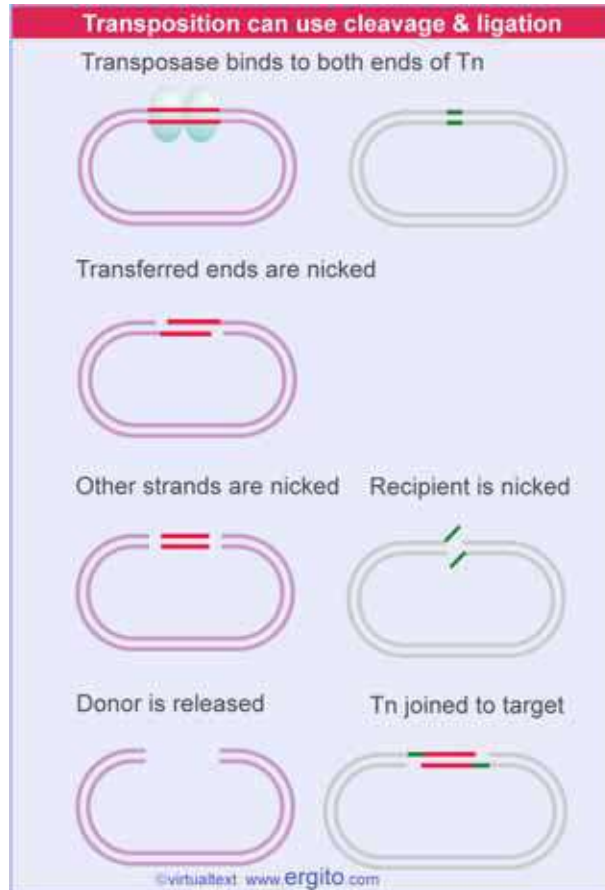

The crossover structure can also be used in nonreplicative transposition. The principle of nonreplicative transposition by this mechanism is that a breakage and reunion reaction allows the target to be reconstructed with the insertion of the transposon; the donor remains broken. No cointegrate is formed.

**Figure 16.15** shows the cleavage events that generate nonreplicative transposition of phage Mu. Once the unbroken donor strands have been nicked, the target strands on either side of the transposon can be ligated. The single-stranded regions generated by the staggered cuts must be filled in by repair synthesis. The product of this reaction is a target replicon in which the transposon has been inserted between repeats of the sequence created by the original single-strand nicks. The donor replicon has a double-strand break across the site where the transposon was originally located.

**Figure 16.15** Nonreplicative transposition results when a crossover structure is released by nicking. This inserts the transposon into the target DNA, flanked by the direct repeats of the target, and the donor is left with a double-strand break.

Nonreplicative transposition can also occur by an alternative pathway in which nicks are made in target DNA, but a double-strand break is made on either side of the transposon, releasing it entirely from flanking donor sequences (as envisaged in **Figure 16.7**). This "cut and paste" pathway is used by Tn10, as illustrated in **Figure 16.16** (564).

**Figure 16.16** Both strands of Tn10 are cleaved sequentially, and then the transposon is joined to the nicked target site.

A neat experiment to prove that Tn10 transposes nonreplicatively made use of an artificially constructed heteroduplex of Tn10 that contained single base mismatches. If transposition involves replication, the transposon at the new site will contain information from only one of the parent Tn10 strands. But if transposition takes place by physical movement of the existing transposon, the mismatches will be conserved at the new site, which proved to be the case (567).

The basic difference in **Figure 16.16** from the model of **Figure 16.15** is that both strands of Tn10 are cleaved before any connection is made to the target site. The first step in the reaction is recognition of the transposon ends by the transposase, forming a proteinaceous structure within which the reaction occurs. At each end of the transposon, the strands are cleaved in a specific order – first the transferred strand (the one to be connected to the target site) is cleaved, then the other strand (this is the same order as in the Mu transposition of **Figure 16.14** and **Figure 16.15**).

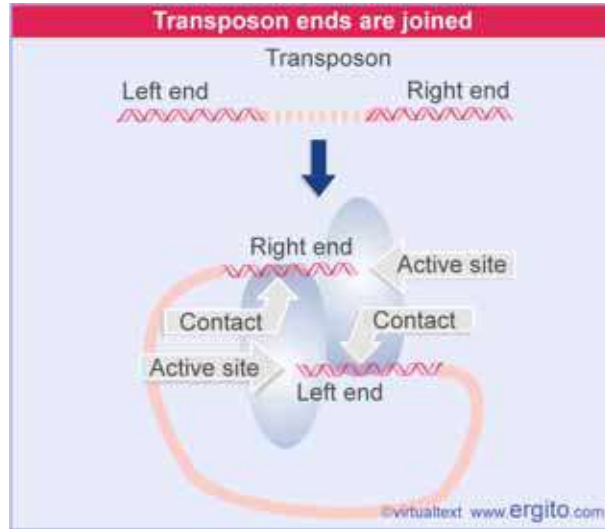

Tn5 also transposes by nonreplicative transposition, and **Figure 16.17** shows the interesting cleavage reaction that separates the transposon from the flanking sequences (1084). First one DNA strand is nicked. The 3' -OH end that is released then attacks the other strand of DNA. This releases the flanking sequence and joins the two strands of the transposon in a hairpin. Then an activated water molecule attacks the hairpin to generate free ends for each strand of the transposon.

**Figure 16.17** Cleavage of Tn5 from flanking DNA involves nicking, interstrand reaction, and hairpin cleavage.

Then the cleaved donor DNA is released, and the transposon is joined to the nicked ends at the target site. The transposon and the target site remain constrained in the proteinaceous structure created by the transposase (and other proteins). The double-strand cleavage at each end of the transposon precludes any replicative-type transposition and forces the reaction to proceed by nonreplicative transposition, thus giving the same outcome as in **Figure 16.14**, but with the individual cleavage and joining steps occurring in a different order.

The Tn5 and Tn10 transposases both function as dimers. Each subunit in the dimer has an active site that successively catalyzes the double-strand breakage of the two strands at one end of the transposon and then catalyzes staggered cleavage of the target site (570). **Figure 16.18** illustrates the structure of the Tn5 transposase bound to the cleaved transposon (1085). Each end of the transposon is located in the active site of one subunit. One end of the subunit also contacts the other end of the transposon. This controls the geometry of the transposition reaction. Each of the active sites will cleave one strand of the target DNA. It is the geometry of the complex that determines the distance between these sites on the two target strands (9 base pairs in the case of Tn5).

**Figure 16.18** Each subunit of the Tn5 transposase has one end of the transposon located in its active site and also makes contact at a different site with the other end of the transposon.

## TRANSPOSONS

### 4.16.9 TnA transposition requires transposase and resolvase

---

#### Key Concepts

- Replicative transposition of TnA requires a transposase to form the cointegrate structure and a resolvase to release the two replicons.
- The action of the resolvase resembles lambda Int protein and belongs to the general family of topoisomerase-like site-specific recombination reactions, which pass through an intermediate in which the protein is covalently bound to the DNA.

---

Replicative transposition is the only mode of mobility of the TnA family, which consists of large (~5 kb) transposons. They are not composites relying on IS-type transposition modules, but comprise independent units carrying genes for transposition as well as for features such as drug resistance. The TnA family includes several related transposons, of which Tn3 and Tn1000 (formerly called  $\gamma$   $\delta$ ) are the best characterized. They have the usual terminal feature of closely related inverted repeats, generally ~38 bp in length. Cis-acting deletions in either repeat prevent transposition of an element. A 5 bp direct repeat is generated at the target site. They carry resistance markers such as *amp<sup>r</sup>*.

The two stages of TnA-mediated transposition are accomplished by the transposase and the resolvase, whose genes, *tnpA* and *tnpR*, are identified by recessive mutations. The transposition stage involves the ends of the element, as it does in IS-type elements. Resolution requires a specific internal site. This feature is unique to the TnA family (for review see 155).

Mutants in *tnpA* cannot transpose. The gene product is a transposase that binds to a sequence of ~25 bp located within the 38 bp of the inverted terminal repeat. A binding site for the *E. coli* protein IHF exists adjacent to the transposase binding site; and transposase and IHF bind cooperatively. The transposase recognizes the ends of the element and also makes the staggered 5 bp breaks in target DNA where the transposon is to be inserted. IHF is a DNA-binding protein that is often involved in assembling large structures in *E. coli*; its role in the transposition reaction may not be essential.

The *tnpR* gene product has dual functions. It acts as a repressor of gene expression and it provides the resolvase function.

Mutations in *tnpR* increase the transposition frequency. The reason is that TnpR represses the transcription of both *tnpA* and its own gene. So inactivation of TnpR protein allows increased synthesis of TnpA, which results in an increased frequency of transposition. This implies that the amount of the TnpA transposase must be a limiting factor in transposition.

The *tnpA* and *tnpR* genes are expressed divergently from an A·T-rich intercistronic control region, indicated in the map of Tn3 given in **Figure 16.19**. Both effects of TnpR are mediated by its binding in this region.

**Figure 16.19** Transposons of the TnA family have inverted terminal repeats, an internal *res* site, and three known genes.

In its capacity as the resolvase, TnpR is involved in recombination between the direct repeats of Tn3 in a cointegrate structure. A cointegrate can in principle be resolved by a homologous recombination between any corresponding pair of points in the two copies of the transposon. But the Tn3 resolution reaction occurs only at a specific site (569).

The site of resolution is called *res*. It is identified by *cis*-acting deletions that block completion of transposition, causing the accumulation of cointegrates. In the absence of *res*, the resolution reaction can be substituted by RecA-mediated general recombination, but this is much less efficient.

The sites bound by the TnpR resolvase are summarized in the lower part of **Figure 16.19**. Binding occurs independently at each of three sites, each 30-40 bp long. The three binding sites share a sequence homology that defines a consensus sequence with dyad symmetry (565).

Site I includes the region genetically defined as the *res* site; in its absence, the resolution reaction does not proceed at all. However, resolution also involves binding at sites II and III, since the reaction proceeds only poorly if either of these sites is deleted. Site I overlaps with the startpoint for *tnpA* transcription. Site II overlaps with the startpoint for *tnpR* transcription; an operator mutation maps just at the left end of the site.

Do the sites interact? One possibility is that binding at all three sites is required to hold the DNA in an appropriate topology. Binding at a single set of sites may repress *tnpA* and *tnpR* transcription without introducing any change in the DNA.

An *in vitro* resolution assay uses a cointegrate-like DNA molecule as substrate. The

substrate must be supercoiled; its resolution produces two catenated circles, each containing one *res* site. The reaction requires large amounts of the TnpR resolvase; no host factors are needed. Resolution occurs in a large nucleoprotein structure. Resolvase binds to each *res* site, and then the bound sites are brought together to form a structure ~10 nm in diameter. Changes in supercoiling occur during the reaction, and DNA is bent at the *res* sites by the binding of transposase.

Resolution occurs by breaking and rejoining bonds without input of energy. The products identify an intermediate stage in cointegrate resolution; they consist of resolvase covalently attached to both 5' ends of double-stranded cuts made at the *res* site. The cleavage occurs symmetrically at a short palindromic region to generate two base extensions. Expanding the view of the crossover region located in site I, we can describe the cutting reaction as:

The reaction resembles the action of lambda Int at the *att* sites (see *Molecular Biology 4.15.17 Site-specific recombination involves breakage and reunion*). Indeed, 15 of the 20 bp of the *res* site are identical to the bases at corresponding positions in *att*. This suggests that the site-specific recombination of lambda and resolution of TnA have evolved from a common type of recombination reaction; and indeed, we see in *Molecular Biology 5.25.9 The RAG proteins catalyze breakage and reunion* that recombination involving immunoglobulin genes has the same basis. The common feature in all these reactions is the transfer of the broken end to the catalytic protein as an intermediate stage before it is rejoined to another broken end (see *Molecular Biology 4.15.18 Site-specific recombination resembles topoisomerase activity*).

The reactions themselves are analogous in terms of manipulation of DNA, although resolution occurs only between intramolecular sites, whereas the recombination between *att* sites is intermolecular and directional (as seen by the differences in *attB* and *attP* sites). However, the mechanism of protein action is different in each case. Resolvase functions in a manner in which four subunits bind to the recombining *res* sites. Each subunit makes a single-strand cleavage. Then a reorganization of the subunits relative to one another physically moves the DNA strands, placing them in a recombined conformation. This allows the nicks to be sealed, along with the release of resolvase.

**TRANSPOSONS****4.16.10 Transposition of Tn10 has multiple controls****Key Concepts**

- Multicopy inhibition reduces the rate of transposition of any one copy of a transposon when other copies of the same transposon are introduced into the genome.
- Multiple mechanisms affect the rate of transposition.

Control of the frequency of transposition is important for the cell. A transposon must be able to maintain a certain minimum frequency of movement in order to survive; but too great a frequency could be damaging to the host cell. Every transposon appears to have mechanisms that control its frequency of transposition. A variety of mechanisms have been characterized for Tn10 (for review see 154; 159).

Tn10 is a composite transposon in which the element IS10R provides the active module. The organization of IS10R is summarized in **Figure 16.20**. Two promoters are found close to the outside boundary. The promoter  $P_{IN}$  is responsible for transcription of IS10R. The promoter  $P_{OUT}$  causes transcription to proceed toward the adjacent flanking DNA. Transcription usually terminates within the transposon, but occasionally continues into the host DNA; sometimes this readthrough transcription is responsible for activating adjacent bacterial genes.

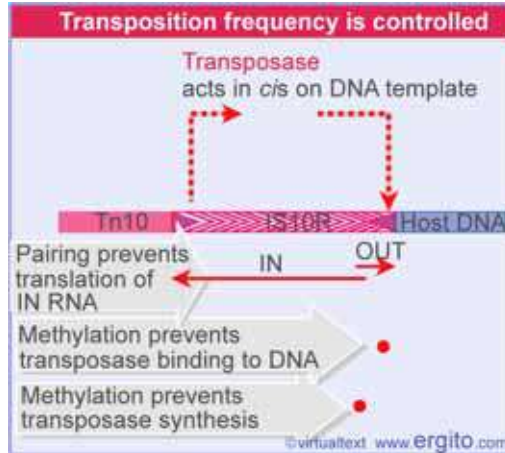

**Figure 16.20** Two promoters in opposite orientation lie near the outside boundary of IS10R. The strong promoter  $P_{OUT}$  sponsors transcription toward the flanking host DNA. The weaker promoter  $P_{IN}$  causes transcription of an RNA that extends the length of IS10R and is translated into the transposase.

The phenomenon of "multicopy inhibition" reveals that expression of the IS10R transposase gene is regulated. Transposition of a Tn10 element on the bacterial chromosome is reduced when additional copies of IS10R are introduced via a multicopy plasmid. The inhibition requires the  $P_{OUT}$  promoter, and is exercised at the

level of translation. The basis for the effect lies with the overlap in the 5' terminal regions of the transcripts from  $P_{IN}$  and  $P_{OUT}$ . OUT RNA is a transcript of 69 bases. It is present at  $>100\times$  the level of IN RNA for two reasons:  $P_{OUT}$  is a much stronger promoter than  $P_{IN}$ ; and OUT RNA is more stable than IN RNA.

OUT RNA functions as an antisense RNA (see *Molecular Biology 3.11.19 Small RNA molecules can regulate translation*). The level of OUT RNA has no effect in a single-copy situation, but has a significant effect when  $>5$  copies are present. There are usually  $\sim 5$  copies of OUT RNA per copy of IS10 (which corresponds to  $\sim 150$  copies of OUT RNA in a typical multicopy situation). OUT RNA base pairs with IN RNA; and the excess of OUT RNA ensures that IN RNA is bound rapidly, before a ribosome can attach. So the paired IN RNA cannot be translated.

The quantity of transposase protein is often a critical feature. Tn10, whose transposase is synthesized at the low level of 0.15 molecules per cell per generation, displays several interesting mechanisms. **Figure 16.21** summarizes the various effects that influence transposition frequency.

**Figure 16.21** Several mechanisms restrain the frequency of Tn10 transposition, by affecting either the synthesis or function of transposase protein. Transposition of an individual transposon is restricted by methylation to occur only after replication. In multicopy situations, *cis*-preference restricts the choice of target, and OUT/IN RNA pairing inhibits synthesis of transposase.

A continuous reading frame on one strand of IS10R codes for the transposase. The level of the transposase limits the rate of transposition. Mutants in this gene can be complemented in *trans* by another, wild-type IS10 element, but only with some difficulty. This reflects a strong preference of the transposase for *cis*-action; the enzyme functions efficiently only with the DNA template from which it was transcribed and translated. *Cis*-preference is a common feature of transposases coded by IS elements. (Other proteins that display *cis*-preference include the A protein involved in  $\phi X174$  replication; see *Molecular Biology 4.13.11 Rolling circles are used to replicate phage genomes.*)

Does *cis*-preference reflect an ability of the transposase to recognize more efficiently

those DNA target sequences that lie nearer to the site where the enzyme is synthesized? One possible explanation is that the transposase binds to DNA so tightly after (or even during) protein synthesis that it has a very low probability of diffusing elsewhere. Another possibility is that the enzyme may be unstable when it is not bound to DNA, so that protein molecules failing to bind quickly (and therefore nearby) never have a chance to become active.

Together the results of *cis*-preference and multicopy inhibition ensure that an increase in the number of copies of Tn10 in a bacterial genome does not cause an increased frequency of transposition that could damage the genome.

The effects of methylation provide the most important system of regulation for an individual element. They reduce the frequency of transposition and (more importantly) couple transposition to passage of the replication fork. The ability of IS10 to transpose is related to the replication cycle by the transposon's response to the state of methylation at two sites. One site is within the inverted repeat at the end of IS10R, where the transposase binds. The other site is in the promoter P<sub>IN</sub>, from which the transposase gene is transcribed.

Both of these sites are methylated by the *dam* system described in *Molecular Biology 4.14.18 Does methylation at the origin regulate initiation?* The Dam methylase modifies the adenine in the sequence GATC on a newly synthesized strand generated by replication. The frequency of Tn10 transposition is increased 1000-fold in *dam*<sup>-</sup> strains in which the two target sites lack methyl groups.

Passage of a replication fork over these sites generates hemimethylated sequences; this activates the transposon by a combination of transcribing the transposase gene more frequently from P<sub>IN</sub> and enhancing binding of transposase to the end of IS10R. In a wild-type bacterium, the sites remain hemimethylated for a short period after replication (566).

Why should it be desirable for transposition to occur soon after replication? The nonreplicative mechanism of Tn10 transposition places the donor DNA at risk of being destroyed (see **Figure 16.7**). The cell's chances of survival may be increased if replication has just occurred to generate a second copy of the donor sequence. The mechanism is effective because only 1 of the 2 newly replicated copies gives rise to a transposition event (determined by which strand of the transposon is unmethylated at the *dam* sites).

Since a transposon selects its target site at random, there is a reasonable probability that it may land in an active operon. Will transcription from the outside continue through the transposon and thus activate the transposase, whose overproduction may in turn lead to high (perhaps lethal) levels of transposition? Tn10 protects itself against such events by two mechanisms. Transcription across the IS10R terminus decreases its activity, presumably by inhibiting its ability to bind transposase. And the mRNA that extends from upstream of the promoter is poorly translated, because it has a secondary structure in which the initiation codon is inaccessible.

## TRANSPOSONS

### 4.16.11 Controlling elements in maize cause breakage and rearrangements

---

#### Key Terms

**Controlling elements** of maize are transposable units originally identified solely by their genetic properties. They may be autonomous (able to transpose independently) or nonautonomous (able to transpose only in the presence of an autonomous element).

A **sector** is a patch of cells made up of a single altered cell and its progeny.

**Variation** of phenotype is produced by a change in genotype during somatic development.

An **acentric fragment** of a chromosome (generated by breakage) lacks a centromere and is lost at cell division.

A **dicentric chromosome** is the product of fusing two chromosome fragments, each of which has a centromere. It is unstable and may be broken when the two centromeres are pulled to opposite poles in mitosis.

The **breakage-fusion-bridge** cycle is a type of chromosomal behavior in which a broken chromatid fuses to its sister, forming a "bridge". When the centromeres separate at mitosis, the chromosome breaks again (not necessarily at the bridge), thereby restarting the cycle.

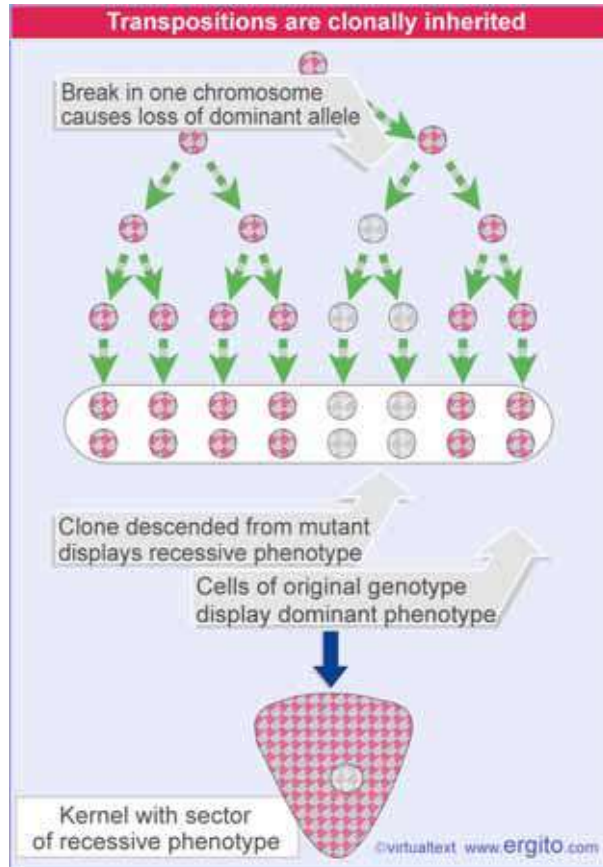

#### Key Concepts

- Transposition in maize was discovered because of the effects of the chromosome breaks generated by transposition of "controlling elements".
- The break generates one chromosome that has a centromere and a broken end and one acentric fragment.
- The acentric fragment is lost during mitosis, and this can be detected by the disappearance of dominant alleles in a heterozygote.
- Fusion between the broken ends of the chromosome generates dicentric chromosomes, which undergo further cycles of breakage and fusion.
- The fusion-breakage-bridge cycle is responsible for the occurrence of somatic variegation.

---

One of the most visible consequences of the existence and mobility of transposons occurs during plant development, when somatic variation occurs. This is due to changes in the location or behavior of **controlling elements** (the name that transposons were given in maize before their molecular nature was discovered. For an account of the discovery see *Great Experiments 2.6 The discovery of transposition*).

Two features of maize have helped to follow transposition events. Controlling elements often insert near genes that have visible but nonlethal effects on the phenotype. And because maize displays clonal development, the occurrence and timing of a transposition event can be visualized as depicted diagrammatically in **Figure 16.22**.

**Figure 16.22** Clonal analysis identifies a group of cells descended from a single ancestor in which a transposition-mediated event altered the phenotype. Timing of the event during development is indicated by the number of cells; tissue specificity of the event may be indicated by the location of the cells.

The nature of the event does not matter: it may be a point mutation, insertion, excision, or chromosome break. What is important is that it occurs in a heterozygote to alter the expression of one allele. Then the descendants of a cell that has suffered the event display a new phenotype, while the descendants of cells not affected by the event continue to display the original phenotype.

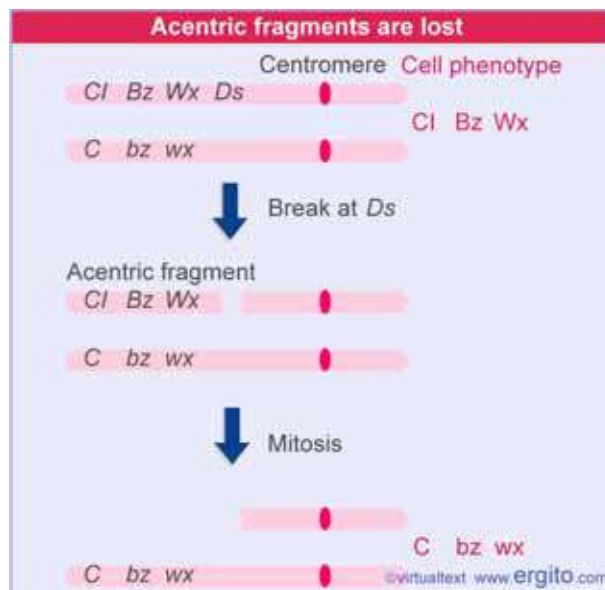

Mitotic descendants of a given cell remain in the same location and give rise to a **sector** of tissue. A change in phenotype during somatic development is called **variegation**; it is revealed by a sector of the new phenotype residing within the tissue of the original phenotype. The size of the sector depends on the number of divisions in the lineage giving rise to it; so the size of the area of the new phenotype is determined by the timing of the change in genotype. The earlier its occurrence in the

cell lineage, the greater the number of descendants and thus the size of patch in the mature tissue. This is seen most vividly in the variation in kernel color, when patches of one color appear within another color.

Insertion of a controlling element may affect the activity of adjacent genes. Deletions, duplications, inversions, and translocations all occur at the sites where controlling elements are present. Chromosome breakage is a common consequence of the presence of some elements. A unique feature of the maize system is that the activities of the controlling elements are regulated during development. The elements transpose and promote genetic rearrangements at characteristic times and frequencies during plant development.

The characteristic behavior of controlling elements in maize is typified by the Ds element, which was originally identified by its ability to provide a site for chromosome breakage. The consequences are illustrated in **Figure 16.23**. Consider a heterozygote in which Ds lies on one homologue between the centromere and a series of dominant markers. The other homologue lacks Ds and has recessive markers (*C*, *bz*, *wx*). Breakage at Ds generates an **acentric fragment** carrying the dominant markers. Because of its lack of a centromere, this fragment is lost at mitosis. So the descendant cells have only the recessive markers carried by the intact chromosome. This gives the type of situation whose results are depicted in **Figure 16.22**.

**Figure 16.23** A break at a controlling element causes loss of an acentric fragment; if the fragment carries the dominant markers of a heterozygote, its loss changes the phenotype. The effects of the dominant markers, *Cl*, *Bz*, *Wx*, can be visualized by the color of the cells or by appropriate staining.

**Figure 16.24** shows that breakage at Ds leads to the formation of two unusual chromosomes. These are generated by joining the broken ends of the products of replication. One is a U-shaped acentric fragment consisting of the joined sister chromatids for the region distal to Ds (on the left as drawn in the figure). The other is a U-shaped **dicentric chromosome** comprising the sister chromatids proximal to Ds

(on its right in the figure). The latter structure leads to the classic **breakage-fusion-bridge** cycle illustrated in the figure.

**Figure 16.24** *Ds* provides a site to initiate the chromatid fusion-bridge-breakage cycle. The products can be followed by clonal analysis.

Follow the fate of the dicentric chromosome when it attempts to segregate on the mitotic spindle. Each of its two centromeres pulls toward an opposite pole. The tension breaks the chromosome at a random site between the centromeres. In the example of the figure, breakage occurs between loci A and B, with the result that one daughter chromosome has a duplication of A, while the other has a deletion. If A is a dominant marker, the cells with the duplication will retain *a* phenotype, but cells

with the deletion will display the recessive *a* phenotype.

The breakage-fusion-bridge cycle continues through further cell generations, allowing genetic changes to continue in the descendants. For example, consider the deletion chromosome that has lost A. In the next cycle, a break occurs between B and C, so that the descendants are divided into those with a duplication of B and those with a deletion. Successive losses of dominant markers are revealed by subsectors within sectors.

## TRANSPOSONS

### 4.16.12 Controlling elements form families of transposons

---

#### Key Terms

An **autonomous controlling element** in maize is an active transposon with the ability to transpose (*compare with* nonautonomous controlling element).

A **nonautonomous controlling element** is a transposon in maize that encodes a non-functional transposase; it can transpose only in the presence of a *trans*-acting autonomous member of the same family.

#### Key Concepts

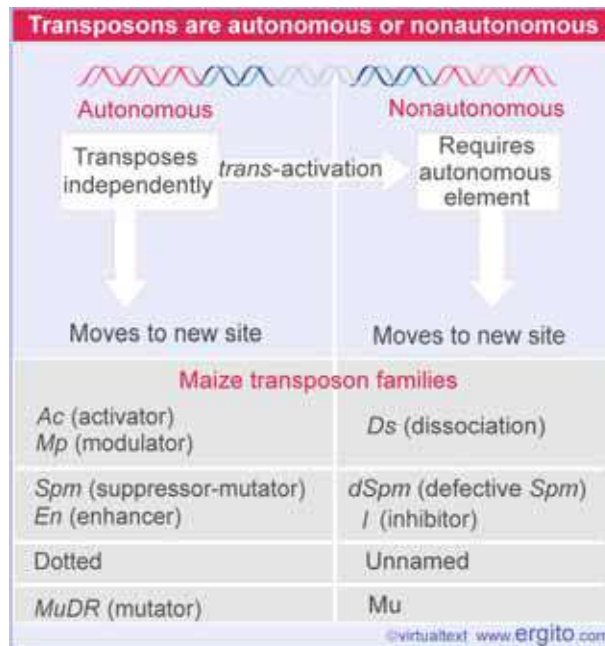

- Each family of transposons in maize has both autonomous and nonautonomous controlling elements.
  - Autonomous controlling elements code for proteins that enable them to transpose.
  - Nonautonomous controlling elements have mutations that eliminate their capacity to catalyze transposition, but they can transpose when an autonomous element provides the necessary proteins.
  - Autonomous controlling elements have changes of phase, when their properties alter as a result of changes in the state of methylation.
- 

The maize genome contains several families of controlling elements. The numbers, types, and locations of the elements are characteristic for each individual maize strain. They may occupy a significant part of the genome (for review see 1182). The members of each family are divided into two classes:

- **Autonomous controlling elements** have the ability to excise and transpose. Because of the continuing activity of an autonomous element, its insertion at any locus creates an unstable or "mutable" allele. Loss of the autonomous element itself, or of its ability to transpose, converts a mutable allele to a stable allele.
- **Nonautonomous controlling elements** are stable; they do not transpose or suffer other spontaneous changes in condition. They become unstable only when an autonomous member of the same family is present elsewhere in the genome. When complemented in *trans* by an autonomous element, a nonautonomous element displays the usual range of activities associated with autonomous elements, including the ability to transpose to new sites. Nonautonomous elements are derived from autonomous elements by loss of *trans*-acting functions needed for transposition.

Families of controlling elements are defined by the interactions between autonomous and nonautonomous elements. A family consists of a single type of autonomous element accompanied by many varieties of nonautonomous elements. A

nonautonomous element is placed in a family by its ability to be activated in *trans* by the autonomous elements. The major families of controlling elements in maize are summarized in **Figure 16.25** (for review see 152; 158).

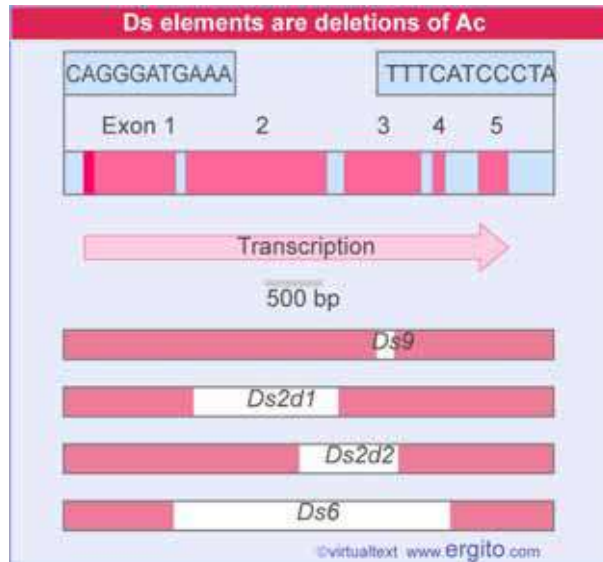

**Figure 16.25** Each controlling element family has both autonomous and nonautonomous members. Autonomous elements are capable of transposition. Nonautonomous elements are deficient in transposition. Pairs of autonomous and nonautonomous elements can be classified in >4 families.

Characterized at the molecular level, the maize transposons share the usual form of organization – inverted repeats at the ends and short direct repeats in the adjacent target DNA – but otherwise vary in size and coding capacity. All families of transposons share the same type of relationship between the autonomous and nonautonomous elements. The autonomous elements have open reading frames between the terminal repeats, whereas the nonautonomous elements do not code for functional proteins. Sometimes the internal sequences are related to those of autonomous elements; sometimes they have diverged completely.

The Mutator transposon is one of the simplest elements. The autonomous element MuDR codes for the genes *mudrA* (which codes for the MURA transposase) and *mudrB* (which codes for a nonessential accessory protein). The ends of the elements are marked by 200 bp inverted repeats. Nonautonomous elements – basically any unit that has the inverted repeats, which may not have any internal sequence relationship to MuDR – are also mobilized by MURA (1860).

There are typically several members (~10) of each transposon family in a plant genome. By analyzing autonomous and nonautonomous elements of the Ac/Ds family, we have molecular information about many individual examples of these elements. **Figure 16.26** summarizes their structures.

**Figure 16.26** The *Ac* element has two open reading frames; *Ds* elements have internal deletions.

Most of the length of the autonomous *Ac* element is occupied by a single gene consisting of 5 exons. The product is the transposase. The element itself ends in inverted repeats of 11 bp; and a target sequence of 8 bp is duplicated at the site of insertion.

*Ds* elements vary in both length and sequence, but are related to *Ac*. They end in the same 11 bp inverted repeats. They are shorter than *Ac*, and the length of deletion varies. At one extreme, the element *Ds9* has a deletion of only 194 bp. In a more extensive deletion, the *Ds6* element retains a length of only 2 kb, representing 1 kb from each end of *Ac*. A complex double *Ds* element has one *Ds6* sequence inserted in reverse orientation into another.

Nonautonomous elements lack internal sequences, but possess the terminal inverted repeats (and possibly other sequence features). Nonautonomous elements are derived from autonomous elements by deletions (or other changes) that inactivate the *trans*-acting transposase, but leave intact the sites (including the termini) on which the transposase acts. Their structures range from minor (but inactivating) mutations of *Ac* to sequences that have major deletions or rearrangements.

At another extreme, the *Ds1* family members comprise short sequences whose only relationship to *Ac* lies in the possession of terminal inverted repeats. Elements of this class need not be directly derived from *Ac*, but could be derived by any event that generates the inverted repeats. Their existence suggests that the transposase recognizes only the terminal inverted repeats, or possibly the terminal repeats in conjunction with some short internal sequence.

Transposition of *Ac/Ds* occurs by a nonreplicative mechanism, and is accompanied by its disappearance from the donor location. Clonal analysis suggests that transposition of *Ac/Ds* almost always occurs soon after the donor element has been replicated. These features resemble transposition of the bacterial element *Tn10* (see *Molecular Biology 4.16.10 Transposition of Tn10 has multiple controls*). The cause

is the same: transposition does not occur when the DNA of the transposon is methylated on both strands (the typical state before methylation), and is activated when the DNA is hemimethylated (the typical state immediately after replication) (3143). The recipient site is frequently on the same chromosome as the donor site, and often quite close to it.

Replication generates two copies of a potential Ac/Ds donor, but usually only one copy actually transposes. What happens to the donor site? The rearrangements that are found at sites from which controlling elements have been lost could be explained in terms of the consequences of a chromosome break, as illustrated previously in **Figure 16.23**.

Autonomous and nonautonomous elements are subject to a variety of changes in their condition. Some of these changes are genetic, others are epigenetic.

The major change is (of course) the conversion of an autonomous element into a nonautonomous element, but further changes may occur in the nonautonomous element. *Cis*-acting defects may render a nonautonomous element impervious to autonomous elements. So a nonautonomous element may become permanently stable because it can no longer be activated to transpose.

Autonomous elements are subject to "changes of phase," heritable but relatively unstable alterations in their properties. These take the form of a reversible inactivation in which the element cycles between an active and inactive condition during plant development.

Phase changes in both the Ac and Mu types of autonomous element result from changes in the methylation of DNA. Comparisons of the susceptibilities of active and inactive elements to restriction enzymes suggest that the inactive form of the element is methylated in the target sequence

CAG  
GTC

element, and we do not know which sites control the effect. In the case of MuDR, demethylation of the terminal repeats increases transposase expression, suggesting that the effect may be mediated through control of the promoter for the transposase gene (1862). We should like to know what controls the methylation and demethylation of the elements.

The effect of methylation is common generally among transposons in plants. The best demonstration of the effect of methylation on activity comes from observations made with the *Arabidopsis* mutant *ddm1*, which causes a loss of methylation in heterochromatin. Among the targets that lose methyl groups is a family of transposons related to MuDR. Direct analysis of genome sequences shows that the demethylation causes transposition events to occur (1861). Methylation is probably the major mechanism that is used to prevent transposons from damaging the genome by transposing too frequently.

There may be self-regulating controls of transposition, analogous to the immunity effects displayed by bacterial transposons. An increase in the number of Ac elements in the genome decreases the frequency of transposition. The Ac element may code for a repressor of transposition; the activity could be carried by the same protein that

provides transposase function.

**TRANSPOSONS****4.16.13 Spm elements influence gene expression****Key Concepts**

- Spm elements affect gene expression at their sites of insertion, when the TnpA protein binds to its target sites at the ends of the transposon.
- Spm elements are inactivated by methylation.

The Spm and En autonomous elements are virtually identical; they differ at <10 positions. **Figure 16.27** summarizes the structure. The 13 bp inverted terminal repeats are essential for transposition, as indicated by the transposition-defective phenotype of deletions at the termini. Transposons related to Spm are found in other plants, and are defined as members of the same family by their generally similar organization. They all share nearly identical inverted terminal repeats, and generate 3 bp duplications of target DNA upon transposition. Named for the terminal similarities, they are known as the CACTA group of transposons.

**Figure 16.27** *Spm/En* has two genes. *tnpA* consists of 11 exons that are transcribed into a spliced 2500 base mRNA. *tnpB* may consist of a 6000 base mRNA containing ORF1 + ORF2.

A sequence of 8300 bp is transcribed from a promoter in the left end of the element. The 11 exons contained in the transcript are spliced into a 2500 base messenger. The mRNA codes for a protein of 621 amino acids. The gene is called *tnpA*, and the protein binds to a 12 bp consensus sequence present in multiple copies in the terminal regions of the element. Function of *tnpA* is required for excision, but may not be sufficient.

All of the nonautonomous elements of this family (denoted dSpm for defective Spm) are closely related in structure to the Spm element itself. They have deletions that affect the exons of *tnpA*.

Two additional open reading frames (ORF1 and ORF2) are located within the first, long intron of *tnpA*. They are contained in an alternatively spliced 6000 base RNA, which is present at 1% of the level of the *tnpA* mRNA. The function containing ORFs 1 and 2 is called *tnpB*. It may provide the protein that binds to the 13 bp terminal inverted repeats to cleave the termini for transposition.

In addition to the fully active Spm element, there are Spm-w derivatives that show weaker activity in transposition. The example given in **Figure 16.27** has a deletion that eliminates both ORF1 and ORF2. This suggests that the need for TnpB in transposition can be bypassed or substituted.

Spm insertions can control the expression of a gene at the site of insertion. A recipient locus may be brought under either negative or positive control. An Spm-suppressible locus suffers inhibition of expression. An Spm-dependent locus is expressed only with the aid of Spm. When the inserted element is a dSpm, suppression or dependence responds to the *trans*-acting function supplied by an autonomous Spm. What is the basis for these opposite effects?

A dSpm-suppressible allele contains an insertion of dSpm within an exon of the gene. This structure raises the immediate question of how a gene with a dSpm insertion in an exon can ever be expressed! The dSpm sequence can be excised from the transcript by using sequences at its termini. The splicing event may leave a change in the sequence of the mRNA, thus explaining a change in the properties of the protein for which it codes. A similar ability to be excised from a transcript has been found for some Ds insertions.

*tnpA* provides the suppressor function for which the Spm element was originally named. The presence of a defective element may reduce, but not eliminate, expression of a gene in which it resides. However, the introduction of an autonomous element, possessing a functional *tnpA* gene, may suppress expression of the target gene entirely. Suppression is caused by the ability of TnpA to bind to its target sites in the defective element, which blocks transcription from proceeding.

A dSpm-dependent allele contains an insertion near but not within a gene. The insertion appears to provide an enhancer that activates the promoter of the gene at the recipient locus.

Suppression and dependence at dSpm elements appear to rely on the same interaction between the *trans*-acting product of the *tnpA* gene of an autonomous Spm element and the *cis*-acting sites at the ends of the element. So a single interaction between the protein and the ends of the element either suppresses or activates a target locus depending on whether the element is located upstream of or within the recipient gene.

Spm elements exist in a variety of states ranging from fully active to cryptic. A cryptic element is silent and neither transposes itself nor activates dSpm elements. A cryptic element may be reactivated transiently or converted to the active state by

interaction with a fully active Spm element. Inactivation is caused by methylation of sequences in the vicinity of the transcription startpoint. The nature of the events that are responsible for inactivating an element by *de novo* methylation or for activating it by demethylation (or preventing methylation) are not yet known.

## TRANSPOSONS

### 4.16.14 The role of transposable elements in hybrid dysgenesis

---

#### Key Terms

**Hybrid dysgenesis** describes the inability of certain strains of *D. melanogaster* to interbreed, because the hybrids are sterile (although otherwise they may be phenotypically normal).

A **P element** is type of transposon in *D. melanogaster*.

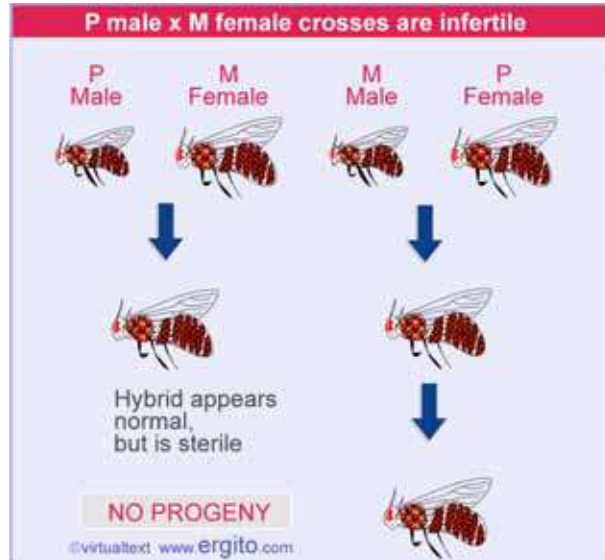

#### Key Concepts

- P elements are transposons that are carried in P strains of *D. melanogaster* but not in M strains.
- When a P male is crossed with an M female, transposition is activated.
- The insertion of P elements at new sites in these crosses inactivates many genes and makes the cross infertile.

---

Certain strains of *D. melanogaster* encounter difficulties in interbreeding. When flies from two of these strains are crossed, the progeny display "dysgenic traits," a series of defects including mutations, chromosomal aberrations, distorted segregation at meiosis, and sterility. The appearance of these correlated defects is called **hybrid dysgenesis**.

Two systems responsible for hybrid dysgenesis have been identified in *D. melanogaster*. In the first, flies are divided into the types I (inducer) and R (reactive). Reduced fertility is seen in crosses of I males with R females, but not in the reverse direction. In the second system, flies are divided into the two types P (paternal contributing) and M (maternal contributing). **Figure 16.28** illustrates the asymmetry of the system; a cross between a P male and an M female causes dysgenesis, but the reverse cross does not.

**Figure 16.28** Hybrid dysgenesis is asymmetrical; it is induced by P male x M female crosses, but not by M male x P female crosses.

Dysgenesis is principally a phenomenon of the germ cells. In crosses involving the P-M system, the F1 hybrid flies have normal somatic tissues. However, their gonads do not develop. The morphological defect in gamete development dates from the stage at which rapid cell divisions commence in the germline.

Any one of the chromosomes of a P male can induce dysgenesis in a cross with an M female. The construction of recombinant chromosomes shows that several regions within each P chromosome are able to cause dysgenesis. This suggests that a P male has sequences at many different chromosomal locations that can induce dysgenesis. The locations differ between individual P strains. The P-specific sequences are absent from chromosomes of M flies.

The nature of the P-specific sequences was first identified by mapping the DNA of *w* mutants found among the dysgenic hybrids. All the mutations result from the insertion of DNA into the *w* locus. (The insertion inactivates the gene, causing the white-eye phenotype for which the locus is named.) The inserted sequence is called the **P element**.

The P element insertions form a classic transposable system. Individual elements vary in length but are homologous in sequence. All P elements possess inverted terminal repeats of 31 bp, and generate direct repeats of target DNA of 8 bp upon transposition. The longest P elements are ~2.9 kb long and have four open reading frames. The shorter elements arise, apparently rather frequently, by internal deletions of a full-length P factor. At least some of the shorter P elements have lost the capacity to produce the transposase, but may be activated in *trans* by the enzyme coded by a complete P element.

A P strain carries 30-50 copies of the P element, about a third of them full length. The elements are absent from M strains. In a P strain, the elements are carried as inert components of the genome. But they become activated to transpose when a P

male is crossed with an M female (for review see 147; 151).

Chromosomes from P-M hybrid dysgenic flies have P elements inserted at many new sites. The insertions inactivate the genes in which they are located and often cause chromosomal breaks. The result of the transpositions is therefore to inactivate the genome.

## TRANSPOSONS

### 4.16.15 P elements are activated in the germline

---

#### Key Terms

**Cyotype** is a cytoplasmic condition that affects P element activity. The effect of cyotype is due to the presence or absence of transposition repressors, which are provided by the mother to the egg.

#### Key Concepts

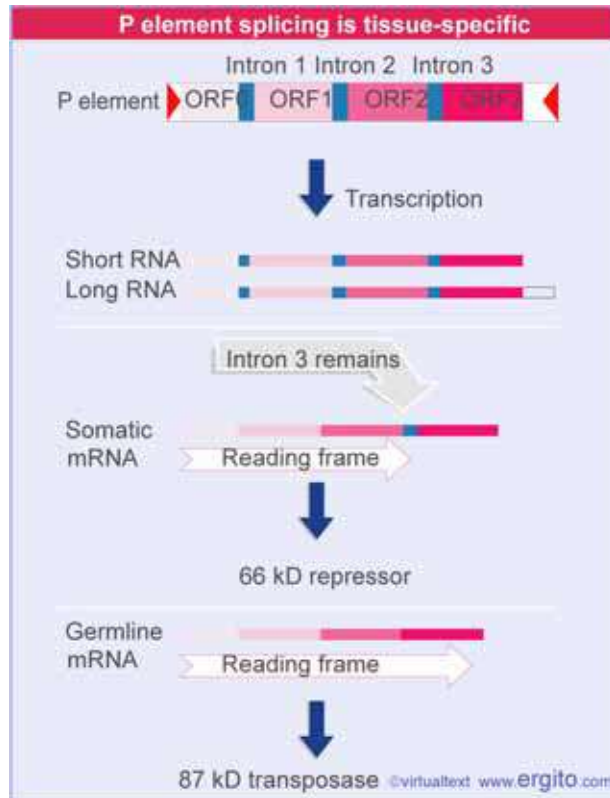

- P elements are activated in the germline of P male × M female crosses because a tissue-specific splicing event removes one intron, generating the coding sequence for the transposase.
- The P element also produces a repressor of transposition, which is inherited maternally in the cytoplasm.
- The presence of the repressor explains why M male × P female crosses remain fertile.

---

Activation of P elements is tissue-specific: it occurs only in the germline. But P elements are transcribed in both germline and somatic tissues. Tissue-specificity is conferred by a change in the splicing pattern (568).

**Figure 16.29** depicts the organization of the element and its transcripts. The primary transcript extends for 2.5 kb or 3.0 kb, the difference probably reflecting merely the leakiness of the termination site. Two protein products can be produced:

**Figure 16.29** The P element has four exons. The first three are spliced together in somatic expression; all four are spliced together in germline expression.

- In somatic tissues, only the first two introns are excised, creating a coding region of ORF0-ORF1-ORF2. Translation of this RNA yields a protein of 66 kD. This protein is a repressor of transposon activity.
- In germline tissues, an additional splicing event occurs to remove intron 3. This connects all four open reading frames into an mRNA that is translated to generate a protein of 87 kD. This protein is the transposase.

Two types of experiment have demonstrated that splicing of the third intron is needed for transposition. First, if the splicing junctions are mutated *in vitro* and the P element is reintroduced into flies, its transposition activity is abolished. Second, if the third intron is deleted, so that ORF3 is constitutively included in the mRNA in all tissues, transposition occurs in somatic tissues as well as the germline.

So whenever ORF3 is spliced to the preceding reading frame, the P element becomes active. This is the crucial regulatory event, and usually it occurs only in the germline. What is responsible for the tissue-specific splicing? Somatic cells contain a protein that binds to sequences in exon 3 to prevent splicing of the last intron (see *Molecular Biology 5.24.12 Alternative splicing involves differential use of splice junctions*). The absence of this protein in germline cells allows splicing to generate the mRNA that codes for the transposase.

Transposition of a P element requires ~150 bp of terminal DNA. The transposase binds to 10 bp sequences that are adjacent to the 31 bp inverted repeats. Transposition occurs by a nonreplicative "cut and paste" mechanism resembling that of Tn10. (It contributes to hybrid dysgenesis in two ways. Insertion of the transposed element at a new site may cause mutations. And the break that is left at the donor site – see **Figure 16.7** – has a deleterious effect.)

It is interesting that, in a significant proportion of cases, the break in donor DNA is repaired by using the sequence of the homologous chromosome. If the homologue has a P element, the presence of a P element at the donor site may be restored (so the event resembles the result of a replicative transposition). If the homologue lacks a P element, repair may generate a sequence lacking the P element, thus apparently providing a precise excision (an unusual event in other transposable systems).

The dependence of hybrid dysgenesis on the sexual orientation of a cross shows that the cytoplasm is important as well as the P factors themselves. The contribution of the cytoplasm is described as the **cytotype**; a line of flies containing P elements has P cytotype, while a line of flies lacking P elements has M cytotype. Hybrid dysgenesis occurs only when chromosomes containing P factors find themselves in M cytotype, that is, when the male parent has P elements and the female parent does not.

Cytotype shows an inheritable cytoplasmic effect; when a cross occurs through P cytotype (the female parent has P elements), hybrid dysgenesis is suppressed for several generations of crosses with M female parents. So something in P cytotype, which can be diluted out over some generations, suppresses hybrid dysgenesis.

The effect of cytotype is explained in molecular terms by the model of **Figure 16.30**. It depends on the ability of the 66 kD protein to repress transposition. The protein is provided as a maternal factor in the egg. In a P line, there must be sufficient protein to prevent transposition from occurring, even though the P elements are present. In any cross involving a P female, its presence prevents either synthesis or activity of the transposase. But when the female parent is M type, there is no repressor in the egg, and the introduction of a P element from the male parent results in activity of transposase in the germline. The ability of P cytotype to exert an effect through more than one generation suggests that there must be enough repressor protein in the egg, and it must be stable enough, to be passed on through the adult to be present in the eggs of the next generation.

**Figure 16.30** Hybrid dysgenesis is determined by the interactions between P elements in the genome and 66 kD repressor in the cytotype.

Strains of *D. melanogaster* descended from flies caught in the wild more than 30 years ago are always M. Strains descended from flies caught in the past 10 years are almost always P. Does this mean that the P element family has invaded wild populations of *D. melanogaster* in recent years? P elements are indeed highly invasive when introduced into a new population; the source of the invading element would have to be another species.

Because hybrid dysgenesis reduces interbreeding, it is a step on the path to speciation. Suppose that a dysgenic system is created by a transposable element in some geographic location. Another element may create a different system in some other location. Flies in the two areas will be dysgenic for two (or possibly more) systems. If this renders them intersterile and the populations become genetically isolated, further separation may occur. Multiple dysgenic systems therefore lead to inability to mate – and to speciation.

## TRANSPOSONS

### 4.16.16 Summary

---

Prokaryotic and eukaryotic cells contain a variety of transposons that mobilize by moving or copying DNA sequences. The transposon can be identified only as an entity within the genome; its mobility does not involve an independent form. The transposon could be selfish DNA, concerned only with perpetuating itself within the resident genome; if it conveys any selective advantage upon the genome, this must be indirect. All transposons have systems to limit the extent of transposition, since unbridled transposition is presumably damaging, but the molecular mechanisms are different in each case.

The archetypal transposon has inverted repeats at its termini and generates direct repeats of a short sequence at the site of insertion. The simplest types are the bacterial insertion sequences (IS), which consist essentially of the inverted terminal repeats flanking a coding frame(s) whose product(s) provide transposition activity. Composite transposons have terminal modules that consist of IS elements; one or both of the IS modules provides transposase activity, and the sequences between them (often carrying antibiotic resistance), are treated as passengers.

The generation of target repeats flanking a transposon reflects a common feature of transposition. The target site is cleaved at points that are staggered on each DNA strand by a fixed distance (often 5 or 9 base pairs). The transposon is in effect inserted between protruding single-stranded ends generated by the staggered cuts. Target repeats are generated by filling in the single-stranded regions.

IS elements, composite transposons, and P elements mobilize by nonreplicative transposition, in which the element moves directly from a donor site to a recipient site. A single transposase enzyme undertakes the reaction. It occurs by a "cut and paste" mechanism in which the transposon is separated from flanking DNA. Cleavage of the transposon ends, nicking of the target site, and connection of the transposon ends to the staggered nicks, all occur in a nucleoprotein complex containing the transposase. Loss of the transposon from the donor creates a double-strand break, whose fate is not clear. In the case of Tn10, transposition becomes possible immediately after DNA replication, when sites recognized by the *dam* methylation system are transiently hemimethylated. This imposes a demand for the existence of two copies of the donor site, which may enhance the cell's chances for survival.

The TnA family of transposons mobilize by replicative transposition. After the transposon at the donor site becomes connected to the target site, replication generates a cointegrate molecule that has two copies of the transposon. A resolution reaction, involving recombination between two particular sites, then frees the two copies of the transposon, so that one remains at the donor site and one appears at the target site. Two enzymes coded by the transposon are required: transposase recognizes the ends of the transposon and connects them to the target site; and resolvase provides a site-specific recombination function.

Phage Mu undergoes replicative transposition by the same mechanism as TnA. It

also can use its cointegrate intermediate to transpose by a nonreplicative mechanism. The difference between this reaction and the nonreplicative transposition of IS elements is that the cleavage events occur in a different order.

The best characterized transposons in plants are the controlling elements of maize, which fall into several families. Each family contains a single type of autonomous element, analogous to bacterial transposons in its ability to mobilize. A family also contains many different nonautonomous elements, derived by mutations (usually deletions) of the autonomous element. The nonautonomous elements lack the ability to transpose, but display transposition activity and other abilities of the autonomous element, when an autonomous element is present to provide the necessary *trans*-acting functions.

In addition to the direct consequences of insertion and excision, the maize elements may also control the activities of genes at or near the sites where they are inserted; this control may be subject to developmental regulation. Maize elements inserted into genes may be excised from the transcripts, which explains why they do not simply impede gene activity. Control of target gene expression involves a variety of molecular effects, including activation by provision of an enhancer and suppression by interference with post-transcriptional events.

Transposition of maize elements (in particular Ac) is nonreplicative, probably requiring only a single transposase enzyme coded by the element. Transposition occurs preferentially after replication of the element. There are probably mechanisms to limit the frequency of transposition. Advantageous rearrangements of the maize genome may have been connected with the presence of the elements.

P elements in *D. melanogaster* are responsible for hybrid dysgenesis, which could be a forerunner of speciation. A cross between a male carrying P elements and a female lacking them generates hybrids that are sterile. A P element has 4 open reading frames, separated by introns. Splicing of the first 3 ORFs generates a 66 kD repressor, and occurs in all cells. Splicing of all 4 ORFs to generate the 87 kD transposase occurs only in the germline, by a tissue-specific splicing event. P elements mobilize when exposed to cytoplasm lacking the repressor. The burst of transposition events inactivates the genome by random insertions. Only a complete P element can generate transposase, but defective elements can be mobilized in *trans* by the enzyme.

## RETROVIRUSES AND RETROPOSONS

### 4.17.1 Introduction

---

#### Key Terms

A **retrovirus** is an RNA virus with the ability to convert its sequence into DNA by reverse transcription.

A **retroposon (retrotransposon)** is a transposon that mobilizes via an RNA form; the DNA element is transcribed into RNA, and then reverse-transcribed into DNA, which is inserted at a new site in the genome. The difference from retroviruses is that the retroposon does not have an infective (viral) form.

---

Transposition that involves an obligatory intermediate of RNA is unique to eukaryotes, and is provided by the ability of **retroviruses** to insert DNA copies (proviruses) of an RNA viral genome into the chromosomes of a host cell. Some eukaryotic transposons are related to retroviral proviruses in their general organization, and they transpose through RNA intermediates. As a class, these elements are called **retroposons** (or sometimes **retrotransposons**). The very simplest such elements do not themselves have transposition activity, but have sequences that are recognized as substrates for transposition by active elements. So elements that use RNA-dependent transposition range from the retroviruses themselves, able freely to infect host cells, to sequences that transpose via RNA, to those that do not themselves possess the ability to transpose. They share with all transposons the diagnostic feature of generating short direct repeats of target DNA at the site of an insertion.

Even in genomes where active transposons have not been detected, footprints of ancient transposition events are found in the form of direct target repeats flanking dispersed repetitive sequences. The features of these sequences sometimes implicate an RNA sequence as the progenitor of the genomic (DNA) sequence. This suggests that the RNA must have been converted into a duplex DNA copy that was inserted into the genome by a transposition-like event.

Like any other reproductive cycle, the cycle of a retrovirus or retroposon is continuous; it is arbitrary at which point we interrupt it to consider a "beginning." But our perspectives of these elements are biased by the forms in which we usually observe them, indicated in **Figure 17.1**. Retroviruses were first observed as infectious virus particles, capable of transmission between cells, and so the intracellular cycle (involving duplex DNA) is thought of as the means of reproducing the RNA virus. Retroposons were discovered as components of the genome; and the RNA forms have been mostly characterized for their functions as mRNAs. So we think of retroposons as genomic (duplex DNA) sequences that may transpose within a genome; they do not migrate between cells.

**Figure 17.1** The reproductive cycles of retroviruses and retroposons involve alternation of reverse transcription from RNA to DNA with transcription from DNA to RNA. Only retroviruses can generate infectious particles. Retroposons are confined to an intracellular cycle.

---

## RETROVIRUSES AND RETROPOSONS

### 4.17.2 The retrovirus life cycle involves transposition-like events

---

#### Key Terms

**Provirus** is a duplex sequence of DNA integrated into a eukaryotic genome that represents the sequence of the RNA genome of a retrovirus.

**Reverse transcriptase** is an enzyme that uses a template of single-stranded RNA to generate a double-stranded DNA copy.

An **integrase** is an enzyme that is responsible for a site-specific recombination that inserts one molecule of DNA into another.

#### Key Concepts

- A retrovirus has two copies of its genome of single-stranded RNA.
- An integrated provirus is a double-stranded DNA sequence.
- A retrovirus generates a provirus by reverse transcription of the retroviral genome.

---

Retroviruses have genomes of single-stranded RNA that are replicated through a double-stranded DNA intermediate. The life cycle of the virus involves an obligatory stage in which the double-stranded DNA is inserted into the host genome by a transposition-like event that generates short direct repeats of target DNA (for review see 168).

The significance of this reaction extends beyond the perpetuation of the virus. Some of its consequences are that:

- A retroviral sequence that is integrated in the germline remains in the cellular genome as an endogenous **provirus**. Like a lysogenic bacteriophage, a provirus behaves as part of the genetic material of the organism.
- Cellular sequences occasionally recombine with the retroviral sequence and then are transposed with it; these sequences may be inserted into the genome as duplex sequences in new locations.
- Cellular sequences that are transposed by a retrovirus may change the properties of a cell that becomes infected with the virus.

The particulars of the retroviral life cycle are expanded in **Figure 17.2**. The crucial steps are that the viral RNA is converted into DNA, the DNA becomes integrated into the host genome, and then the DNA provirus is transcribed into RNA.

**Figure 17.2** The retroviral life cycle proceeds by reverse transcribing the RNA genome into duplex DNA, which is inserted into the host genome, in order to be transcribed into RNA.

The enzyme responsible for generating the initial DNA copy of the RNA is **reverse transcriptase**. The enzyme converts the RNA into a linear duplex of DNA in the cytoplasm of the infected cell. The DNA also is converted into circular forms, but these do not appear to be involved in reproduction (573; 574).

The linear DNA makes its way to the nucleus. One or more DNA copies become integrated into the host genome. A single enzyme, called **integrase**, is responsible for integration. The provirus is transcribed by the host machinery to produce viral RNAs, which serve both as mRNAs and as genomes for packaging into virions. Integration is a normal part of the life cycle and is necessary for transcription.

Two copies of the RNA genome are packaged into each virion, making the individual virus particle effectively diploid. When a cell is simultaneously infected by two different but related viruses, it is possible to generate heterozygous virus particles carrying one genome of each type. The diploidy may be important in allowing the virus to acquire cellular sequences. The enzymes reverse transcriptase and integrase are carried with the genome in the viral particle.

## RETROVIRUSES AND RETROPOSONS

### 4.17.3 Retroviral genes codes for polyproteins

#### Key Concepts

- A typical retrovirus has three genes, *gag*, *pol*, *env*.
- Gag and Pol proteins are translated from a full-length transcript of the genome.
- Translation of Pol requires a frameshift by the ribosome.
- Env is translated from a separate mRNA that is generated by splicing.
- Each of the three protein products is processed by proteases to give multiple proteins.

A typical retroviral sequence contains three or four "genes," the term here identifying coding regions each of which actually gives rise to multiple proteins by processing reactions. A typical retrovirus genome with three genes is organized in the sequence *gag-pol-env* as indicated in **Figure 17.3**.

**Figure 17.3** The genes of the retrovirus are expressed as polyproteins that are processed into individual products.

Retroviral mRNA has a conventional structure; it is capped at the 5' end and polyadenylated at the 3' end. It is represented in two mRNAs. The full length mRNA is translated to give the Gag and Pol polyproteins. The Gag product is translated by reading from the initiation codon to the first termination codon. This termination codon must be bypassed to express Pol.

Different mechanisms are used in different viruses to proceed beyond the *gag* termination codon, depending on the relationship between the *gag* and *pol* reading frames. When *gag* and *pol* follow continuously, suppression by a glutamyl-tRNA that recognizes the termination codon allows a single protein to be generated. When *gag* and *pol* are in different reading frames, a ribosomal frameshift occurs to generate a single protein. Usually the readthrough is ~5% efficient, so Gag protein outnumbers Gag-Pol protein about 20-fold.

The Env polyprotein is expressed by another means: splicing generates a shorter *subgenomic* messenger that is translated into the Env product.

The *gag* gene gives rise to the protein components of the nucleoprotein core of the virion. The *pol* gene codes for functions concerned with nucleic acid synthesis and recombination. The *env* gene codes for components of the envelope of the particle, which also sequesters components from the cellular cytoplasmic membrane.

Both the Gag or Gag-Pol and the Env products are polyproteins that are cleaved by a protease to release the individual proteins that are found in mature virions. The protease activity is coded by the virus in various forms: it may be part of Gag or Pol, or sometimes takes the form of an additional independent reading frame

The production of a retroviral particle involves packaging the RNA into a core, surrounding it with capsid proteins, and pinching off a segment of membrane from the host cell. The release of infective particles by such means is shown in **Figure 17.4**. The process is reversed during infection; a virus infects a new host cell by fusing with the plasma membrane and then releasing the contents of the virion.

## RETROVIRUSES AND RETROPOSONS

### 4.17.4 Viral DNA is generated by reverse transcription

---

#### Key Terms

A **plus strand virus** has a single-stranded nucleic acid genome whose sequence directly codes for the protein products.

**Minus strand DNA** is the single-stranded DNA sequence that is complementary to the viral RNA genome of a plus strand virus.

**Plus strand DNA** is the strand of the duplex sequence representing a retrovirus that has the same sequence as that of the RNA.

The **R segments** are the sequences that are repeated at the ends of a retroviral RNA. They are called R-U5 and U3-R.

**U5** is the repeated sequence at the 5' end of a retroviral RNA.

**U3** is the repeated sequence at the 3' end of a retroviral RNA.

The **long terminal repeat (LTR)** is the sequence that is repeated at each end of the integrated retroviral genome.

**Copy choice** is a type of recombination used by RNA viruses, in which the RNA polymerase switches from one template to another during synthesis.

#### Key Concepts

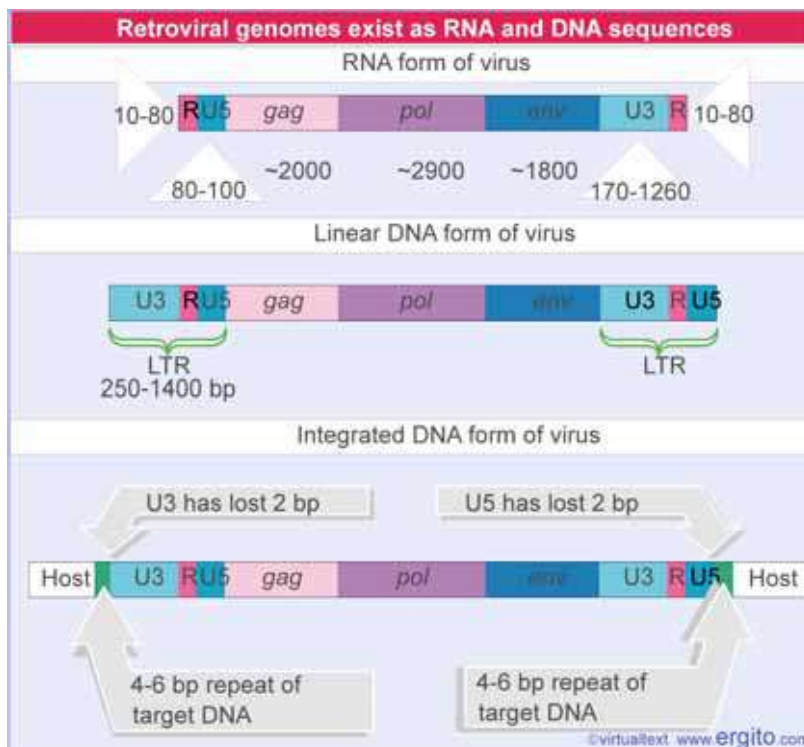

- A short sequence (R) is repeated at each end of the viral RNA, so the 5' and 3' ends respectively are R-U5 and U3-R.
  - Reverse transcriptase starts synthesis when a tRNA primer binds to a site 100-200 bases from the 5' end.
  - When the enzyme reaches the end, the 5'-terminal bases of RNA are degraded, exposing the 3' end of the DNA product.
  - The exposed 3' end base pairs with the 3' terminus of another RNA genome.
  - Synthesis continues, generating a product in which the 5' and 3' regions are repeated, giving each end the structure U3-R-U5.
  - Similar strand switching events occur when reverse transcriptase uses the DNA product to generate a complementary strand.
  - Strand switching is an example of the copy choice mechanism of recombination.
- 

Retroviruses are called **plus strand viruses**, because the viral RNA itself codes for the protein products. As its name implies, reverse transcriptase is responsible for converting the genome (plus strand RNA) into a complementary DNA strand, which is called the **minus strand DNA**. Reverse transcriptase also catalyzes subsequent stages in the production of duplex DNA. It has a DNA polymerase activity, which

enables it to synthesize a duplex DNA from the single-stranded reverse transcript of the RNA. The second DNA strand in this duplex is called **plus strand DNA**. And as a necessary adjunct to this activity, the enzyme has an RNAase H activity, which can degrade the RNA part of the RNA-DNA hybrid. All retroviral reverse transcriptases share considerable similarities of amino acid sequence, and homologous sequences can be recognized in some other retroposons (see later; for review see 171).

The structures of the DNA forms of the virus are compared with the RNA in **Figure 17.5**. The viral RNA has direct repeats at its ends. These **R segments** vary in different strains of virus from 10-80 nucleotides. The sequence at the 5' end of the virus is **R-U5**, and the sequence at the 3' end is **U3-R**. The R segments are used during the conversion from the RNA to the DNA form to generate the more extensive direct repeats that are found in linear DNA (see **Figure 17.6** and **Figure 17.7**). The shortening of 2 bp at each end in the integrated form is a consequence of the mechanism of integration (see **Figure 17.9**).

**Figure 17.5** Retroviral RNA ends in direct repeats (R), the free linear DNA ends in LTRs, and the provirus ends in LTRs that are shortened by two bases each.

Like other DNA polymerases, reverse transcriptase requires a primer. The native primer is tRNA. An uncharged host tRNA is present in the virion. A sequence of 18 bases at the 3' end of the tRNA is base paired to a site 100-200 bases from the 5' end of one of the viral RNA molecules. The tRNA may also be base paired to another site near the 5' end of the other viral RNA, thus assisting in dimer formation between the viral RNAs.

Here is a dilemma. Reverse transcriptase starts to synthesize DNA at a site only 100-200 bases downstream from the 5' end. How can DNA be generated to

represent the intact RNA genome? (This is an extreme variant of the general problem in replicating the ends of any linear nucleic acid; see *Molecular Biology 4.13.8 The ends of linear DNA are a problem for replication.*)

Synthesis *in vitro* proceeds to the end, generating a short DNA sequence called minus strong-stop DNA. This molecule is not found *in vivo* because synthesis continues by the reaction illustrated in **Figure 17.6**. Reverse transcriptase switches templates, carrying the nascent DNA with it to the new template. This is the first of two jumps between templates.

**Figure 17.6** Minus strand DNA is generated by switching templates during reverse transcription.

In this reaction, the R region at the 5' terminus of the RNA template is degraded by the RNAase H activity of reverse transcriptase. Its removal allows the R region at a 3' end to base pair with the newly synthesized DNA. Then reverse transcription continues through the U3 region into the body of the RNA.

The source of the R region that pairs with the strong stop minus DNA can be either the 3' end of the same RNA molecule (intramolecular pairing) or the 3' end of a different RNA molecule (intermolecular pairing). The switch to a different RNA template is used in the figure because there is evidence that the sequence of the tRNA primer is not inherited in a retroposon life cycle. (If intramolecular pairing occurred, we would expect the sequence to be inherited, because it would provide the only source for the primer binding sequence in the next cycle. Intermolecular pairing allows another retroviral RNA to provide this sequence.)

The result of the switch and extension is to add a U3 segment to the 5' end. The stretch of sequence U3-R-U5 is called the **long terminal repeat (LTR)** because a similar series of events adds a U5 segment to the 3' end, giving it the same structure of U5-R-U3. Its length varies from 250-1400 bp (see **Figure 17.5**).

We now need to generate the plus strand of DNA and to generate the LTR at the other end. The reaction is shown in **Figure 17.7**. Reverse transcriptase primes synthesis of plus strand DNA from a fragment of RNA that is left after degrading the original RNA molecule. A strong stop plus strand DNA is generated when the enzyme reaches the end of the template. This DNA is then transferred to the other end of a minus strand. Probably it is released by a displacement reaction when a second round of DNA synthesis occurs from a primer fragment farther upstream (to its left in the figure). It uses the R region to pair with the 3' end of a minus strand DNA. This double-stranded DNA then requires completion of both strands to generate a duplex LTR at each end.

**Figure 17.7** Synthesis of plus strand DNA requires a second jump.

Each retroviral particle carries two RNA genomes. This makes it possible for recombination to occur during a viral life cycle. In principle this could occur during minus strand synthesis and/or during plus strand synthesis:

- The intermolecular pairing shown in **Figure 17.6** allows a recombination to occur between sequences of the two successive RNA templates when minus strand DNA is synthesized. Retroviral recombination is mostly due to strand transfer at this stage, when the nascent DNA strand is transferred from one RNA template to another during reverse transcription (for review see 2292).
- Plus strand DNA may be synthesized discontinuously, in a reaction that involves several internal initiations. Strand transfer during this reaction can also occur, but is less common.

The common feature of both events is that recombination results from a change in the template during the act of DNA synthesis. This is a general example of a mechanism for recombination called **copy choice**. For many years this was regarded as a possible mechanism for general recombination. It is unlikely to be employed by cellular systems, but is a common basis for recombination during infection by RNA viruses, including those that replicate exclusively through RNA forms, such as

poliovirus (579; for review see 170).

Strand switching occurs with a certain frequency during each cycle of reverse transcription, that is, in addition to the transfer reaction that is forced at the end of the template strand. The principle is illustrated in **Figure 17.8**, although we do not know much about the mechanism. Reverse transcription *in vivo* occurs in a ribonucleoprotein complex, in which the RNA template strand is bound to virion components, including the major protein of the capsid. In the case of HIV, addition of this protein (NCp7) to an *in vitro* system causes recombination to occur (1181). The effect is probably indirect: NCp7 affects the structure of the RNA template, which in turn affects the likelihood that reverse transcriptase will switch from one template strand to another.

**Figure 17.8** Copy choice recombination occurs when reverse transcriptase releases its template and resumes DNA synthesis using a new template. Transfer between template strands probably occurs directly, but is shown here in separate steps to illustrate the process.

## RETROVIRUSES AND RETROPOSONS

### 4.17.5 Viral DNA integrates into the chromosome

---

#### Key Concepts

- The organization of proviral DNA in a chromosome is the same as a transposon, with the provirus flanked by short direct repeats of a sequence at the target site.
- Linear DNA is inserted directly into the host chromosome by the retroviral integrase enzyme.
- Two base pairs of DNA are lost from each end of the retroviral sequence during the integration reaction.

---

The organization of the integrated provirus resembles that of the linear DNA. The LTRs at each end of the provirus are identical. The 3' end of U5 consists of a short inverted repeat relative to the 5' end of U3, so the LTR itself ends in short inverted repeats. The integrated proviral DNA is like a transposon: the proviral sequence ends in inverted repeats and is flanked by short direct repeats of target DNA.

The provirus is generated by directly inserting a linear DNA into a target site. [In addition to linear DNA, there are circular forms of the viral sequences. One has two adjacent LTR sequences generated by joining the linear ends. The other has only one LTR [presumably generated by a recombination event and actually comprising the majority of circles. Although for a long time it appeared that the circle might be an integration intermediate (by analogy with the integration of lambda DNA), we now know that the linear form is used for integration; for review see 169).]

Integration of linear DNA is catalyzed by a single viral product, the integrase. Integrase acts on both the retroviral linear DNA and the target DNA. The reaction is illustrated in **Figure 17.9**.

**Figure 17.9** Integrase is the only viral protein required for the integration reaction, in which each LTR loses 2 bp and is inserted between 4 bp repeats of target DNA.

The ends of the viral DNA are important; as is the case with transposons, mutations in the ends prevent integration. The most conserved feature is the presence of the dinucleotide sequence CA close to the end of each inverted repeat. The integrase brings the ends of the linear DNA together in a ribonucleoprotein complex, and converts the blunt ends into recessed ends by removing the bases beyond the conserved CA; usually this involves loss of 2 bases (578).

Target sites are chosen at random with respect to sequence. The integrase makes staggered cuts at a target site. In the example of **Figure 17.9**, the cuts are separated by 4 bp. The length of the target repeat depends on the particular virus; it may be 4, 5, or 6 bp. Presumably it is determined by the geometry of the reaction of integrase with target DNA.

The 5' ends generated by the cleavage of target DNA are covalently joined to the 3' recessed ends of the viral DNA. At this point, both termini of the viral DNA are joined by one strand to the target DNA. The single-stranded region is repaired by enzymes of the host cell, and in the course of this reaction the protruding 2 bases at each 5' end of the viral DNA are removed. The result is that the integrated viral DNA has lost 2 bp at each LTR; this corresponds to the loss of 2 bp from the left end of the 5' terminal U3 and loss of 2 bp from the right end of the 3' terminal U5. There is a characteristic short direct repeat of target DNA at each end of the integrated retroviral genome.

The viral DNA integrates into the host genome at randomly selected sites. A successfully infected cell gains 1-10 copies of the provirus. (An infectious virus enters the cytoplasm, of course, but the DNA form becomes integrated into the genome in the nucleus. Retroviruses can replicate only in proliferating cells, because entry into the nucleus requires the cell to pass through mitosis, when the viral genome gains access to the nuclear material.)

The U3 region of each LTR carries a promoter. The promoter in the left LTR is responsible for initiating transcription of the provirus. Recall that the generation of proviral DNA is required to place the U3 sequence at the left LTR; so we see that the promoter is in fact generated by the conversion of the RNA into duplex DNA.

Sometimes (probably rather rarely), the promoter in the right LTR sponsors transcription of the host sequences that are adjacent to the site of integration. The LTR also carries an enhancer (a sequence that activates promoters in the vicinity) that can act on cellular as well as viral sequences. Integration of a retrovirus can be responsible for converting a host cell into a tumorigenic state when certain types of genes are activated in this way (see *Molecular Biology 6.30.6 Retroviruses activate or incorporate cellular genes*).

Can integrated proviruses be excised from the genome? Homologous recombination could take place between the LTRs of a provirus; solitary LTRs that could be relics of an excision event are present in some cellular genomes.

We have dealt so far with retroviruses in terms of the infective cycle, in which integration is necessary for the production of further copies of the RNA. However, when a viral DNA integrates in a germline cell, it becomes an inherited "endogenous provirus" of the organism. Endogenous viruses usually are not expressed, but sometimes they are activated by external events, such as infection with another virus.

**RETROVIRUSES AND RETROPOSONS****4.17.6 Retroviruses may transduce cellular sequences****Key Terms**

A **transducing virus** carries part of the host genome in place of part of its own sequence. The best known examples are retroviruses in eukaryotes and DNA phages in *E. coli*.

A **replication-defective** virus cannot perpetuate an infective cycle because some of the necessary genes are absent (replaced by host DNA in a transducing virus) or mutated.

A **helper virus** provides functions absent from a defective virus, enabling the latter to complete the infective cycle during a mixed infection.

**Transformation (Oncogenesis)** of eukaryotic cells refers to their conversion to a state of unrestrained growth in culture, resembling or identical with the tumorigenic condition.

**Key Concepts**

- Transforming retroviruses are generated by a recombination event in which a cellular RNA sequence replaces part of the retroviral RNA.

An interesting light on the viral life cycle is cast by the occurrence of **transducing viruses**, variants that have acquired cellular sequences in the form illustrated in **Figure 17.10**. Part of the viral sequence has been replaced by the *v-onc* gene. Protein synthesis generates a Gag-v-Onc protein instead of the usual Gag, Pol, and Env proteins. The resulting virus is **replication-defective**; it cannot sustain an infective cycle by itself. However, it can be perpetuated in the company of a **helper virus** that provides the missing viral functions.

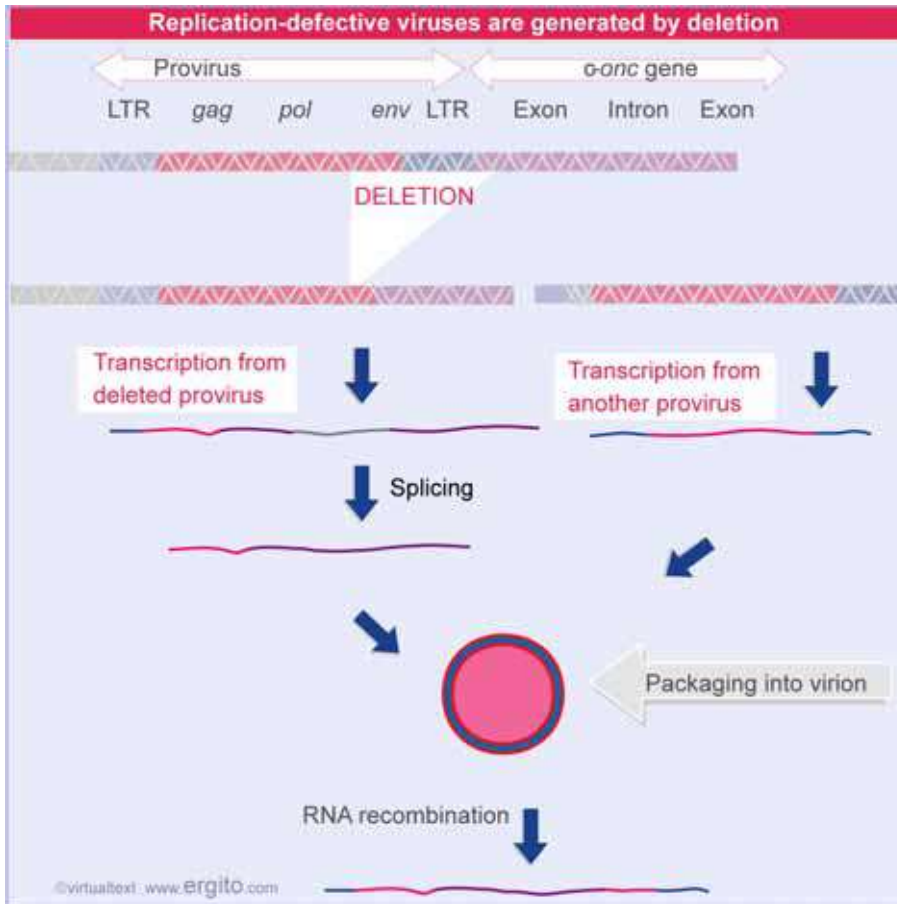

**Figure 17.10** Replication-defective transforming viruses have a cellular sequence substituted for part of the viral sequence. The defective virus may replicate with the assistance of a helper virus that carries the wild-type functions.

*Onc* is an abbreviation for **oncogenesis**, the ability to *transform* cultured cells so that the usual regulation of growth is released to allow unrestricted division. Both viral and cellular *onc* genes may be responsible for creating tumorigenic cells (see *Molecular Biology* 6.30.7 *Retroviral oncogenes have cellular counterparts*).

A *v-onc* gene confers upon a virus the ability to transform a certain type of host cell. Loci with homologous sequences found in the host genome are called *c-onc* genes. How are the *onc* genes acquired by the retroviruses? A revealing feature is the discrepancy in the structures of *c-onc* and *v-onc* genes. The *c-onc* genes usually are interrupted by introns, but the *v-onc* genes are uninterrupted. This suggests that the *v-onc* genes originate from spliced RNA copies of the *c-onc* genes.

A model for the formation of transforming viruses is illustrated in **Figure 17.11**. A retrovirus has integrated near a *c-onc* gene. A deletion occurs to fuse the provirus to the *c-onc* gene; then transcription generates a joint RNA, containing viral sequences at one end and cellular *onc* sequences at the other end. Splicing removes the introns in both the viral and cellular parts of the RNA. The RNA has the appropriate signals for packaging into the virion; virions will be generated if the cell also contains another, intact copy of the provirus. Then some of the diploid virus particles may contain one fused RNA and one viral RNA.

**Figure 17.11** Replication-defective viruses may be generated through integration and deletion of a viral genome to generate a fused viral-cellular transcript that is packaged with a normal RNA genome. Nonhomologous recombination is necessary to generate the replication-defective transforming genome.

A recombination between these sequences could generate the transforming genome, in which the viral repeats are present at both ends. (Recombination occurs at a high frequency during the retroviral infective cycle, by various means. We do not know anything about its demands for homology in the substrates, but we assume that the nonhomologous reaction between a viral genome and the cellular part of the fused RNA proceeds by the same mechanisms responsible for viral recombination.)

The common features of the entire retroviral class suggest that it may be derived from a single ancestor. Primordial IS elements could have surrounded a host gene for a nucleic acid polymerase; the resulting unit would have the form LTR-pol-LTR. It might evolve into an infectious virus by acquiring more sophisticated abilities to manipulate both DNA and RNA substrates, including the incorporation of genes whose products allowed packaging of the RNA. Other functions, such as transforming genes, might be incorporated later. (There is no reason to suppose that the mechanism involved in acquisition of cellular functions is unique for *onc* genes; but viruses carrying these genes may have a selective advantage because of their stimulatory effect on cell growth.)

## RETROVIRUSES AND RETROPOSONS

### 4.17.7 Yeast Ty elements resemble retroviruses

---

#### Key Terms

**Ty** stands for transposon yeast, the first transposable element to be identified in yeast.

A **retroposon (retrotransposon)** is a transposon that mobilizes via an RNA form; the DNA element is transcribed into RNA, and then reverse-transcribed into DNA, which is inserted at a new site in the genome. The difference from retroviruses is that the retroposon does not have an infective (viral) form.

#### Key Concepts

- Ty transposons have a similar organization to endogenous retroviruses.
- They are retroposons, with a reverse transcriptase activity, that transpose via an RNA intermediate.

---

Ty elements comprise a family of dispersed repetitive DNA sequences that are found at different sites in different strains of yeast. **Ty** is an abbreviation for "transposon yeast." A transposition event creates a characteristic footprint: 5 bp of target DNA are repeated on either side of the inserted Ty element. Ty elements are **retroposons** that transpose by the same mechanism as retroviruses. The frequency of Ty transposition is lower than that of most bacterial transposons,  $\sim 10^{-7}$ - $10^{-8}$ .

There is considerable divergence between individual Ty elements. Most elements fall into one of two major classes, called *Ty1* and *Ty917*. They have the same general organization illustrated in **Figure 17.12**. Each element is 6.3 kb long; the last 330 bp at each end constitute direct repeats, called  $\delta$ . Individual Ty elements of each type have many changes from the prototype of their class, including base pair substitutions, insertions, and deletions. There are  $\sim 30$  copies of the *Ty1* type and  $\sim 6$  of the *Ty917* type in a typical yeast genome. In addition, there are  $\sim 100$  independent *delta* elements, called solo  $\delta$ s.

**Figure 17.12** Ty elements terminate in short direct repeats and are transcribed into two overlapping RNAs. They have two reading frames, with sequences related to the retroviral *gag* and *pol* genes.

The *delta* sequences also show considerable heterogeneity, although the two repeats of an individual Ty element are likely to be identical or at least very closely related. The *delta* sequences associated with Ty elements show greater conservation of sequence than the solo *delta* elements, which suggests that recognition of the repeats is involved in transposition.

The Ty element is transcribed into two poly(A)<sup>+</sup> RNA species, which constitute >5% of the total mRNA of a haploid yeast cell. Both initiate within a promoter in the  $\delta$  element at the left end. One terminates after 5 kb; the other terminates after 5.7 kb, within the delta sequence at the right end.

The sequence of the Ty element has two open reading frames, expressed in the same direction, but read in different phases and overlapping by 13 amino acids. The sequence of TyA suggests that it codes for a DNA-binding protein. The sequence of TyB contains regions that have homologies with reverse transcriptase, protease, and integrase sequences of retroviruses.

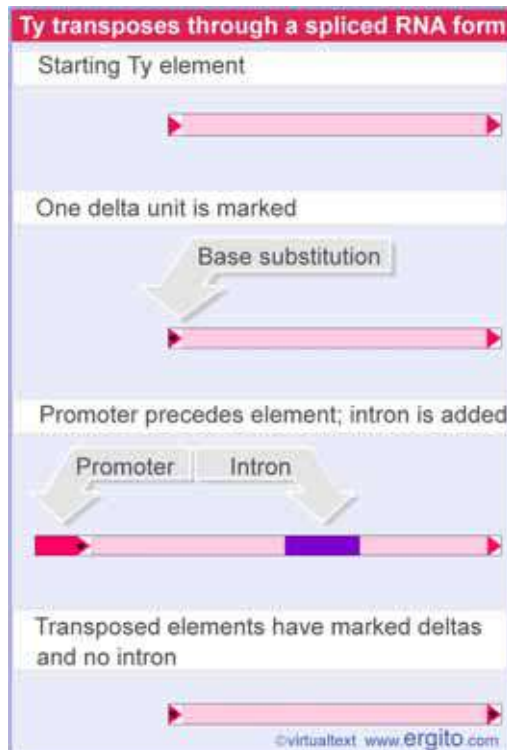

The organization and functions of TyA and TyB are analogous to the behavior of the retroviral *gag* and *pol* functions. The reading frames TyA and TyB are expressed in two forms. The TyA protein represents the TyA reading frame, and terminates at its end. The TyB reading frame, however, is expressed only as part of a joint protein, in which the TyA region is fused to the TyB region by a specific frameshift event that allows the termination codon to be bypassed (analogous to *gag-pol* translation in retroviruses).

Recombination between Ty elements seems to occur in bursts; when one event is detected, there is an increased probability of finding others. Gene conversion occurs between Ty elements at different locations, with the result that one element is "replaced" by the sequence of the other.

*Ty* elements can excise by homologous recombination between the directly repeated *delta* sequences. The large number of solo *delta* elements may be footprints of such events. An excision of this nature may be associated with reversion of a mutation caused by the insertion of *Ty*; the level of reversion may depend on the exact *delta* sequences left behind.

A paradox is that both *delta* elements have the same sequence, yet a promoter is active in the *delta* at one end and a terminator is active in the *delta* at the other end. (A similar feature is found in other transposable elements, including the retroviruses.)

*Ty* elements are classic retroposons, transposing through an RNA intermediate. An ingenious protocol used to detect this event is illustrated in **Figure 17.13**. An intron was inserted into an element to generate a unique *Ty* sequence. This sequence was placed under the control of a *GAL* promoter on a plasmid and introduced into yeast cells. Transposition results in the appearance of multiple copies of the transposon in the yeast genome; but they all lack the intron (575).

**Figure 17.13** A unique *Ty* element, engineered to contain an intron, transposes to give copies that lack the intron. The copies possess identical terminal repeats, generated from one of the termini of the original *Ty* element.

We know of only one way to remove introns: RNA splicing. This suggests that transposition occurs by the same mechanism as with retroviruses. The *Ty* element is transcribed into an RNA that is recognized by the splicing apparatus. The spliced RNA is recognized by a reverse transcriptase and regenerates a duplex DNA copy.

The analogy with retroviruses extends further. The original *Ty* element has a difference in sequence between its two *delta* elements. But the transposed elements possess identical *delta* sequences, derived from the 5' *delta* of the original element. If we consider the *delta* sequence to be exactly like an LTR, consisting of the regions U3-R-U5, the *Ty* RNA extends from R region to R region. Just as shown for retroviruses in **Figure 17.3**, **Figure 17.4**, **Figure 17.5**, **Figure 17.6**, the complete LTR is regenerated by adding a U5 to the 3' end and a U3 to the 5' end.

Transposition is controlled by genes within the *Ty* element. The *GAL* promoter used to control transcription of the marked *Ty* element is inducible: it is turned on by the addition of galactose. Induction of the promoter has two effects. It is necessary to activate transposition of the marked element. And its activation also increases the frequency of transposition of the other *Ty* elements on the yeast chromosome. This implies that the products of the *Ty* element can act in *trans* on other elements (actually on their RNAs).

Although the *Ty* element does not give rise to infectious particles, virus-like particles (VLPs) accumulate within the cells in which transposition has been induced. The particles can be seen in **Figure 17.14**. They contain full-length RNA, double-stranded DNA, reverse transcriptase activity, and a TyB product with integrase activity. The TyA product is cleaved like a *gag* precursor to produce the mature core proteins of the VLP. This takes the analogy between the *Ty* transposon and the retrovirus even further. The *Ty* element behaves in short like a retrovirus that has lost its *env* gene and therefore cannot properly package its genome.

**Figure 17.14** Ty elements generate virus-like particles. Photograph kindly provided by Alan Kingsman.

Only some of the *Ty* elements in any yeast genome are active: most have lost the ability to transpose (and are analogous to inert endogenous proviruses). Since these "dead" elements retain the  $\delta$  repeats, however, they provide targets for transposition in response to the proteins synthesized by an active element.

**RETROVIRUSES AND RETROPOSONS****4.17.8 Many transposable elements reside in *D. melanogaster*****Key Concepts**

- *copia* is a retroposon that is abundant in *D. melanogaster*.

The presence of transposable elements in *D. melanogaster* was first inferred from observations analogous to those that identified the first insertion sequences in *E. coli*. Unstable mutations are found that revert to wild type by deletion, or that generate deletions of the flanking material with an endpoint at the original site of mutation. They are caused by several types of transposable sequence, which are illustrated in **Figure 17.15**. They include the *copia* retroposon, the FB family, and the P elements discussed previously in *Molecular Biology 4.16.14 The role of transposable elements in hybrid dysgenesis*.

**Figure 17.15** Three types of transposable element in *D. melanogaster* have different structures.

The best-characterized family of retroposons is *copia*. Its name reflects the presence of a large number of closely related sequences that code for abundant mRNAs. The *copia* family is taken as a paradigm for several other types of elements whose sequences are unrelated, but whose structure and general behavior appear to be similar.

The number of copies of the *copia* element depends on the strain of fly; usually it is 20-60. The members of the family are widely dispersed. The locations of *copia*

---

elements show a different (although overlapping) spectrum in each strain of *D. melanogaster*.

These differences have developed over evolutionary periods. Comparisons of strains that have diverged recently (over the past 40 years or so) as the result of their propagation in the laboratory reveal few changes. We cannot estimate the rate of change, but the nature of the underlying events is indicated by the result of growing cells in culture. The number of *copia* elements per genome then increases substantially, up to 2-3 times. The additional elements represent insertions of *copia* sequences at new sites. Adaptation to culture in some unknown way transiently increases the rate of transposition to a range of  $10^{-3}$  to  $10^{-4}$  events per generation.

The *copia* element is ~5000 bp long, with identical direct terminal repeats of 276 bp. Each of the direct repeats itself ends in related inverted repeats. A direct repeat of 5 bp of target DNA is generated at the site of insertion. The divergence between individual members of the *copia* family is slight, <5%; variants often contain small deletions. All of these features are common to the other *copia*-like families, although their individual members display greater divergence (576).

The identity of the two direct repeats of each *copia* element implies either that they interact to permit correction events, or that both are generated from one of the direct repeats of a progenitor element during transposition. As in the similar case of *Ty* elements, this is suggestive of a relationship with retroviruses.

The *copia* elements in the genome are always intact; individual copies of the terminal repeats have not been detected (although we would expect them to be generated if recombination deleted the intervening material). *copia* elements sometimes are found in the form of free circular DNA; like retroviral DNA circles, the longer form has two terminal repeats and the shorter form has only one. Particles containing *copia* RNA have been noticed.

The *copia* sequence contains a single long reading frame of 4227 bp. There are homologies between parts of the *copia* open reading frame and the *gag* and *pol* sequences of retroviruses. A notable absence from the homologies is any relationship with retroviral *env* sequences required for the envelope of the virus, which means that *copia* is unlikely to be able to generate virus-like particles.

Transcripts of *copia* are found as abundant poly(A)<sup>+</sup> mRNAs, representing both full-length and part-length transcripts. The mRNAs have a common 5' terminus, resulting from initiation in the middle of one of the terminal repeats. Several proteins are produced, probably involving events such as splicing of RNA and cleavage of polyproteins.

Although we lack direct evidence for *copia*'s mode of transposition, there are so many resemblances with retroviral organization that the conclusion seems inevitable that *copia* must have an origin related to the retroviruses. It is hard to say how many retroviral functions it possesses. We know, of course, that it transposes; but (as is the case with *Ty* elements) there is no evidence for any infectious capacity.

## RETROVIRUSES AND RETROPOSONS

### 4.17.9 Retroposons fall into three classes

#### Key Terms

The **viral superfamily** comprises transposons that are related to retroviruses. They are defined by sequences that code for reverse transcriptase or integrase.

The **nonviral superfamily** of transposons originated independently of retroviruses.

**Interspersed repeats** were originally defined as short sequences that are common and widely distributed in the genome. They are now known to consist of transposable elements.

#### Key Concepts

- Retroposons of the viral superfamily are transposons that mobilize via an RNA that does not form an infectious particle.
- Some directly resemble retroviruses in their use of LTRs, but others do not have LTRs.
- Other elements can be found that were generated by an RNA-mediated transposition event, but do not themselves code for enzymes that can catalyze transposition.
- Transposons and retroposons constitute almost half of the human genome.

Retroposons are defined by their use of mechanisms for transposition that involve reverse transcription of RNA into DNA. Three classes of retroposons are distinguished in **Figure 17.16**:

Mammalian genomes have three types of retroposons			
	Viral Superfamily	LINES	Nonviral Superfamily
Common types	<i>Ty</i> ( <i>S. cerevisiae</i> ) <i>copia</i> ( <i>D. melanogaster</i> )	L1 (human) B1, B2 ID, B4 (mouse)	SINES (mammals) Pseudogenes of pol III transcripts
Termini	Long terminal repeats	No repeats	No repeats
Target repeats	4-6 bp	7-21 bp	7-21 bp
Enzyme activities	Reverse transcriptase and/or integrase	Reverse transcriptase /endonuclease	None (or none coding for transposon products)
Organization	May contain introns (removed in subgenomic mRNA)	1 or 2 uninterrupted ORFs	No introns

©virtualtext www.ergito.com

**Figure 17.16** Retroposons can be divided into the viral superfamilies that are retrovirus-like or LINES and the nonviral superfamilies that do not have coding functions.

- Members of the **viral superfamily** code for reverse transcriptase and/or integrase activities. Like other retroposons, they reproduce like retroviruses but differ from them in not passing through an independent infectious form. They are best characterized in the *Ty* and *copia* elements of yeast and flies.
- The LINES also have reverse transcriptase activity (and may therefore be considered to comprise more distant members of the viral superfamily), but they lack LTRs and use a different mechanism from retroviruses to prime the reverse transcription reaction. They are derived from RNA polymerase II transcripts. A minority of the elements in the genome are fully functional and can transpose autonomously; others have mutations and so can only transpose as the result of the action of a *trans*-acting autonomous element.
- Members of the **nonviral superfamily** are identified by external and internal features that suggest that they originated in RNA sequences, although in these cases we can only speculate on how a DNA copy was generated (for review see 165). We assume that they were targets for a transposition event by an enzyme system coded elsewhere, that is, they are always nonautonomous. They originated in cellular transcripts. They do not code for proteins that have transposition functions. The most prominent component of this family is called SINES. They are derived from RNA polymerase III transcripts (for review see 166).

**Figure 17.17** shows the organization and sequence relationships of elements that code for reverse transcriptase. Like retroviruses, the LTR-containing retroposons can be classified into groups according to the number of independent reading frames for *gag*, *pol*, and *int*, and the order of the genes. In spite of these superficial differences of organization, the common feature is the presence of reverse transcriptase and integrase activities. Typical mammalian LINES elements have two reading frames, one coding for a nucleic acid-binding protein, the other for reverse transcriptase and endonuclease activity.

**Figure 17.17** Retroposons that are closely related to retroviruses have a similar organization, but LINES share only the reverse transcriptase activity.

LTR-containing elements can vary from integrated retroviruses to retroposons that have lost the capacity to generate infectious particles. Yeast and fly genomes have

the *Ty* and *copia* elements that cannot generate infectious particles. Mammalian genomes have endogenous retroviruses that, when active, can generate infectious particles. The mouse genome has several active endogenous retroviruses which are able to generate particles that propagate horizontal infections. By contrast, almost all endogenous retroviruses lost their activity some 50 million years ago in the human lineage, and the genome now has mostly inactive remnants of the endogenous retroviruses.

LINES and SINES comprise a major part of the animal genome. They were defined originally by the existence of a large number of relatively short sequences that are related to one another (comprising the moderately repetitive DNA described in *Molecular Biology 1.3.6 Eukaryotic genomes contain both nonrepetitive and repetitive DNA sequences*). The LINES comprise long interspersed sequences, and the SINES comprise short interspersed sequences. (They are described as interspersed sequences or interspersed repeats because of their common occurrence and widespread distribution.)

Plants contain another type of small mobile element, called MITE (for miniature inverted-repeat transposable element). Such elements terminate in inverted repeats, have a 2 or 3 bp target sequence, do not have coding sequences, and are 200-500 bp long. At least 9 such families exist in (for example) the rice genome. They are often found in the regions flanking protein-coding genes (2838; 2837). They have no relationship to SINES or LINES.

LINES and SINES comprise a significant part of the repetitive DNA of animal genomes. In many higher eukaryotic genomes, they occupy ~50% of the total DNA. **Figure 17.18** summarizes the distribution of the different types of transposons that constitute almost half of the human genome (1442). Except for the SINES, which are always nonfunctional, the other types of elements all consist of both functional elements and elements that have suffered deletions eliminating parts of the reading frames that code for the protein(s) needed for transposition. The relative proportions of these types of transposons are generally similar in the mouse genome (3203).

Retroviruses and transposons constitute half the human genome						
Element	Organization	Length (Kb)	Human genome Number	Fraction		
Retrovirus/retroposon	LTR gag pol (env) LTR	1-11	450,000	8%		
LINES (autonomous) e.g. L1	ORF1 (pol) (A) <sub>n</sub>	6-8	850,000	17%		
SINES (nonautonomous) e.g. Alu	(A) <sub>n</sub>	<0.3	1,500,000	15%		
DNA transposon	Transposase	2-3	300,000	3%		

©virtualtext www.ergito.com

**Figure 17.18** Four types of transposable elements constitute almost half of the human genome.

A common LINES in mammalian genomes is called L1 (for review see 2296). The typical member is ~6,500 bp long, terminating in an A-rich tract. The two open reading frames of a full-length element are called ORF1 and ORF2. The number of full-length elements is usually small (~50), and the remainder of the copies are truncated. Transcripts can be found. As implied by its presence in repetitive DNA,

the LINES family shows sequence variation among individual members. However, the members of the family within a species are relatively homogeneous compared to the variation shown between species (577; for review see 167). L1 is the only member of the LINES family that has been active in either the mouse or human lineages, and it seems to have remained highly active in the mouse, but has declined in the human lineage.

Only one SINES has been active in the human lineage; this is the common Alu element. The mouse genome has a counterpart to this element (B1), and also other SINES (B2, ID, B4) that have been active. Human Alu and mouse B1 SINES are probably derived from the 7SL RNA (see *Molecular Biology 4.17.10 The Alu family has many widely dispersed members*). The other mouse SINES appear to have originated from reverse transcripts of tRNAs. The transposition of the SINES probably results from their recognition as substrates by an active L1 element.

## RETROVIRUSES AND RETROPOSONS

### 4.17.10 The Alu family has many widely dispersed members

---

#### Key Terms

The **Alu family** is a set of dispersed, related sequences, each ~300 bp long, in the human genome. The individual members have Alu cleavage sites at each end (hence the name).

#### Key Concepts

- A major part of repetitive DNA in mammalian genomes consists of repeats of a single family organized like transposons and derived from RNA polymerase III transcripts.

---

The most prominent SINES comprises members of a single family. Its short length and high degree of repetition make it comparable to simple sequence (satellite) DNA, except that the individual members of the family are dispersed around the genome instead of being confined to tandem clusters. Again there is significant similarity between the members within a species compared with variation between species.

In the human genome, a large part of the moderately repetitive DNA exists as sequences of ~300 bp that are interspersed with nonrepetitive DNA. At least half of the renatured duplex material is cleaved by the restriction enzyme AluI at a single site, located 170 bp along the sequence. The cleaved sequences all are members of a single family, known as the **Alu family** after the means of its identification. There are ~300,000 members in the haploid genome (equivalent to one member per 6 kb of DNA). The individual Alu sequences are widely dispersed. A related sequence family is present in the mouse (where the 50,000 members are called the B1 family), in the Chinese hamster (where it is called the Alu-equivalent family), and in other mammals.

The individual members of the Alu family are related rather than identical. The human family seems to have originated by a 130 bp tandem duplication, with an unrelated sequence of 31 bp inserted in the right half of the dimer. The two repeats are sometimes called the "left half" and "right half" of the Alu sequence. The individual members of the Alu family have an average identity with the consensus sequence of 87%. The mouse B1 repeating unit is 130 bp long, corresponding to a monomer of the human unit. It has 70-80% homology with the human sequence.

The Alu sequence is related to 7SL RNA, a component of the signal recognition particle (see *Molecular Biology 2.8.10 The SRP interacts with the SRP receptor*). The 7SL RNA corresponds to the left half of an Alu sequence with an insertion in the middle. So the 90 5' terminal bases of 7SL RNA are homologous to the left end of Alu, the central 160 bases of 7SL RNA have no homology to Alu, and the 40 3' terminal bases of 7SL RNA are homologous to the right end of Alu. The 7SL RNA is coded by genes that are actively transcribed by RNA polymerase III. It is possible

that these genes (or genes related to them) gave rise to the inactive Alu sequences.

The members of the Alu family resemble transposons in being flanked by short direct repeats. However, they display the curious feature that the lengths of the repeats are different for individual members of the family. Because they derive from RNA polymerase III transcripts, it is possible that individual members carry internal active promoters.

A variety of properties have been found for the Alu family, and its ubiquity has prompted many suggestions for its function, but it is not yet possible to discern its true role.

At least some members of the family can be transcribed into independent RNAs. In the Chinese hamster, some (although not all) members of the Alu-equivalent family appear to be transcribed *in vivo*. Transcription units of this sort are found in the vicinity of other transcription units.

Members of the Alu family may be included within structural gene transcription units, as seen by their presence in long nuclear RNA. The presence of multiple copies of the Alu sequence in a single nuclear molecule can generate secondary structure. In fact, the presence of Alu family members in the form of inverted repeats is responsible for most of the secondary structure found in mammalian nuclear RNA.

*This content is available online at <http://www.ergito.com/main.jsp?bcs=MBIO.4.17.10>*

## RETROVIRUSES AND RETROPOSONS

### 4.17.11 Processed pseudogenes originated as substrates for transposition

#### Key Terms

A **processed pseudogene** is an inactive gene copy that lacks introns, contrasted with the interrupted structure of the active gene. Such genes originate by reverse transcription of mRNA and insertion of a duplex copy into the genome.

#### Key Concepts

- A processed pseudogene is derived from an mRNA sequence by reverse transcription.

When a sequence generated by reverse transcription of an mRNA is inserted into the genome, we can recognize its relationship to the gene from which the mRNA was transcribed. Such a sequence is called a **processed pseudogene** to reflect the fact that it was processed from RNA and is not active. The characteristic features of a processed pseudogene are compared in **Figure 17.19** with the features of the original gene and the mRNA. The figure shows all the relevant diagnostic features, only some of which are found in any individual example. Any transcript of RNA polymerase II could in principle give rise to such a pseudogene, and there are many examples, including the processed globin pseudogenes that were the first to be discovered (see *Molecular Biology 1.4.6 Pseudogenes are dead ends of evolution*).

**Figure 17.19** Pseudogenes could arise by reverse transcription of RNA to give duplex DNAs that become integrated into the genome.

The pseudogene may start at the point equivalent to the 5' terminus of the RNA, which would be expected only if the DNA had originated from the RNA. Several pseudogenes consist of precisely joined exon sequences; we know of no mechanism to recognize introns in DNA, so this feature argues for an RNA-mediated stage. The pseudogene may end in a short stretch of A·T base pairs, presumably derived from the poly(A) tail of the RNA. On either side of the pseudogene is a short direct repeat, presumed to have been generated by a transposition-like event. Processed pseudogenes reside at locations unrelated to their presumed sites of origin.

The processed pseudogenes do not carry any information that might be used to sponsor a transposition event (or to carry out the preceding reverse transcription of the RNA). This suggests that the RNA was a substrate for another system, coded by a retroposon. In fact, it seems likely that the active LINES elements provide most of the reverse transcriptase activity, and they are responsible not only for their own transposition, but also for acting on the SINES and for generating processed pseudogenes.

## RETROVIRUSES AND RETROPOSONS

### 4.17.12 LINES use an endonuclease to generate a priming end

---

#### Key Terms

A **processed pseudogene** is an inactive gene copy that lacks introns, contrasted with the interrupted structure of the active gene. Such genes originate by reverse transcription of mRNA and insertion of a duplex copy into the genome.

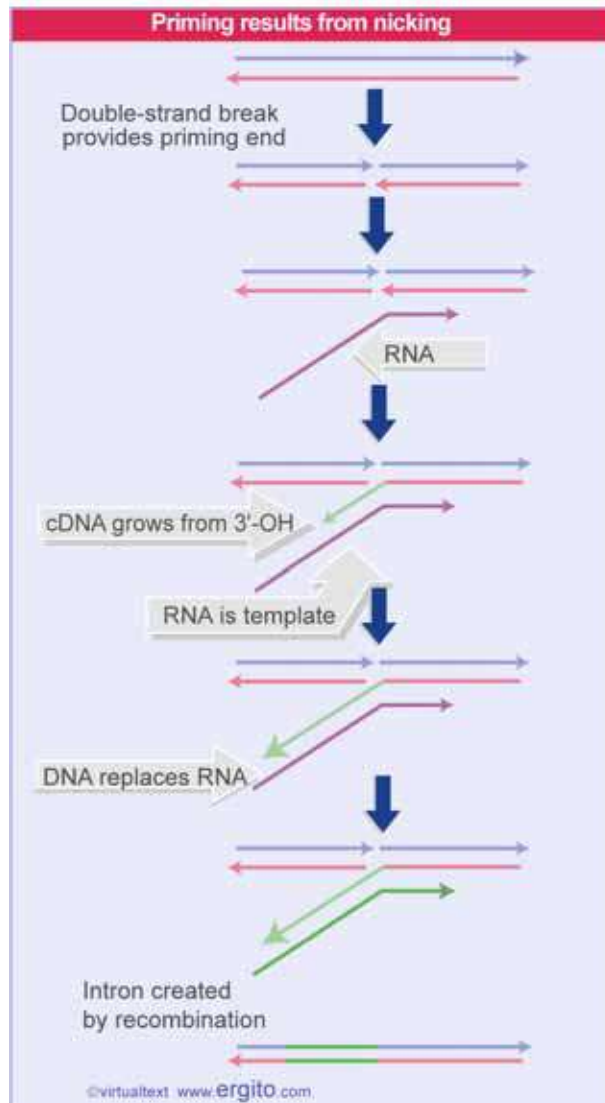

#### Key Concepts

- LINES do not have LTRs and require the retroposon to code for an endonuclease that generates a nick to prime reverse transcription.

---

LINES elements, and some others, do not terminate in the LTRs that are typical of retroviral elements. This poses the question: how is reverse transcription primed? It does not involve the typical reaction in which a tRNA primer pairs with the LTR (see **Figure 17.6**). The open reading frames in these elements lack many of the retroviral functions, such as protease or integrase domains, but typically have reverse transcriptase-like sequences and code for an endonuclease activity. In the human LINES L1, ORF1 is a DNA-binding protein and ORF2 has both reverse transcriptase and endonuclease activities; both products are required for transposition (3152; 3153).

**Figure 17.20** shows how these activities support transposition. A nick is made in the DNA target site by an endonuclease activity coded by the retroposon. The RNA product of the element associates with the protein bound at the nick. The nick provides a 3' -OH end that primes synthesis of cDNA on the RNA template. A second cleavage event is required to open the other strand of DNA, and the RNA/DNA hybrid is linked to the other end of the gap either at this stage or after it has been converted into a DNA duplex. A similar mechanism is used by some mobile introns (see **Figure 26.11**) (580; 581).

**Figure 17.20** Retrotransposition of non-LTR elements occurs by nicking the target to provide a primer for cDNA synthesis on an RNA template. The arrowheads indicate 3' ends.

When elements originate from RNA polymerase II transcripts, the genomic sequences are necessarily inactive: they lack the promoter that was upstream of the original startpoint for transcription. Because they usually possess the features of the mature transcript, they are called **processed pseudogenes**.

One of the reasons why LINES elements are so effective lies with their method of propagation. When a LINES mRNA is translated, the protein products show a *cis*-preference for binding to the mRNA from which they were translated. **Figure 17.21** shows that the ribonucleoprotein complex then moves to the nucleus, where the proteins insert a DNA copy into the genome. Often reverse transcription does not proceed fully to the end, so the copy is inactive. However, there is the potential for insertion of an active copy, because the proteins are acting on a transcript of the original active element.

**Figure 17.21** A LINEs is transcribed into an RNA that is translated into proteins that assemble into a complex with the RNA. The complex translocates to the nucleus, where it inserts a DNA copy into the genome.

By contrast, the proteins produced by the DNA transposons must be imported into the nucleus after being synthesized in the cytoplasm, but they have no means of distinguishing full-length transposons from inactive deleted transposons. **Figure 17.22** shows that instead, they will indiscriminately recognize any element by virtue of the repeats that mark the ends, much reducing their chance of acting on a full-length as opposed to deleted element. The consequence is that inactive elements accumulate and eventually the family dies out because a transposase has such a small chance of finding a target that is a fully functional transposon.

**Figure 17.22** A transposon is transcribed into an RNA that is translated into proteins that move independently to the nucleus, where they act on any pair of inverted repeats with the same sequence as the original transposon.

Are transposition events currently occurring in these genomes or are we seeing only the footprints of ancient systems? This varies with the species. There are few currently active transposons in the human genome, but by contrast several active transposons are known in the mouse genome. This explains the fact that spontaneous mutations caused by LINES insertions occur at a rate of ~3% in mouse, but only 0.1% in man. There appear to be ~10-50 active LINES elements in the human genome. Some human diseases can be pinpointed as the result of transposition of L1 into genes, and others result from unequal crossing-over events involving repeated copies of L1 (for review see 2296). A model system in which LINES transposition occurs in tissue culture cells suggests that a transposition event can introduce several types of collateral damage as well as inserting into a new site; the damage includes chromosomal rearrangements and deletions (3150; 3151). Such events may be viewed as agents of genetic change. Neither DNA transposons nor retroviral-like retroposons seem to have been active in the human genome for 40-50 million years, but several active examples of both are found in the mouse.

Note that for transpositions to survive, they must occur in the germline. Presumably similar events occur in somatic cells, but do not survive beyond one generation.

## RETROVIRUSES AND RETROPOSONS

### 4.17.13 Summary

---

Reverse transcription is the unifying mechanism for reproduction of retroviruses and perpetuation of retroposons. The cycle of each type of element is in principle similar, although retroviruses are usually regarded from the perspective of the free viral (RNA) form, while retroposons are regarded from the stance of the genomic (duplex DNA) form.

Retroviruses have genomes of single-stranded RNA that are replicated through a double-stranded DNA intermediate. An individual retrovirus contains two copies of its genome. The genome contains the *gag*, *pol*, and *env* genes, which are translated into polyproteins, each of which is cleaved into smaller functional proteins. The Gag and Env components are concerned with packing RNA and generating the virion; the Pol components are concerned with nucleic acid synthesis.

Reverse transcriptase is the major component of Pol, and is responsible for synthesizing a DNA (minus strand) copy of the viral (plus strand) RNA. The DNA product is longer than the RNA template; by switching template strands, reverse transcriptase copies the 3' sequence of the RNA to the 5' end of the DNA, and copies the 5' sequence of the RNA to the 3' end of the DNA. This generates the characteristic LTRs (long terminal repeats) of the DNA. A similar switch of templates occurs when the plus strand of DNA is synthesized using the minus strand as template. Linear duplex DNA is inserted into a host genome by the integrase enzyme. Transcription of the integrated DNA from a promoter in the left LTR generates further copies of the RNA sequence.

Switches in template during nucleic acid synthesis allow recombination to occur by copy choice. During an infective cycle, a retrovirus may exchange part of its usual sequence for a cellular sequence; the resulting virus is usually replication-defective, but can be perpetuated in the course of a joint infection with a helper virus. Many of the defective viruses have gained an RNA version (*v-onc*) of a cellular gene (*c-onc*). The *onc* sequence may be any one of a number of genes whose expression in *v-onc* form causes the cell to be transformed into a tumorigenic phenotype.

The integration event generates direct target repeats (like transposons that mobilize via DNA). An inserted provirus therefore has direct terminal repeats of the LTRs, flanked by short repeats of target DNA. Mammalian and avian genomes have endogenous (inactive) proviruses with such structures. Other elements with this organization have been found in a variety of genomes, most notably in *S. cerevisiae* and *D. melanogaster*. *Ty* elements of yeast and *copia* elements of flies have coding sequences with homology to reverse transcriptase, and mobilize via an RNA form. They may generate particles resembling viruses, but do not have infectious capability. The LINES sequences of mammalian genomes are further removed from the retroviruses, but retain enough similarities to suggest a common origin. They use a different type of priming event to initiate reverse transcription, in which an endonuclease activity associated with the reverse transcriptase makes a nick that provides a 3' -OH end for priming synthesis on an RNA template. The frequency of LINES transposition is increased because its protein products are *cis*-acting; they

associate with the mRNA from which they were translated to form a ribonucleoprotein complex that is transported into the nucleus.

Another class of retroposons have the hallmarks of transposition via RNA, but have no coding sequences (or at least none resembling retroviral functions). They may have originated as passengers in a retroviral-like transposition event, in which an RNA was a target for a reverse transcriptase. Processed pseudogenes arise by such events. A particularly prominent family apparently originating from a processing event is the mammalian SINES, including the human Alu family. Some snRNAs, including 7SL snRNA (a component of the SRP) are related to this family.

## REARRANGEMENT OF DNA

### 4.18.1 Introduction

---

Although genomic DNA is usually unaltered by somatic development, there are some cases in which sequences are moved within a genome, modified, amplified, or even lost, as a natural event. In this chapter, we discuss a variety of such events in yeast, plants, and lower eukaryotes. Examples of rearrangement or loss of specific sequences are especially common in the lower eukaryotes. Usually these changes involve somatic cells; the germline remains inviolate. (However, there are organisms whose reproductive cycle involves the loss of whole chromosomes or sets of chromosomes.) We also discuss the introduction of new sequences into the genome by experimental means. Reorganization of particular sequences is rare in animals, although an extensive case is represented by the immune system. In *Molecular Biology 5.25 Immune diversity*, we discuss the rearrangement and expression of immunoglobulin genes.

There are two types of circumstances in which gene rearrangement is used to control expression:

- Rearrangement may create new genes, needed for expression in particular circumstances, as in the case of the immunoglobulins.
- Rearrangement may be responsible for switching expression from one preexisting gene to another. This provides a mechanism for regulating gene expression.

Yeast mating type switching and trypanosome antigen variation share a similar type of plan in which gene expression is controlled by manipulation of DNA sequences. Phenotype is determined by the gene copy present at a particular, active locus. But the genome also contains a store of other, alternative sequences, which are silent. A silent copy can be activated only by a rearrangement of sequences in which it replaces the active gene copy. Such a substitution is equivalent to a unidirectional transposition with a specific target site.

The simplest example of this strategy is found in the yeast, *S. cerevisiae*. Haploid *S. cerevisiae* can have either of two mating types. The type is determined by the sequence present at the active mating type locus. But the genome also contains two other, silent loci, one representing each mating type. Transition between mating types is accomplished by substituting the sequence at the active locus with the sequence from the silent locus carrying the other mating type.

A range of variations is made possible by DNA rearrangement in the African trypanosomes, unicellular parasites that evade the host immune response by varying their surface antigens. The type of surface antigen is determined by the gene sequence at an active locus. This sequence can be changed, however, by substituting a sequence from any one of many silent loci. It seems fitting that the mechanism used to combat the flexibility of the immune apparatus is analogous to that used to generate immune diversity: it relies on physical rearrangements in the genome to

change the sequences that are expressed.

Another means of increasing genetic capacity is employed in parasite- or symbiote-host interactions, in which exogenous DNA is introduced from a bacterium into a host cell. The mechanism resembles bacterial conjugation. Expression of the bacterial DNA in its new host changes the phenotype of the cell. In the example of the bacterium *Agrobacterium tumefaciens*, the result is to induce tumor formation by an infected plant cell.

Alterations in the relative proportions of components of the genome during somatic development occur to allow insect larvae to increase the number of copies of certain genes. And the occasional amplification of genes in cultured mammalian cells is indicated by our ability to select variant cells with an increased copy number of some gene. Initiated within the genome, the amplification event can create additional copies of the gene that survive in either intrachromosomal or extrachromosomal form.

When extraneous DNA is introduced into eukaryotic cells, it may give rise to extrachromosomal forms or may be integrated into the genome. The relationship between the extrachromosomal and genomic forms is irregular, depending on chance and to some degree unpredictable events, rather than resembling the regular interchange between free and integrated forms of bacterial plasmids.

Yet, however accomplished, the process may lead to stable change in the genome; following its injection into animal eggs, DNA may even be incorporated into the genome and inherited thereafter as a normal component, sometimes continuing to function. Injected DNA may enter the germline as well as the soma, creating a transgenic animal. The ability to introduce specific genes that function in an appropriate manner could become a major medical technique for curing genetic diseases.

The converse of the introduction of new genes is the ability to disrupt specific endogenous genes. Additional DNA can be introduced within a gene to prevent its expression and to generate a null allele. Breeding from an animal with a null allele can generate a homozygous "knockout," which has no active copy of the gene. This is a powerful method to investigate directly the importance and function of a gene.

Considerable manipulation of DNA sequences therefore is achieved both in authentic situations and by experimental fiat. We are only just beginning to work out the mechanisms that permit the cell to respond to selective pressure by changing its bank of sequences or that allow it to accommodate the intrusion of additional sequences.

## REARRANGEMENT OF DNA

### 4.18.2 The mating pathway is triggered by pheromone-receptor interactions

#### Key Terms

The **mating type** is a property of haploid yeast that makes it able to fuse to form a diploid only with a cell of the opposite mating type.

A **pheromone** is a small molecule secreted by one mating type of an organism in order to interact with a member of the opposite mating type.

#### Key Concepts

- Yeast of a given mating type secrete a small polypeptide that binds to a receptor on cells of the opposite mating type.

The yeast *S. cerevisiae* can propagate in either the haploid or diploid condition. Conversion between these states takes place by mating (fusion of haploid spores to give a diploid) and by sporulation (meiosis of diploids to give haploid spores). The ability to engage in these activities is determined by the **mating type** of the strain.

The properties of the two mating types are summarized in **Figure 18.1**. We may view them as resting on the rationale that there is no point in mating unless the haploids are of different genetic types; and sporulation is productive only when the diploid is heterozygous and therefore able to generate recombinants.

Haploids and diploids are different			
	<i>MATa</i>	<i>MAT<math>\alpha</math></i>	<i>MATa/MAT<math>\alpha</math></i>
Cell type	a	$\alpha$	a/ $\alpha$
Mating	yes	yes	no
Sporulation	no	no	yes
Pheromone	a factor	a factor	none
Receptor	binds $\alpha$ factor	binds a factor	none

©virtualtext www.ergito.com

**Figure 18.1** Mating type controls several activities.

The mating type of a (haploid) cell is determined by the genetic information present at the MAT locus. Cells that carry the *MATa* allele at this locus are type *a*; likewise, cells that carry the *MAT $\alpha$*  allele are type  $\alpha$ . Cells of opposite types can mate; cells of the same type cannot.

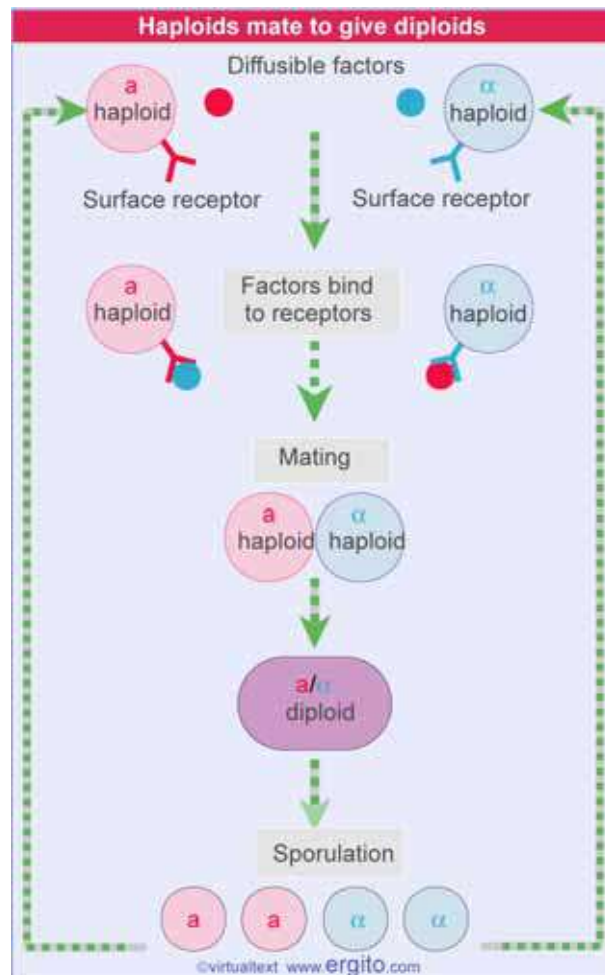

Recognition of cells of opposite mating type is accomplished by the secretion of **pheromones**.  $\alpha$  cells secrete the small polypeptide  $\alpha$ -factor; *a* cells secrete *a*-factor. The  $\alpha$ -factor is a peptide of 13 amino acids; the *a*-factor is a peptide of 12 amino acids that is modified by addition of a farnesyl (lipid-like) group and carboxymethylation. Each of these peptides is synthesized in the form of a precursor

polypeptide that is cleaved to release the mature peptide sequence.

A cell of one mating type carries a surface receptor for the pheromone of the opposite type. When an *a* cell and an  $\alpha$  cell encounter one another, the pheromones bind to their receptors to arrest the cells in the G1 phase of the cell cycle, and various morphological changes occur. In a successful mating, the cell cycle arrest is followed by cell and nuclear fusion to produce an *a*/ $\alpha$  diploid cell.

The *a*/ $\alpha$  cell carries both the *MATa* and *MAT*  $\alpha$  alleles and has the ability to sporulate. **Figure 18.2** demonstrates how this design maintains the normal haploid/diploid life cycle. Note that only heterozygous diploids can sporulate; homozygous diploids (either *a/a* or  $\alpha/\alpha$ ) cannot sporulate.

**Figure 18.2** The yeast life cycle proceeds through mating of *MATa* and *MAT*  $\alpha$  haploids to give heterozygous diploids that sporulate to generate haploid spores.

Much of the information about the yeast mating type pathway was deduced from the properties of mutations that eliminate the ability of *a* and/or  $\alpha$  cells to mate. The genes identified by such mutations are called *STE* (for sterile). Mutations in the genes *STE2* and *STE3* are specific for individual mating types; but mutations in the

other *STE* genes eliminate mating in both *a* and  $\alpha$  cells. This situation is explained by the fact that the events that follow the interaction of factor with receptor are identical for both types (for review see 172).

Mating is a symmetrical process that is initiated by the interaction of pheromone secreted by one cell type with the receptor carried by the other cell type. The only genes that are uniquely required for the response pathway in a particular mating type are those coding for the receptors. Either the *a* factor-receptor or the  $\alpha$  factor-receptor interaction switches on the same response pathway. Mutations that eliminate steps in the common pathway have the same effects in both cell types (584).

## REARRANGEMENT OF DNA

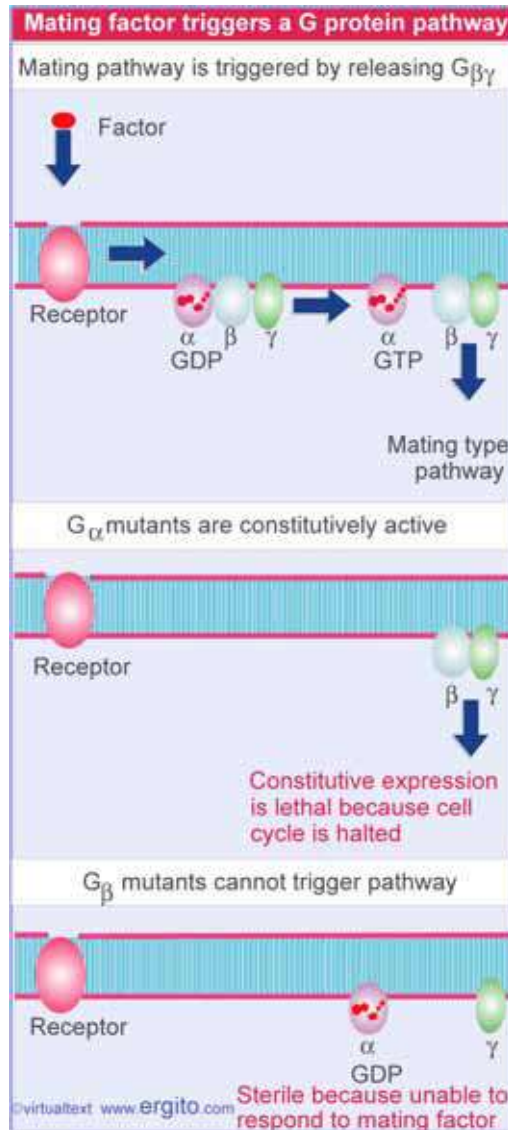

### 4.18.3 The mating response activates a G protein

---

#### Key Concepts

- Binding of mating type factor to receptor activates a trimeric G protein.
  - The  $\beta \gamma$  dimer is released and activates a signal transduction pathway.
- 

The initial steps in the mating-type response are summarized in **Figure 18.3**. The components are similar to those of the "classical" receptor-G protein coupled systems, in which a membrane receptor interacts with a trimeric G protein (see *Molecular Biology 6.28.5 G proteins may activate or inhibit target proteins*). Ste2 is the  $\alpha$ -receptor in the *a* cell; Ste3 is the *a*-receptor in the  $\alpha$  cell. When either receptor is activated, it interacts with the same G protein. *This means that the identical pathway is triggered when either type of mating factor interacts with a receptor of the opposite type* (584).

**Figure 18.3** Either  $\alpha$  or  $\beta$  factor/receptor interaction triggers the activation of a G protein, whose  $\beta$   $\gamma$  subunits transduce the signal to the next stage in the pathway.

The trimeric G protein consists of the subunits,  $\alpha$ ,  $\beta$ , and  $\gamma$ . The  $\alpha$  subunit binds a guanine nucleotide. In the intact (trimeric) G protein, the  $\alpha$  subunit carries GDP. When the pheromone receptor is activated, it causes the GDP to be displaced by GTP. As a result, the  $\alpha$  subunit is released from the  $\beta$   $\gamma$  dimer. This separation of subunits allows the G protein to activate the next protein in the pathway (see *Molecular Biology* 6.28.6 *G proteins function by dissociation of the trimer*; for review see 2286).

The most common mechanism used in such pathways is for the activated  $\alpha$  subunit to interact with the target protein. However, the situation is different in the mating type pathway, where the  $\beta$   $\gamma$  dimer activates the next stage in the pathway. The component proteins of the G-trimer are identified by mutations in three genes, *SCG1*,

*STE4*, and *STE18*, that affect the response to binding pheromone. Inactivation of *SCG1*, which codes for the  $G_{\alpha}$  protein, causes constitutive expression of the pheromone response pathway (because  $G_{\alpha}$  is unable to maintain  $G_{\beta\gamma}$  in the inactive trimeric form). The mutation is lethal, because its effects include arrest of the cell cycle. Inactivation of *STE4* (codes for  $G_{\beta}$ ) or of *STE18* (codes for  $G_{\alpha}$ ) create sterility by abolishing the mating-type response (because the next step in the pathway cannot be activated; for review see 174; 176).

## REARRANGEMENT OF DNA

### 4.18.4 The signal is passed to a kinase cascade

---

#### Key Concepts

- $G_{\beta\gamma}$  activates the monomeric G protein Cdc42.
- Cdc42 directly controls the structure of the cytoskeleton and activates a kinase cascade.
- In the kinase cascade, the signal passes through a series of kinases.
- The last kinase in the cascade activates a transcription factor and also phosphorylates other targets.
- The effect of the pathway is to repress functions needed for the cell cycle and to activate functions needed for mating.

---

**Figure 18.4** summarizes the main steps of the mating type pathway (for review see 2286). (There are also some branches that are not shown in the figure.) When the  $G_{\beta\gamma}$  dimer is released, it causes a monomeric G protein to be activated. Actually, the immediate target of  $G_{\beta\gamma}$  is Cdc24, which is a nucleotide exchange factor that then activates the monomeric G protein Cdc42. The effect of Cdc24 on Cdc42 is a typical interaction in which the monomeric G protein is activated by replacing its bound GDP with GTP (see *Molecular Biology Supplement 32.10 G proteins*). Cdc42 resembles the Rho family of G proteins that control actin filament structures in higher eukaryotic cells (see *Molecular Biology 6.28.15 The activation of Ras is controlled by GTP*).

**Figure 18.4** The same mating type response is triggered by interaction of either pheromone with its receptor. The signal is transmitted through a series of kinases to a transcription factor; there may be branches to some of the final functions.

Cdc42 then activates two pathways:

- one affects the structure of the cell by changing the organization of the cytoskeleton;
- the other is a cascade of kinases that ultimately activates transcription.

Cdc42 acts on many proteins that are involved in modifying the state of assembly of

actin filaments, and in this way changes the structure of the cell. It is necessary for budding, which generates the new daughter cell when division occurs. After mating, division stops and budding ceases, although cell growth continues in the direction of the pheromone. It is Cdc42 that is responsible for this change.

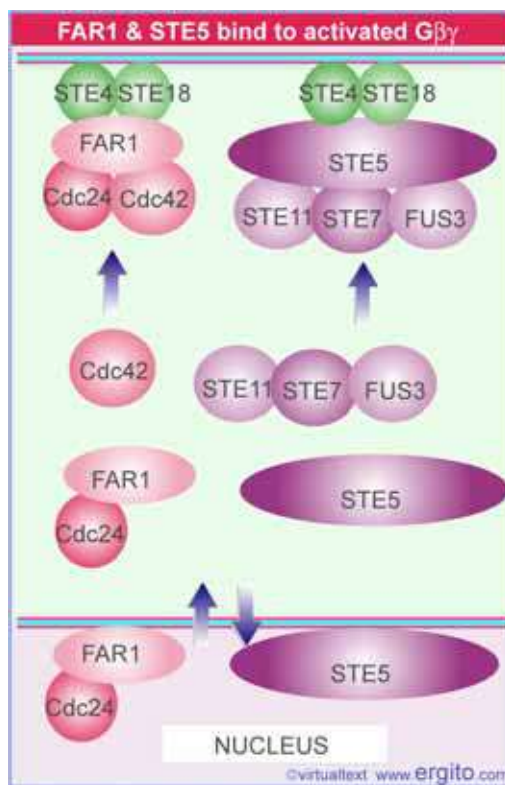

The pathway to regulating transcription is identified by a group of *STE* genes. They form a kinase cascade in which each member activates the next in the pathway by phosphorylating it. This is an example of a MAP kinase cascade (see *Molecular Biology 6.28.16 A MAP kinase pathway is a cascade*). Analogous pathways are found in higher organisms, and are compared with the yeast cascade in **Figure 28.38**. In the case of the yeast pathway, Cdc42 directly activates the kinase STE20. STE20 initiates the kinase cascade by activating STE11, which activates STE7, which activates FUS3, which finally triggers the response by phosphorylating the transcription factor STE12. This causes STE12 to migrate to the nucleus, where it activates transcription.

Some components in the signaling pathways do not have catalytic activities but act to assist the other components. Both FAR1 and STE5 in the pathways detailed in **Figure 18.4** are scaffold proteins that hold together the other members of the pathway. This may be necessary to ensure specificity in the response, for example, to ensure that each kinase in the MAPK cascade is directed to phosphorylate only the intended next member of the pathway (see *Molecular Biology 6.28.17 What determines specificity in signaling?*). Packaging the members of the pathway together also increases the efficiency of the response.

Both FAR1 and STE5 shuttle between the nucleus and cytoplasm. **Figure 18.5** shows that in a dividing cell, before the mating response is triggered, they are concentrated in the nucleus. **Figure 18.6** shows that they both interact with the activated  $G_{\beta\gamma}$  dimer, and therefore become concentrated in the cytoplasm as a result of the pheromone-receptor interaction (2334). FAR1 is bound to Cdc24 (2333); the result of its relocalization to the cytoplasm is to enable the Cdc24 to activate Cdc42. STE5 binds to the three components of the MAPK cascade (808); actually, its interaction with the kinases may enhance the ability of STE20 to make the initial phosphorylation of STE11. So we see that, although  $G_{\beta\gamma}$  directly activates the effector pathways through its effect on the Cdc24/Cdc42 interaction, it indirectly enhances the pathways by causing the necessary components to accumulate in the cytoplasm.

**Figure 18.5** In a dividing cell, FAR1 (bound to Cdc24) and STE5 shuttle between the nucleus and cytoplasm. The  $G_{\alpha\beta\gamma}$  complex of SCG1, STE4, STE18 is associated with the plasma membrane.

**Figure 18.6** The mating pathway frees the active  $G_{\beta\gamma}$  dimer (STE4-STE18). It forms complexes with the scaffolding proteins FAR1 and STE5. FAR1 is bound to Cdc24, which binds Cdc42. STE5 binds the three kinases of the MAPK pathway.

Branches from the cascade generate additional reactions. STE7 activates two kinases.

One is FUS3, whose action is dedicated to carrying forward the mating type pathway, as shown in **Figure 18.4**. FUS3 acts on earlier components of the pathway, specifically FAR1 and STE5, to enhance their actions, on the transcription factor STE12, and also on proteins that would otherwise inhibit STE12. The second target for STE7 is KSS1, which has ancillary functions (its main function is in vegetative growth).

Some of the end targets for the cascade are direct substrates of one of the kinases; for example, FUS3 kinase acts on Cln3, which is one of 3 Cln proteins needed for cell cycle progression. Other targets are controlled at the level of gene expression.

## REARRANGEMENT OF DNA

### 4.18.5 Yeast can switch silent and active loci for mating type

---

#### Key Terms

The **cassette model** for yeast mating type proposes that there is a single active locus (the active cassette) and two inactive copies of the locus (the silent cassettes).

Mating type is changed when an active cassette of one type is replaced by a silent cassette of the other type.

#### Key Concepts

- The yeast mating type locus *MAT* has either the *MAT<sub>a</sub>* or *MAT<sub>α</sub>* genotype.
- Yeast with the dominant allele *HO* switch their mating type at a frequency  $\sim 10^{-6}$ .
- The allele at *MAT* is called the active cassette.
- There are also two silent cassettes, *HML<sub>α</sub>* and *HMR<sub>a</sub>*.
- Switching occurs if *MAT<sub>a</sub>* is replaced by *HML<sub>α</sub>* or *MAT<sub>α</sub>* is replaced by *HMR<sub>a</sub>*.

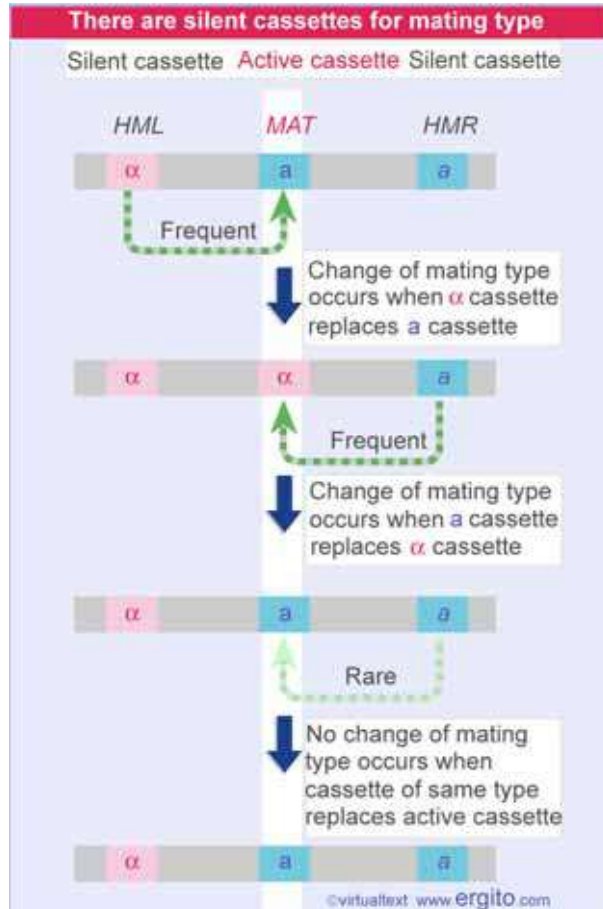

---

Yeast mating type is determined by the locus *MAT*, which can have either of the alleles *MAT<sub>a</sub>* or *MAT<sub>α</sub>*. Some yeast strains have the remarkable ability to switch their mating types. These strains carry a dominant allele *HO* and change their mating type frequently, as often as once every generation. Strains with the recessive allele *ho* have a stable mating type, subject to change with a frequency  $\sim 10^{-6}$ .

The presence of *HO* causes the genotype of a yeast population to change. Irrespective of the initial mating type, in a very few generations there are large numbers of cells of both mating types, leading to the formation of *MAT<sub>a</sub>/MAT<sub>α</sub>* diploids that take over the population. The production of stable diploids from a haploid population can be viewed as the *raison d'être* for switching.

The existence of switching suggests that all cells contain the potential information needed to be either *MAT<sub>a</sub>* or *MAT<sub>α</sub>*, but express only one type. Where does the information to change mating types come from? Two additional loci are needed for switching. *HML<sub>α</sub>* is needed for switching to give a *MAT<sub>α</sub>* type; *HMR<sub>a</sub>* is needed for switching to give a *MAT<sub>a</sub>* type. These loci lie on the same chromosome that carries *MAT*. *HML* is far to the left, *HMR* far to the right.

The **cassette model** for mating type is illustrated in **Figure 18.7**. It proposes that *MAT* has an *active cassette* of either type  $\alpha$  or type *a*. *HML* and *HMR* have *silent cassettes*. Usually *HML* carries an  $\alpha$  cassette, while *HMR* carries an *a* cassette. All cassettes carry information that codes for mating type, but only the active cassette at *MAT* is expressed. Mating-type switching occurs when the active cassette is replaced by information from a silent cassette. The newly installed cassette is then expressed (582).

**Figure 18.7** Changes of mating type occur when silent cassettes replace active cassettes of opposite genotype; when transpositions occur between cassettes of the same type, the mating type remains unaltered.

Switching is nonreciprocal; the copy at *HML* or *HMR* replaces the allele at *MAT*. We know this because a mutation at *MAT* is lost permanently when it is replaced by switching – it does not exchange with the copy that replaces it.

If the silent copy present at *HML* or *HMR* is mutated, switching introduces a mutant allele into the *MAT* locus. The mutant copy at *HML* or *HMR* remains there through an indefinite number of switches. Like replicative transposition, the donor element generates a new copy at the recipient site, while itself remaining inviolate.

Mating-type switching is a directed event, in which there is only one recipient (*MAT*), but two potential donors (*HML* and *HMR*). Switching usually involves replacement of *MATa* by the copy at *HML*  $\alpha$  or replacement of *MAT*  $\alpha$  by the copy at *HMRa*. In 80-90% of switches, the *MAT* allele is replaced by one of opposite type. This is determined by the phenotype of the cell. Cells of *a* phenotype preferentially choose *HML* as donor; cells of  $\alpha$  phenotype preferentially choose *HMR*.

Several groups of genes are involved in establishing and switching mating type. As well as the genes that directly determine mating type, they include genes needed to

repress the silent cassettes, to switch mating type, or to execute the functions involved in mating.

By comparing the sequences of the two silent cassettes (*HML*  $\alpha$  and *HMRa*) with the sequences of the two types of active cassette (*MATa* and *MAT*  $\alpha$ ), we can delineate the sequences that determine mating type. The organization of the mating type loci is summarized in **Figure 18.8**. Each cassette contains common sequences that flank a central region that differs in the *a* and  $\alpha$  types of cassette (called *Ya* or *Y*  $\alpha$ ). On either side of this region, the flanking sequences are virtually identical, although they are shorter at *HMR*. The active cassette at *MAT* is transcribed from a promoter within the *Y* region.

**Figure 18.8** Silent cassettes have the same sequences as the corresponding active cassettes, except for the absence of the extreme flanking sequences in *HMRa*. Only the *Y* region changes between *a* and  $\alpha$  types.

## REARRANGEMENT OF DNA

### 4.18.6 The *MAT* locus codes for regulator proteins

#### Key Concepts

- In  $\alpha$ -type haploids, *MAT*  $\alpha$  turns on genes required to specify  $\alpha$ -specific functions required for mating, and turns off genes required for *a*-mating type.
- In *a*-type cells, *MATa* is not required.
- In diploids, *a1* and  $\alpha 2$  products cooperate to repress haploid-specific genes.

The basic function of the *MAT* locus is to control expression of pheromone and receptor genes, and other functions involved in mating. *MAT*  $\alpha$  codes for two proteins,  $\alpha 1$  and  $\alpha 2$ . *MATa* codes for a single protein, *a1*. The *a* and  $\alpha$  proteins directly control transcription of various target genes; they function by both positive and negative regulation. They function independently in haploids, and in conjunction in diploids. Their interactions are summarized in the table on the right of **Figure 18.9** in terms of three groups of target genes:

**Figure 18.9** In diploids the  $\alpha 1$  and  $\alpha 2$  proteins cooperate to repress haploid-specific functions. In *a* haploids, mating functions are constitutive. In  $\alpha$  haploids, the  $\alpha 2$  protein represses *a* mating functions, while  $\alpha 1$  induces  $\alpha$  mating functions.

- *a*-specific genes are expressed constitutively in *a* cells. They are repressed in  $\alpha$  cells. The *a*-specific genes include the *a*-factor structural gene, and *STE2*, which

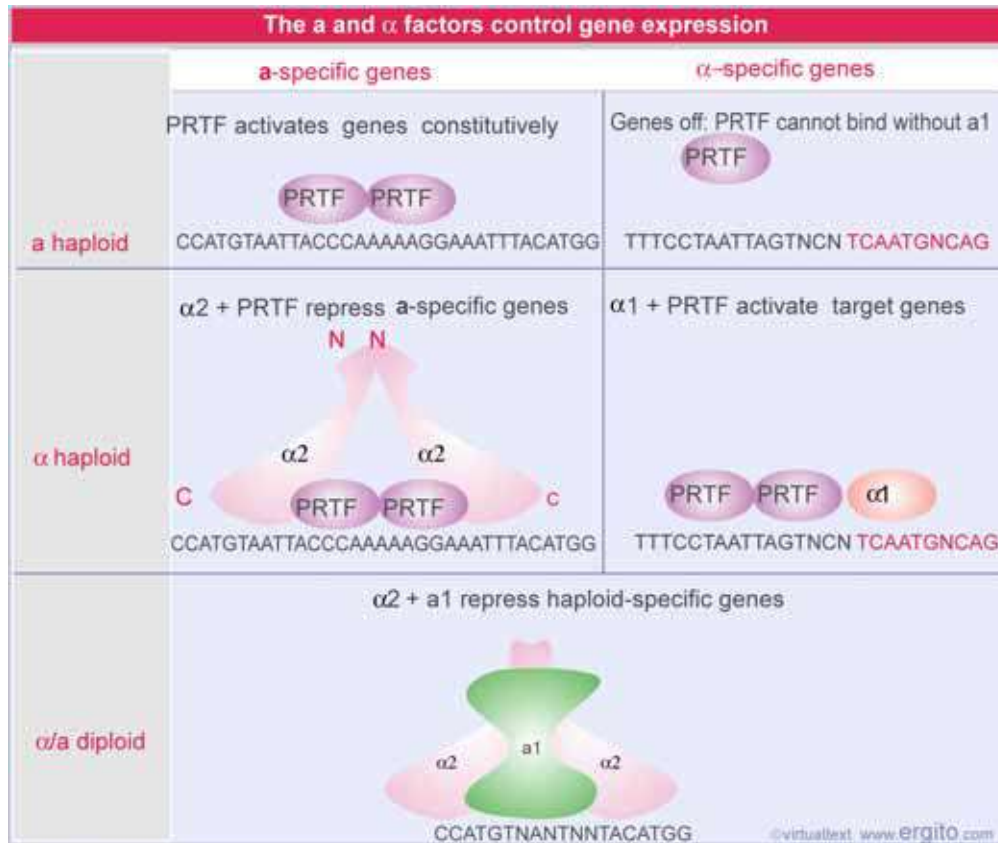

codes for the  $\alpha$ -factor receptor. So the *a* phenotype is associated with readiness to recognize the pheromone produced by the opposite mating type.

- $\alpha$ -specific functions are induced in  $\alpha$  cells, but are not expressed in *a* cells. They include the  $\alpha$ -factor structural gene, and the *a*-factor receptor gene, *STE3*. Again, the expression of pheromone of one type is associated with expression of receptor for the pheromone of the opposite type.
- Haploid-specific functions include genes that are needed for transcription of pheromone and receptor genes, the *HO* gene involved in switching, and *RME*, a repressor of sporulation. They are expressed constitutively in both types of haploid, but are repressed in *a*/ $\alpha$  diploids. As a result, the *a*-specific and  $\alpha$ -specific functions also remain unexpressed in diploids.

We may now view the functions of the regulators and their targets from the perspective of the *MAT* functions expressed in haploid and diploid yeast cells, as outlined in the diagram on the left of **Figure 18.9**. The *a* and  $\alpha$  mating types are regulated by different mechanisms:

- In *a* haploids, *a* mating functions are expressed constitutively. The functions of the products of *MATa* in the *a* cell (if any) are unknown. It may be required only to repress haploid functions in diploid cells.
- In  $\alpha$  haploids, the  $\alpha 1$  product turns on  $\alpha$ -specific genes whose products are needed for  $\alpha$  mating type. The  $\alpha 2$  product represses the genes responsible for producing *a* mating type, by binding to an operator sequence located upstream of target genes.
- In diploids, the *a1* and  $\alpha 2$  products cooperate to repress haploid-specific genes. They combine to recognize an operator sequence different from the target for  $\alpha 2$  alone.

The abilities of the  $\alpha 2$ , *a1*, and  $\alpha 1$  proteins to regulate transcription rely upon some interesting protein-protein interactions between themselves and with other protein(s). The pattern of gene control in *a* cells,  $\alpha$  cells, and diploids, is summarized in **Figure 18.10**.

**Figure 18.10** Combinations of PRTF,  $\alpha 1$ ,  $\alpha 1$  and  $\alpha 2$  activate or repress specific groups of genes to correspond with the mating type of the cell.

A protein called PRTF (which is not specific for mating type) is involved in many of these interactions. PRTF binds to a short consensus sequence called the P box. The role of PRTF in gene regulation may be quite extensive, because P boxes are found in a variety of locations. In some of these sites, the P box is required for activation of the gene; but at other loci, PRTF is needed for repression. Its effects may therefore depend on the other proteins that bind at sites adjacent to the P box.

Genes that are *a*-specific may be activated by PRTF alone. This is adequate to ensure their expression in an *a* haploid.

The *a*-specific genes are repressed in an  $\alpha$  haploid by the combined action of the  $\alpha 2$  protein and PRTF. The  $\alpha 2$  protein contains two domains. The C-terminal domain binds to short palindromic elements at the ends of an operator consensus sequence of 32 bp. However, binding of this fragment to DNA does not cause repression. The N-terminal domain is needed for repression and is responsible for making contacts with PRTF. The binding site for PRTF is a P box in the center of the operator. In fact,  $\alpha$  and PRTF bind to the operator cooperatively.

Expression of  $\alpha$ -specific genes requires the  $\alpha 1$  activator. This is another small protein, 175 amino acids long. *Cis*-acting sequences that confer  $\alpha$ -specific transcription are 26 bp long, and can be divided into two parts. The first 16 bp form the P box, where PRTF binds; the adjacent 10 bp sequence forms the binding site for

$\alpha 1$ . The  $\alpha 1$  factor binds only when PRTF is present to bind to the P box. Neither protein alone can bind to its target box, but together they can bind to DNA, presumably as a result of protein-protein interactions.

The  $\alpha$ -specific genes are turned off by default in *a* haploids, because in the absence of  $\alpha 1$  protein, PRTF is unable to bind to activate them.

The  $\alpha 2$  protein can also cooperate with the  $\alpha 1$  protein. The combination of these proteins recognizes a different operator. The operator shares the outlying palindromic sequences with the sequence recognized by  $\alpha 2$  alone, but is shorter because the sequence between them is different. The  $\alpha 1/ \alpha 2$  combination represses genes with this motif in diploid cells.

The major point to be made from these results is that the phenotype of each type of cell (*a* or  $\alpha$  haploid or *a/ \alpha* diploid) is determined by the combination of *a* and  $\alpha$  proteins that are expressed. One aspect is the distinction between the haploid and diploid phenotypes; another is the distinction between *a* and  $\alpha$  haploid phenotypes. The latter extends to expression of genes corresponding to the appropriate mating type and to the determination of the direction of switching of mating type (see **Figure 18.7**). *MATa* cells activate a recombination enhancer on the left arm of chromosome III, which increases recombination over a 40 kb region that includes *HML*. *MAT \alpha* cells inactivate the left end of chromosome III (for review see 173).

## REARRANGEMENT OF DNA

### 4.18.7 Silent cassettes at *HML* and *HMR* are repressed

---

#### Key Terms

A **silencer** is a short sequence of DNA that can inactivate expression of a gene in its vicinity.

#### Key Concepts

- *HML* and *HMR* are repressed by silencer elements.
- Loci required to maintain silencing include *SIR1-4*, *RAP1*, and genes for histone H4.
- Binding of ORC (origin recognition complex) at the silencers is necessary for inactivation.

---

The transcription map in **Figure 18.8** reveals an intriguing feature. Transcription of either *MAT $\alpha$*  or *MAT a* initiates within the *Y* region. Only the *MAT* locus is expressed; yet the same *Y* region is present in the corresponding nontranscribed cassette (*HML* or *HMR*). This implies that regulation of expression is not accomplished by direct recognition of some site overlapping with the promoter. A site outside the cassettes must distinguish *HML* and *HMR* from *MAT*.

Deletion analysis shows that sites on either side of both *HML* and *HMR* are needed to repress their expression. They are called **silencers**. The sites on the left of each cassette are called the E silencers, and the sites on the right side are called the I silencers. These control sites can function at a distance (up to 2.5 kb away from a promoter) and in either orientation. They behave like negative enhancers (enhancers are elements distant from the promoter that activate transcription; see *Molecular Biology 5.21.15 Enhancers contain bidirectional elements that assist initiation*; for review see 175).

Can we find the basis for the control of cassette activity by identifying genes that are responsible for keeping the cassettes silent? We would expect the products of these genes to act on the silencers. A convenient assay for mutation in such genes is provided by the fact that, when a mutation allows the usually silent cassettes at *HML* and *HMR* to be expressed, both *a* and  $\alpha$  functions are produced, so the cells behave like *MAT $\alpha$ /MAT a* diploids.

Mutations in several loci abolish silencing and lead to expression of *HML* and *HMR*. The first to be discovered were the four *SIR* loci (silent information regulators). All four wild-type *SIR* loci are needed to maintain *HML* and *HMR* in the repressed state; mutation in any one of these loci to give a *sir<sup>-</sup>* allele has two effects. Both *HML* and *HMR* can be transcribed. And both the silent cassettes become targets for replacement by switching. So the same regulatory event is involved in repressing a

silent cassette and in preventing it from being a recipient for replacement by another cassette.

Other loci required for silencing include *RAP1* (which is also required to maintain telomeric heterochromatin in its inert state) and the genes coding for histone H4. Deletions of the N-terminus of histone H4 or individual point mutations activate the silent cassettes. The effects of these mutations can be overcome either by introducing new mutations in *SIR3* or by over-expressing *SIR1*, which suggests that there is a specific interaction between H4 and the SIR proteins.

The general model suggested by these results is that the SIR proteins act on chromatin structure to prevent expression of the genes. Because mutations in the SIR proteins have the same effects on genes that have been inactivated by the proximity of telomeric heterochromatin, it seems likely that SIR proteins are involved generally in interacting with histones to form heterochromatic (inert) structures (see *Molecular Biology 5.23.15 Heterochromatin depends on interactions with histones*).

There is an interesting connection between repression at the silencers and DNA replication. Each silencer contains an *ARS* sequence (an origin of replication). The *ARS* is bound by the ORC (the origin recognition complex) that is involved in initiating replication. Mutations in *ORC* genes prevent silencing, indicating that the binding of ORC protein at the silencer is required for silencing.

There are two separate types of connection between silencing and the replication apparatus:

- The presence of Sir1 is necessary.
- And replication is required.

If a Sir1 protein is localized at the silencer (by linkage to another protein that is bound there), the binding of ORC is no longer necessary. This means that the role of ORC is solely to bring in Sir1; it is not required to initiate replication. As illustrated in **Figure 18.11**, the role of ORC could therefore be to provide an initiating center from which the silencing effect can spread. ORC provides the structure to which Sir1p binds, and Sir1p then recruits the other SIR proteins. This is different from its role in replication.

**Figure 18.11** Silencing at HMR depends on recruiting Sir1p.

However, passage through S phase is necessary for silencing to be established. This does not require initiation to occur at the *ARS* in the silencer. The effect could depend on the passage of a replication fork through the silencer, perhaps in order to allow the chromatin structure to be changed.

## REARRANGEMENT OF DNA

### 4.18.8 Unidirectional transposition is initiated by the recipient *MAT* locus

---

#### Key Concepts

- Mating type switching is initiated by a double strand break made at the *MAT* locus by the HO endonuclease.

---

A switch in mating type is accomplished by a gene conversion in which the recipient site (*MAT*) acquires the sequence of the donor type (*HML* or *HMR*). Sites needed for transposition have been identified by mutations at *MAT* that prevent switching. The unidirectional nature of the process is indicated by lack of mutations in *HML* or *HMR*.

The mutations identify a site at the right boundary of *Y* at *MAT* that is crucial for the switching event. The nature of the boundary is shown by analyzing the locations of these point mutations relative to the site of switching (this is done by examining the results of rare switches that occur in spite of the mutation). Some mutations lie within the region that is replaced (and thus disappear from *MAT* after a switch), while others lie just outside the replaced region (and therefore continue to impede switching). So sequences both within and outside the replaced region are needed for the switching event.

Switching is initiated by a double-strand break close to the *Y-Z* boundary that coincides with a site that is sensitive to attack by DNAase. (This is a common feature of chromosomal sites that are involved in initiating transcription or recombination.) It is recognized by an endonuclease coded by the *HO* locus. The HO endonuclease makes a staggered double-strand break just to the right of the *Y* boundary. Cleavage generates the single-stranded ends of 4 bases drawn in **Figure 18.12**. The nuclease does not attack mutant *MAT* loci that cannot switch. Deletion analysis shows that most or all of the sequence of 24 bp surrounding the *Y* junction is required for cleavage *in vitro*. The recognition site is relatively large for a nuclease, and it occurs only at the three mating-type cassettes (583).

**Figure 18.12** HO endonuclease cleaves *MAT* just to the right of the Y region, generating sticky ends with a base overhang.

Only the *MAT* locus and not the *HML* or *HMR* loci are targets for the endonuclease. It seems plausible that the same mechanisms that keep the silent cassettes from being transcribed also keep them inaccessible to the HO endonuclease. This inaccessibility ensures that switching is unidirectional.

The reaction triggered by the cleavage is illustrated schematically in **Figure 18.13** in terms of the general reaction between donor and recipient regions. In terms of the interactions of individual strands of DNA, it follows the scheme for recombination via a double-strand break drawn in **Figure 15.8**; and the stages following the initial cut require the enzymes involved in general recombination. Mutations in some of these genes prevent switching.

**Figure 18.13** Cassette substitution is initiated by a double-strand break in the recipient (*MAT*) locus, and may involve pairing on either side of the *Y* region with the donor (*HMR* or *HML*) locus.

Suppose that the free end of *MAT* invades either the *HML* or *HMR* locus and pairs with the region of homology on the right side. The *Y* region of *MAT* is degraded until a region with homology on the left side is exposed. At this point, *MAT* is paired with *HML* or *HMR* at both the left side and the right side. The *Y* region of *HML* or *HMR* is copied to replace the region lost from *MAT* (which might extend beyond the limits of *Y* itself). The paired loci separate. (The order of events could be different.)

Like the double-strand break model for recombination, the process is initiated by *MAT*, the locus that is to be replaced. In this sense, the description of *HML* and *HMR* as donor loci refers to their ultimate role, but not to the mechanism of the process. Like replicative transposition, the donor site is unaffected, but a change in sequence occurs at the recipient; unlike transposition, the recipient locus suffers a substitution rather than addition of material.

## REARRANGEMENT OF DNA

### 4.18.9 Regulation of HO expression controls switching

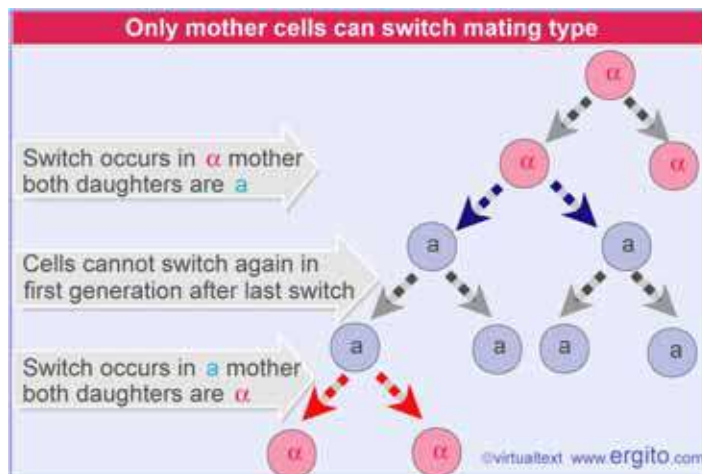

#### Key Concepts

- HO endonuclease is synthesized in haploid mother cells, so that a switching event causes both daughters to have the new mating type.

Production of the HO endonuclease is regulated at the level of gene transcription. There are three separate control systems:

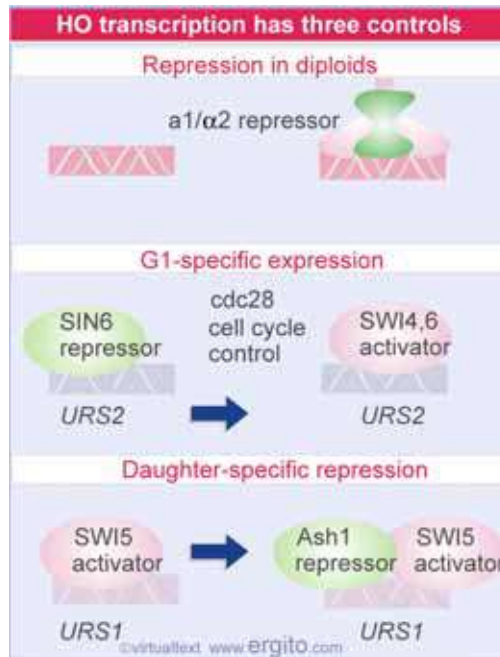

- *HO* is under mating-type control. It is not synthesized in *MATa/MAT α* diploids. The reason could be that there is no need for switching when both *MAT* alleles are expressed anyway.
- *HO* is transcribed in mother cells but not in daughter cells.
- *HO* transcription also responds to the cell cycle. The gene is expressed only at the end of the G1 phase of a mother cell.

The timing of nuclease production explains the relationship between switching and cell lineage. **Figure 18.14** shows that switching is detected only in the products of a division; both daughter cells have the same mating type, switched from that of the parent. The reason is that the restriction of *HO* expression to G1 phase ensures that the mating type is switched before the *MAT* locus is replicated, with the result that both progeny have the new mating type.

**Figure 18.14** Switching occurs only in mother cells; both daughter cells have the new mating type. A daughter cell must pass through an entire cycle before it becomes a mother cell that is able to switch again.

*cis*-acting sites that control *HO* transcription reside in the 1500 bp upstream of the gene. The general pattern of control is that repression at any one of many sites, responding to several regulatory circuits, may prevent transcription of *HO*. **Figure 18.15** summarizes the types of sites that are involved.

**Figure 18.15** Three regulator systems act on transcription of the *HO* gene. Transcription occurs only when all repression is lifted.

Mating type control resembles that of other haploid-specific genes. Transcription is prevented (in diploids) by the *a1/ α2* repressor. There are 10 binding sites for the repressor in the upstream region. These sites vary in their conformity to the consensus sequence; we do not know which and how many of them are required for haploid-specific repression.

The control of *HO* transcription involves interplay between a series of activating and repressing events. The genes *SWI1-5* are required for *HO* transcription. They function by preventing products of the genes *SIN1-6* from repressing *HO*. The *SWI* genes were discovered first, as mutants unable to switch; then the *SIN* genes were discovered for their ability to release the blocks caused by particular *SWI* mutations. *SWI-SIN* interactions are involved in both cell-cycle control and the restriction of expression to mother cells.

Some of the *SWI* and *SIN* genes are not specifically concerned with mating type, but are global regulators of transcription, whose functions are needed for expression of many loci. They include the activator complex *SWI1,2,3* and the loci *SIN1-4* that code for chromosomal proteins. Their role in mating type expression is incidental. The "real" regulator is therefore the *SWI* protein that counteracts the general repression system specifically at the *HO* locus.

Cell-cycle control is conferred by 9 copies of an octanucleotide sequence called

*URS2*. A copy of the consensus sequence can confer cell-cycle control on a gene to which it is attached. A gene linked to this sequence is repressed except during a transient period toward the end of G1 phase. SWI4 and SWI6 are the activators that release repression at *URS2*. Their activity depends on the function of the cell-cycle regulator CDC28, which executes the decision that commits the cell to divide (see *Molecular Biology 6.29 Cell cycle and growth regulation*).

The target for restricting expression to alternate generations is the activator SWI5 (which antagonizes a general repression system exercised by SIN3,4). In mutants that lack these functions, *HO* is transcribed equally well in mother and daughter cells. This system acts on *URS1* elements in the far upstream region.

SWI5 is not itself the regulator of mother-cell specificity, but is antagonized by Ash1p, a repressor that accumulates preferentially in daughter cells at the end of anaphase. Mutations in *ASH1* allow daughter cells to switch mating type. The localization of Ash1p is determined by the transport of its mRNA from the mother cell along actin filaments into the daughter bud (*Molecular Biology 2.5.16 mRNA can be specifically localized*). Its presence prevents SWI5 from activating the *HO* gene. It works by binding to many copies of a consensus sequence that are distributed throughout the regulatory regions *URS1* and *URS2* (3154). When the daughter cell grows to become a mother cell, the concentration of Ash1p is diluted, and it becomes possible to express the *HO* gene again (585).

## REARRANGEMENT OF DNA

### 4.18.10 Trypanosomes switch the VSG frequently during infection

---

#### Key Terms

The **variable surface glycoprotein (VSG)** is the protein on the surface of a trypanosome that changes during an infection so as to prevent the infected host from mounting an immune reaction to it.

**Antigenic variation** describes the ability of a trypanosome to change its surface protein, so that the host is challenged with a different antigen.

#### Key Concepts

- The trypanosome life cycle alternates between tsetse fly and mammal.
  - The form of the parasite that is transmitted to the mammal has a coat of a VSG (variable surface glycoprotein).
  - The VSG is replaced every 1-2 weeks.
- 

Sleeping sickness in man (and a related disease in cows) is caused by infection with African trypanosomes. The unicellular parasite follows the life cycle illustrated in **Figure 18.16**, in which it alternates between tsetse fly and mammal. The trypanosome may be transferred either to or from the fly when it bites a mammal.

**Figure 18.16** A trypanosome passes through several morphological forms when its life cycle alternates between a tsetse fly and mammalian host.

During its life cycle, the parasite undergoes several morphological and biochemical changes. The most significant biochemical change is in the **variable surface glycoprotein (VSG)**, the major component of the surface coat. The coat covers the plasma membrane and consists of a monolayer of  $5-10 \times 10^6$  molecules of a single VSG, which is the only antigenic structure exposed on the surface. A trypanosome expresses only one VSG at any time, and its ability to change the VSG is responsible for its survival through the fly-mammal infective cycle.

Consider the cycle as starting when a fly gains a trypanosome by biting an infected mammal. The trypanosome enters the gut of the fly in the "procyclic form," and loses its VSG. After about three weeks, its progeny differentiate into the "metacyclic form," which re-acquires a VSG coat. This form is transmitted to the mammalian bloodstream during a bite by the fly. The trypanosome multiplies in the mammalian bloodstream. Its progeny continue to express the metacyclic VSG for about a week. Then a new VSG is synthesized, and further transitions occur every 1-2 weeks.

Each of the successive VSG species is immunologically distinct. As a result, the antigen presented to the mammalian immune system is constantly changing. The process of transition is called **antigenic variation**. The immune response of the organism always lags behind the change in surface antigen, so that the trypanosome evades immune surveillance, and thereby perpetuates itself indefinitely. Each transition of the VSG is accompanied by a new wave of parasitemia, with symptoms

of fever, rash, etc.; the parasites eventually invade the central nervous system, after which the mammalian host becomes progressively more lethargic and eventually comatose.

Trypanosomes vary in their host range. The best investigated species is a variety of *Trypanosoma brucei* that grows well on laboratory animals (although not on man). Laboratory strains of *T. brucei* switch VSGs spontaneously at a rate of  $10^{-4}$  -  $10^{-6}$  per division. Switching occurs independently of the host immune system. In effect, new variants then are selected by the host, because it mounts a response against the old VSG, but fails to recognize and act against the new VSG (for review see 177; 178; 2515).

A general view of VSG structure is depicted in **Figure 18.17**. A nascent VSG is ~500 amino acids long; it has an N-terminal signal sequence, followed by a long variable region that provides the unique antigenic determinant, and a C-terminal homology region ending in a short hydrophobic tail. The nascent VSG is processed at both ends to give the mature form. The signal sequence is cleaved during secretion. The hydrophobic tail is removed before the VSG reaches the outside surface. The new C-terminus is covalently attached to the trypanosome membrane; three types of homology region are distinguished according to the C-terminal amino acid.

**Figure 18.17** The C-terminus of VSG is cleaved and covalently linked to the membrane through a glycolipid.

The VSG is attached to the membrane via a phosphoglycolipid. As a result, VSG can

be released from the membrane by an enzyme that removes fatty acid. This reaction (which is used in purifying the VSG) may be important *in vivo* in allowing one VSG to be replaced by another on the surface of the trypanosome.

---

## REARRANGEMENT OF DNA

### 4.18.11 New VSG sequences are generated by gene switching

---

#### Key Terms

Each VSG (variable surface glycoprotein) of a trypanosome is coded by a **basic copy gene**.

The **expression-linked copy in (ELC)** a trypanosome genome is the one copy of a VSG gene that is expressed.

An **expression site** in a trypanosome genome is a locus near a telomere that can express the VSG gene that is located there.

#### Key Concepts

- The trypanosome has ~1000 basic copy VSG genes.
- Only a single expression-linked copy located near a telomere is expressed at any given time.
- A basic copy gene is activated by having its sequence copied into the expression site.
- There are only a few potential expression sites.

---

How many varieties of VSG can be expressed by any one trypanosome? It is not clear that any limit is encountered before death of the host. A single trypanosome can make at least 100 VSGs sufficiently different in sequence that antibodies against any one do not react against the others.

VSG variation is coded in the trypanosome genome. Every individual trypanosome carries the entire VSG repertoire of its strain. Diversity therefore depends on changing expression from one preexisting gene to another.

The trypanosome genome has an unusual organization, consisting of a large number of segregating units. In addition to an unknown number of chromosomes, it contains ~100 "minichromosomes," each containing ~50-150 kb of DNA. Hybridization experiments identify ~1000 VSG genes, scattered among all size classes of chromosomal material.

Each VSG is coded by a **basic copy gene**. These genes can be divided into two classes according to their chromosomal location:

- Telomeric genes lie within 5-15 kb of a telomere. There could be >200 of these genes if every telomere has one.
- Internal genes reside within chromosomes (more formally, they lie >50 kb from

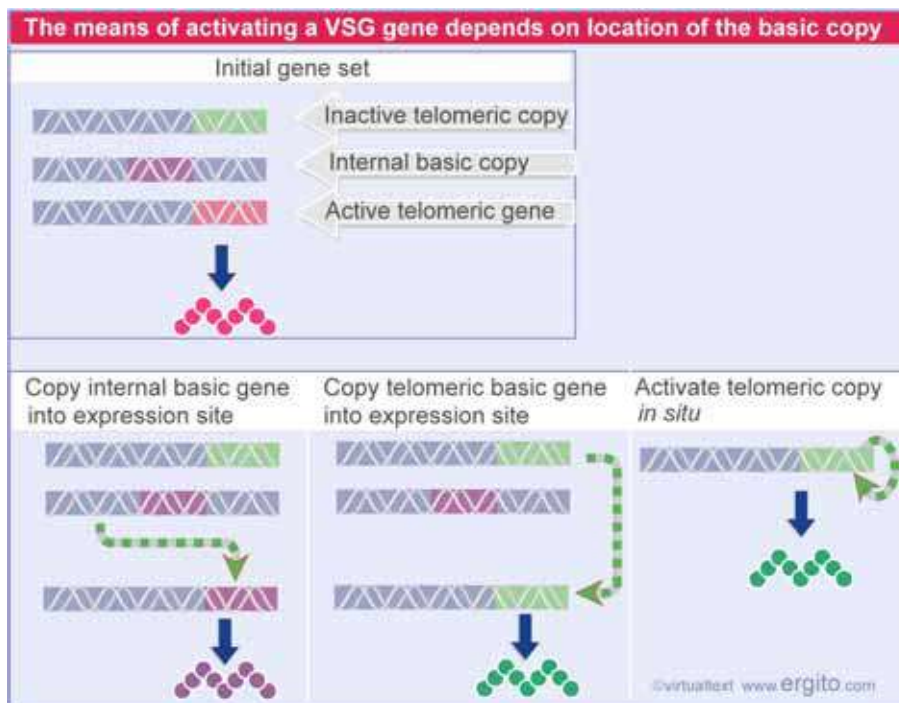

a telomere).

As might be expected of a large family of genes, individual basic copies show varying degrees of relationship, presumably reflecting their origin by duplication and variation. Genes that are closely related, and which provoke the same antigenic response, are called isogenes.

How is a single VSG gene selected for expression? Only one VSG gene is transcribed in a trypanosome at a given time. The copy of the gene that is active is called the **expression-linked copy (ELC)**. It is said to be located at an **expression site**. An expression site has a characteristic property: it is located near a telomere.

These features immediately suggest that the route followed to select a gene for expression depends on whether the basic copy is itself telomeric or internal. The two types of event that can create an ELC are summarized in **Figure 18.18**:

**Figure 18.18** VSG genes may be created by duplicative transfer from an internal or telomeric basic copy into an expression site, or by activating a telomeric copy that is already present at a potential expression site.

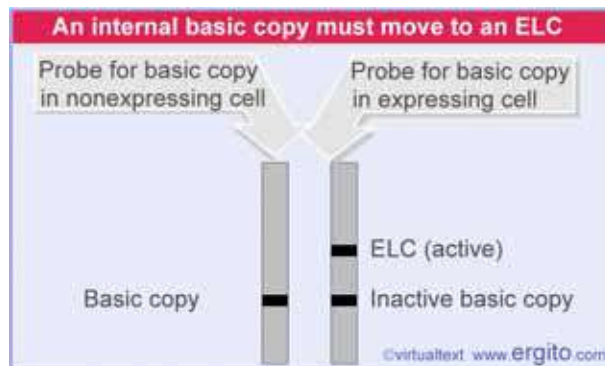

- The expression site remains the same, but the ELC is changed. Duplication transfers the sequence of a basic copy to replace the sequence currently occupying the expression site. Either internal or telomeric copies may be activated directly by duplication into the expression site. The substitution of one cassette for another does not interfere with the activity of the site.
- The expression site is changed. Activation *in situ* is available only to a sequence already present at a telomere. When a telomeric site is activated *in situ*, the

previous expression site must cease to be active and the new site now becomes the expression site.

Internal basic copies probably can be copied into non-expressed telomeric locations as well as into expression sites. So an internal gene could be activated by a two-stage process, in which first it is transposed to a non-expressed telomere, and then this site is activated.

We can follow the fate of genes involved in activation by restriction mapping. A probe representing an expressed sequence can be derived from the mRNA. Then we can determine the status of genes corresponding to the probe. We see different results for internal and telomeric basic copy genes:

- Activation of an internal gene requires generation of new sequences. **Figure 18.19** shows that when an internal gene is activated, a new fragment is found. The original basic-copy gene remains unaltered; the new fragment is generated by the duplication of the gene into a new context (where the sites recognized by the restriction enzyme are in the surrounding sequences and therefore generate a distinct fragment). The new fragment identifies an ELC, located close to a telomere. The ELC appears when the gene is expressed and disappears when the gene is switched off. Duplication into the ELC is the only pathway by which an internal basic copy can be generated.
- Activation of a telomeric gene can occur *in situ*. **Figure 18.20** shows that when a telomeric gene is activated, the gene number need not change. The structure of the gene may be essentially unaffected as detected by restriction mapping. The size of the fragment containing the gene may vary slightly, because the length of the telomere is constantly changing. Telomeric basic copies can also be activated by the same duplication pathway as internal copies; in this case, the basic copy remains at its telomere, while an expression-linked copy appears at another telomere (generating a new fragment as illustrated for internal basic copies in **Figure 18.19**).

**Figure 18.19** Internal basic copies can be activated only by generating a duplication of the gene at an expression-linked site

**Figure 18.20** Telomeric basic copies can be activated *in situ*; the size of the restriction fragment may change (slightly) when the telomere is extended.

Formation of the ELC occurs by a gene conversion process that requires genetic recombination enzymes – for example, it is greatly reduced by mutation in *RAD51* (3156). Like the switch in yeast mating type, it represents the replacement of a "cassette" at the active (telomeric) locus by a stored cassette. The VSG system is more versatile in the sense that there are many potential donor cassettes (and also more than a single potential recipient site).

Almost all switches in VSG type involve replacement of the ELC by a pre-existing silent copy. Some exceptional cases have been found, however, in which the sequence of the ELC does not match any of the repertoire of silent copies in the genome. A new sequence may be created by a series of gene conversions in which short stretches of different silent copies are connected. This resembles the mechanism for generating diversity in chicken  $\lambda$  immunoglobulins (see *Molecular Biology 5.25.16 Avian immunoglobulins are assembled from pseudogenes*). Although rare, such occurrences extend VSG diversity.

There are ~20 potential expression sites, which means that only a subset of telomeres can function in this capacity. All the expression sites appear similar in sequence and organization. Switching from one expression site to another occurs at a low frequency. This is not a principal means of changing coat expression, but has the effect of switching expression of other genes located within the expression site. Among these genes are two coding for the subunits of a (heterodimeric) transferrin receptor. Changing the transferrin receptor that is expressed by the trypanosome has a strong effect on its affinity for the host transferrin protein.

## REARRANGEMENT OF DNA

### 4.18.12 VSG genes have an unusual structure

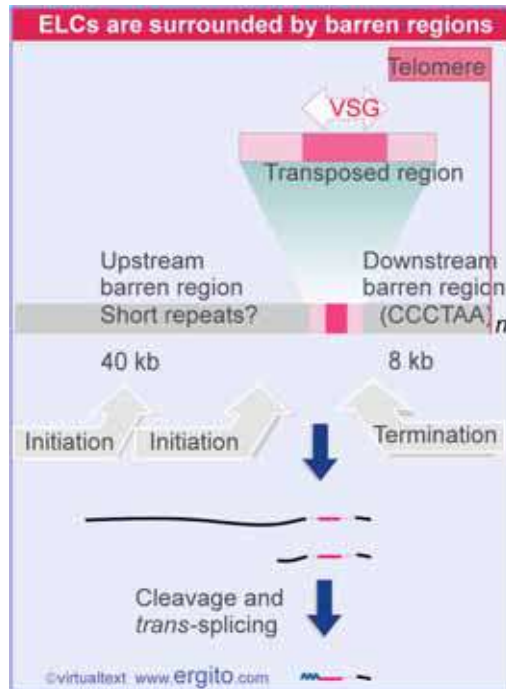

---

#### Key Concepts

- The coding region of the VSG gene is flanked by barren regions of repetitive DNA.
- The VSG sequence is transferred into the ELC between the promoter and terminator.
- The 5' end of VSG mRNA is added by a *trans*-splicing reaction to the 5' end that is generated by transcription.
- Activation of an expression site involves a change in the region upstream of the promoter.
- The expression site may be contained in a special extranucleolar body where the VSG is transcribed by RNA polymerase I.

---

The structure of the VSG gene at the ELC is unusual, as illustrated in **Figure 18.21**. The length of DNA transferred into the ELC is 2500-3500 bp, somewhat longer than the VSG-coding region of 1500 bp. Most of the additional length is upstream of the gene. The crossover points at which the duplicated sequence joins the ELC do not appear to be precisely determined (for review see 179).

**Figure 18.21** The expression-linked copy of a VSG gene contains barren regions on either side of the transposed region, which extends from ~1000 bp upstream of the VSG coding region to a site near the 3' terminus of the mRNA.

Analysis of events at the 5' end of the VSG mRNA is complicated by the fact that the mature RNA starts with a 35 base sequence coded elsewhere, and added in *trans* to the newly synthesized 5' end (see *Molecular Biology 5.24.13 trans-splicing reactions use small RNAs*). The signals for initiating and terminating transcription (and sometimes also the end of the coding region itself) are provided by the sequences flanking the transposed region. In fact, transcription may be initiated several kb upstream of the VSG gene itself. Promoters have been mapped at 4 kb and ~60 kb upstream of the VSG sequence. Use of the more distant promoter generates a transcript that contains other genes as well as the active VSG. The VSG sequence (and other gene sequences) must be released by cleavage from the transcript, after which the 35 base spliced leader is added to the 5' end.

The RNA polymerase that transcribes the expression locus is not the usual RNA polymerase II, but is RNA polymerase I (the enzyme that usually transcribes rRNA.) The ELC is sequestered in a discrete nuclear body, called the expression site body (ESB) (2517). The ESB takes the form of an extranucleolar body containing RNA polymerase I, and is found only in the bloodstream form. This may explain why only one of the potential 20 expression copies is in fact expressed in a given trypanosome. If the ESB is necessary for expression and can only accommodate a single copy, then by default it will prevent expression of all the other copies.

On either side of the transposed region are extensive regions that are not cut by restriction enzymes. These "barren regions" consist of repetitive DNA; they extend some 8 kb downstream and for up to 40 kb upstream of the ELC. Going downstream, the barren region consists largely of repeats of the sequence CCCTAA, and extends

to the telomere. Proceeding upstream, it may also consist of repetitive sequences, but their nature is not yet clear. The existence of the barren regions, however, has been an impediment to characterizing ELC genes by cloning.

The order in which VSG genes are expressed during an infection is erratic, but not completely random. This may be an important feature in survival of the trypanosome. If VSG genes were used in a predetermined order, a host could knock out the infection by mounting a reaction against one of the early elements. The need for unpredictability in the production of VSGs may be responsible for the evolution of a system with many donor sequences and multiple recipients.

Antigenic variation is not a unique phenomenon of trypanosomes. The bacterium *Borrelia hermsii* causes relapsing fever in man and analogous diseases in other mammals. The name of the disease reflects its erratic course: periods of illness are spaced by periods of relief. When the fevers occur, spirochetes are found in the blood; they disappear during periods of relief, as the host responds with specific antibodies.

Like the trypanosomes, *Borrelia* survives by altering a surface protein, called the variable major protein (VMP). Changes in the VMP are associated with rearrangements in the genome. The active VMP is located near the telomere of a linear plasmid. We do not yet know the extent of the coded variants or the mechanisms used to alter their expression. It is intriguing, however, that the eukaryote *Trypanosoma* and the prokaryote *Borrelia* should both rely upon antigenic variation as a means for evading immune surveillance.

## REARRANGEMENT OF DNA

### 4.18.13 The bacterial Ti plasmid causes crown gall disease in plants

---

#### Key Terms

**Crown gall disease** is a tumor that can be induced in many plants by infection with the bacterium *Agrobacterium tumefaciens*.

The **Ti plasmid** is an episome of the bacterium *Agrobacterium tumefaciens* that carries the genes responsible for the induction of crown gall disease in infected plants.

An **opine** is a derivative of arginine that is synthesized by plant cells infected with crown gall disease.

**Nopaline** plasmids are Ti plasmids of *Agrobacterium tumefaciens* that carry genes for synthesizing the opine, nopaline. They retain the ability to differentiate into early embryonic structures.

A **teratoma** is a growth in which many differentiated cell types - including skin, teeth, bone and others - grow in disorganized manner after an early embryo is transplanted into one of the tissues of an adult animal.

**Octopine** plasmids of *Agrobacterium tumefaciens* carry genes coding the synthesis of opines of the octopine type. The tumors are undifferentiated.

**Agropine plasmids** carry genes coding for the synthesis of opines of the agropine type. The tumors usually die early.

**Ri plasmids** are found in *Agrobacterium tumefaciens*. Like Ti plasmids, they carry genes that cause disease in infected plants. The disease may take the form of either hairy root disease or crown gall disease.

#### Key Concepts

- Infection with the bacterium *A. tumefaciens* can transform plant cells into tumors.
- The infectious agent is a plasmid carried by the bacterium.
- The plasmid also carries genes for synthesizing and metabolizing opines (arginine derivatives) that are used by the tumor cell.

---

Most events in which DNA is rearranged or amplified occur within a genome, but the interaction between bacteria and certain plants involves the transfer of DNA from the bacterial genome to the plant genome. **Crown gall disease**, shown in **Figure 18.22**, can be induced in most dicotyledonous plants by the soil bacterium *Agrobacterium tumefaciens*. The bacterium is a parasite that effects a genetic change in the eukaryotic host cell, with consequences for both parasite and host. It improves conditions for survival of the parasite. And it causes the plant cell to grow as a tumor.

**Figure 18.22** An *Agrobacterium* carrying a Ti plasmid of the nopaline type induces a teratoma, in which differentiated structures develop. Photograph kindly provided by Jeff Schell.

*Agrobacteria* are required to induce tumor formation, but the tumor cells do not require the continued presence of bacteria. Like animal tumors, the plant cells have been transformed into a state in which new mechanisms govern growth and differentiation. Transformation is caused by the expression within the plant cell of genetic information transferred from the bacterium.

The tumor-inducing principle of *Agrobacterium* resides in the **Ti plasmid**, which is perpetuated as an independent replicon within the bacterium. The plasmid carries genes involved in various bacterial and plant cell activities, including those required to generate the transformed state, and a set of genes concerned with synthesis or utilization of **opines** (novel derivatives of arginine).

Ti plasmids (and thus the *Agrobacteria* in which they reside) can be divided into four groups, according to the types of opine that are made:

- **Nopaline** plasmids carry genes for synthesizing nopaline in tumors and for utilizing it in bacteria. Nopaline tumors can differentiate into shoots with abnormal structures. They have been called **teratomas** by analogy with certain mammalian tumors that retain the ability to differentiate into early embryonic structures.
- **Octopine** plasmids are similar to nopaline plasmids, but the relevant opine is different. However, octopine tumors are usually undifferentiated and do not form teratoma shoots.
- **Agropine** plasmids carry genes for agropine metabolism; the tumors do not differentiate, develop poorly, and die early.

- **Ri plasmids** can induce hairy root disease on some plants and crown gall on others. They have agropine type genes, and may have segments derived from both nopaline and octopine plasmids.

The types of genes carried by a Ti plasmid are summarized in **Figure 18.23**. Genes utilized in the bacterium code for plasmid replication and incompatibility, for transfer between bacteria, sensitivity to phages, and for synthesis of other compounds, some of which are toxic to other soil bacteria. Genes used in the plant cell code for transfer of DNA into the plant, for induction of the transformed state, and for shoot and root induction.

Ti genes function in bacteria and in plants		
Locus	Function	Ti Plasmid
<i>vir</i>	DNA transfer into plant	all
<i>shi</i>	shoot induction	all
<i>roi</i>	root induction	all
<i>nos</i>	nopaline synthesis	nopaline
<i>noc</i>	nopaline catabolism	nopaline
<i>ocs</i>	octopine synthesis	octopine
<i>occ</i>	octopine catabolism	octopine
<i>tra</i>	bacterial transfer genes	all
<i>Inc</i>	incompatibility genes	all
<i>oriV</i>	origin for replication	all

**Figure 18.23** Ti plasmids carry genes involved in both plant and bacterial functions.

The specificity of the opine genes depends on the type of plasmid. Genes needed for opine synthesis are linked to genes whose products catabolize the same opine; thus each strain of *Agrobacterium* causes crown gall tumor cells to synthesize opines that are useful for survival of the parasite. The opines can be used as the sole carbon and/or nitrogen source for the inducing *Agrobacterium* strain. The principle is that the transformed plant cell synthesizes those opines that the bacterium can use (for review see 182).

## REARRANGEMENT OF DNA

### 4.18.14 T-DNA carries genes required for infection

---

#### Key Terms

**T-DNA** is the segment of the Ti plasmid of *Agrobacterium tumefaciens* that is transferred to the plant cell nucleus during infection. It carries genes that transform the plant cell.

#### Key Concepts

- Part of the DNA of the Ti plasmid is transferred to the plant cell nucleus.
- The *vir* genes of the Ti plasmid are located outside the transferred region and are required for the transfer process.
- The *vir* genes are induced by phenolic compounds released by plants in response to wounding.
- The membrane protein VirA is autophosphorylated on histidine when it binds an inducer.
- VirA activates VirG by transferring the phosphate group to it.
- The VirA-VirG is one of several bacterial two component systems that use a phosphohistidine relay.

---

The interaction between *Agrobacterium* and a plant cell is illustrated in **Figure 18.24**. The bacterium does not enter the plant cell, but transfers part of the Ti plasmid to the plant nucleus. The transferred part of the Ti genome is called **T-DNA**. It becomes integrated into the plant genome, where it expresses the functions needed to synthesize opines and to transform the plant cell.

**Figure 18.24** T-DNA is transferred from *Agrobacterium* carrying a Ti plasmid into a plant cell, where it becomes integrated into the nuclear genome and expresses functions that transform the host cell.

Transformation of plant cells requires three types of function carried in the *Agrobacterium*:

- Three loci on the *Agrobacterium* chromosome, *chvA*, *chvB*, *pscA*, are required for the initial stage of binding the bacterium to the plant cell. They are responsible for synthesizing a polysaccharide on the bacterial cell surface.
- The *vir* region carried by the Ti plasmid outside the T-DNA region is required to release and initiate transfer of the T-DNA.
- The T-DNA is required to transform the plant cell.

The organization of the major two types of Ti plasmid is illustrated in **Figure 18.25**. About 30% of the ~200 kb Ti genome is common to nopaline and octopine plasmids. The common regions include genes involved in all stages of the interaction between *Agrobacterium* and a plant host, but considerable rearrangement of the sequences has

occurred between the plasmids.

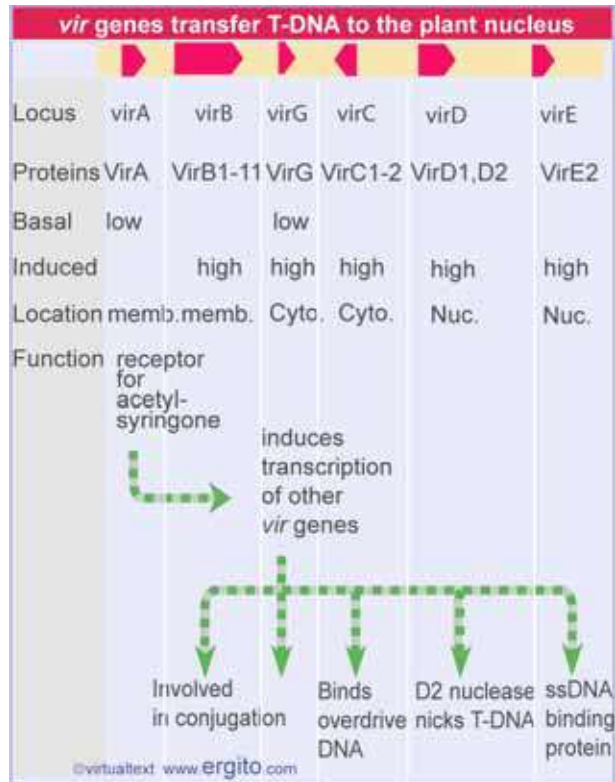

**Figure 18.25** Nopaline and octopine Ti plasmids carry a variety of genes, including T-regions that have overlapping functions

The T-region occupies ~23 kb. Some 9 kb is the same in the two types of plasmid. The Ti plasmids carry genes for opine synthesis (*Nos* or *Ocs*) within the T-region; corresponding genes for opine catabolism (*Noc* or *Occ*) reside elsewhere on the plasmid. The plasmids code for similar, but not identical, morphogenetic functions, as seen in the induction of characteristic types of tumors.

Functions affecting oncogenicity – the ability to form tumors – are not confined to the T-region. Those genes located outside the T-region must be concerned with establishing the tumorigenic state, but their products are not needed to perpetuate it. They may be concerned with transfer of T-DNA into the plant nucleus or perhaps with subsidiary functions such as the balance of plant hormones in the infected tissue. Some of the mutations are host-specific, preventing tumor formation by some plant species, but not by others.

The virulence genes code for the functions required for the transfer process. Six loci *virA-G* reside in a 40 kb region outside the T-DNA. Their organization is summarized in **Figure 18.26**. Each locus is transcribed as an individual unit; some contain more than one open reading frame.

**Figure 18.26** The *vir* region of the Ti plasmid has six loci that are responsible for transferring T-DNA to an infected plant.

We may divide the transforming process into (at least) two stages:

- Agrobacterium contacts a plant cell, and the *vir* genes are induced.
- *vir* gene products cause T-DNA to be transferred to the plant cell nucleus, where it is integrated into the genome.

The *vir* genes fall into two groups, corresponding to these stages. Genes *virA* and *virG* are regulators that respond to a change in the plant by inducing the other genes. So mutants in *virA* and *virG* are avirulent and cannot express the remaining *vir* genes. Genes *virB,C,D,E* code for proteins involved in the transfer of DNA. Mutants in *virB* and *virD* are avirulent in all plants, but the effects of mutations in *virC* and *virE* vary with the type of host plant.

*virA* and *virG* are expressed constitutively (at a rather low level). The signal to which they respond is provided by phenolic compounds generated by plants as a response to wounding. **Figure 18.27** presents an example. *N. tabacum* (tobacco) generates the molecules acetosyringone and  $\alpha$ -hydroxyacetosyringone. Exposure to these compounds activates *virA*, which acts on *virG*, which in turn induces the expression de novo of *virB,C,D,E*. This reaction explains why *Agrobacterium* infection succeeds only on wounded plants.

**Figure 18.27** Acetosyringone (4-acetyl-2,6-dimethoxyphenol) is produced by *N. tabacum* upon wounding, and induces transfer of T-DNA from *Agrobacterium*.

VirA and VirG are an example of a classic type of bacterial system in which stimulation of a sensor protein causes autophosphorylation and transfer of the phosphate to the second protein (see *Molecular Biology Supplement 32.13 Two-component signal transduction*). The relationship is illustrated in **Figure 18.28**. The VirA-VirG system resembles the EnvZ-OmpR system that responds to osmolarity. The sequence of *virA* is related to *envZ*; and the sequences of *virG* and *ompR* are closely related, suggesting that the effector proteins function in a similar manner.

**Figure 18.28** The two-component system of VirA-VirG responds to phenolic signals by activating transcription of target genes. This is a static version of an interactive figure; see <http://www.ergito.com/main.jsp?bcs=MBIO.4.18.14> to view properly.

VirA forms a homodimer that is located in the inner membrane; it may respond to the presence of the phenolic compounds in the periplasmic space. Exposure to these compounds causes VirA to become autophosphorylated on histidine. The phosphate group is then transferred to an Asp residue in VirG. The phosphorylated VirG binds to promoters of the *virB,C,D,E* genes to activate transcription. When *virG* is activated, its transcription is induced from a new startpoint, different from that used for constitutive expression, with the result that the amount of VirG protein is increased.

Of the other *vir* loci, *virD* is the best characterized. The *virD* locus has 4 open reading frames. Two of the proteins coded at *virD*, VirD1 and VirD2, provide an endonuclease that initiates the transfer process by nicking T-DNA at a specific site.

## REARRANGEMENT OF DNA

### 4.18.15 Transfer of T-DNA resembles bacterial conjugation

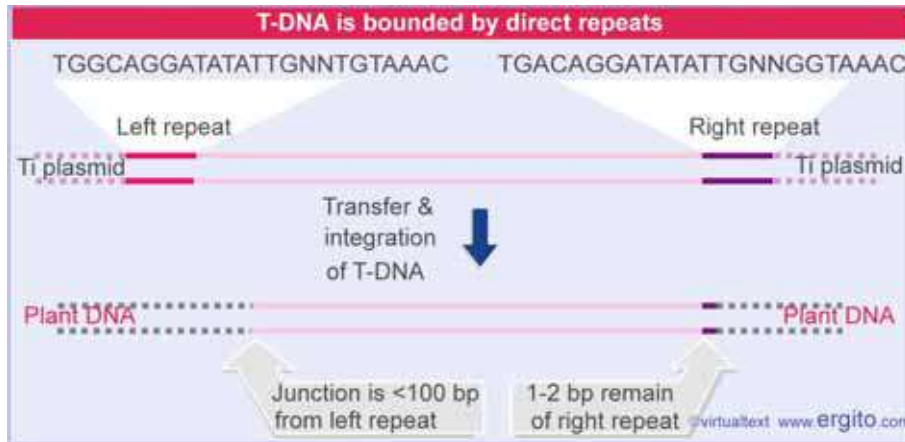

---

#### Key Concepts

- T-DNA is generated when a nick at the right boundary creates a primer for synthesis of a new DNA strand.
- The preexisting single-strand that is displaced by the new synthesis is transferred to the plant cell nucleus.
- Transfer is terminated when DNA synthesis reaches a nick at the left boundary.
- The T-DNA is transferred as a complex of single-stranded DNA with the VirE2 single strand-binding protein.
- The single stranded T-DNA is converted into double-stranded DNA and integrated into the plant genome.
- The mechanism of integration is not known. T-DNA can be used to transfer genes into a plant nucleus.

---

The transfer process actually selects the T-region for entry into the plant. **Figure 18.29** shows that the T-DNA of a nopaline plasmid is demarcated from the flanking regions in the Ti plasmid by repeats of 25 bp, which differ at only two positions between the left and right ends. When T-DNA is integrated into a plant genome, it has a well-defined right junction, which retains 1-2 bp of the right repeat. The left junction is variable; the boundary of T-DNA in the plant genome may be located at the 25 bp repeat or at one of a series of sites extending over ~100 bp within the T-DNA. Sometimes multiple tandem copies of T-DNA are integrated at a single site.

**Figure 18.29** T-DNA has almost identical repeats of 25 bp at each end in the Ti plasmid. The right repeat is necessary for transfer and integration to a plant genome. T-DNA that is integrated in a plant genome has a precise junction that retains 1-2 bp of the right repeat, but the left junction varies and may be up to 100 bp short of the left repeat.

A model for transfer is illustrated in **Figure 18.30**. A nick is made at the right 25 bp repeat. It provides a priming end for synthesis of a DNA single strand. Synthesis of the new strand displaces the old strand, which is used in the transfer process. Transfer is terminated when DNA synthesis reaches a nick at the left repeat. This model explains why the right repeat is essential, and it accounts for the polarity of the process. If the left repeat fails to be nicked, transfer could continue farther along the Ti plasmid.

**Figure 18.30** T-DNA is generated by displacement when DNA synthesis starts at a nick made at the right repeat. The reaction is terminated by a nick at the left repeat.

The transfer process involves production of a single molecule of single-stranded DNA in the infecting bacterium. It is transferred in the form of a DNA-protein complex, sometimes called the T-complex. The DNA is covered by the VirE2 single-strand binding protein, which has a nuclear localization signal and is responsible for transporting T-DNA into the plant cell nucleus. A single molecule of the D2 subunit of the endonuclease remains bound at the 5' end. The *virB* operon codes for 11 products that are involved in the transfer reaction (586; for review see 180; 1133).

Outside T-DNA, but immediately adjacent to the right border, is another short sequence, called *overdrive*, which greatly stimulates the transfer process. Overdrive functions like an enhancer: it must lie on the same molecule of DNA, but enhances the efficiency of transfer even when located several thousand base pairs away from the border. VirC1, and possibly VirC2, may act at the overdrive sequence.

Octopine plasmids have a more complex pattern of integrated T-DNA than nopaline plasmids. The pattern of T-strands is also more complex, and several discrete species can be found, corresponding to elements of T-DNA. This suggests that octopine T-DNA has several sequences that provide targets for nicking and/or termination of DNA synthesis.

This model for transfer of T-DNA closely resembles the events involved in bacterial conjugation, when the *E. coli* chromosome is transferred from one cell to another in single-stranded form. The genes of the *virB* operon are homologous to the *tra* genes of certain bacterial plasmids that are involved in conjugation (see *Molecular Biology 4.13.13 Conjugation transfers single-stranded DNA*). A difference is that the transfer of T-DNA is (usually) limited by the boundary of the left repeat, whereas transfer of bacterial DNA is indefinite.

We do not know how the transferred DNA is integrated into the plant genome. At some stage, the newly generated single strand must be converted into duplex DNA. Circles of T-DNA that are found in infected plant cells appear to be generated by recombination between the left and right 25 bp repeats, but we do not know if they are intermediates. The actual event is likely to involve a nonhomologous recombination, because there is no homology between the T-DNA and the sites of integration.

Is T-DNA integrated into the plant genome as an integral unit? How many copies are integrated? What sites in plant DNA are available for integration? Are genes in T-DNA regulated exclusively by functions on the integrated segment? These questions are central to defining the process by which the Ti plasmid transforms a plant cell into a tumor.

What is the structure of the target site? Sequences flanking the integrated T-DNA tend to be rich in A·T base pairs (a feature displayed in target sites for some transposable elements). The sequence rearrangements that occur at the ends of the integrated T-DNA make it difficult to analyze the structure. We do not know whether the integration process generates new sequences in the target DNA comparable to the target repeats created in transposition.

T-DNA is expressed at its site of integration. The region contains several transcription units, each probably containing a gene expressed from an individual promoter. Their functions are concerned with the state of the plant cell, maintaining its tumorigenic properties, controlling shoot and root formation, and suppressing differentiation into other tissues. None of these genes is needed for T-DNA transfer.

The Ti plasmid presents an interesting organization of functions. Outside the T-region, it carries genes needed to initiate oncogenesis; at least some are concerned with the transfer of T-DNA, and we should like to know whether others function in the plant cell to affect its behavior at this stage. Also outside the T-region are the genes that enable the *Agrobacterium* to catabolize the opine that the transformed plant cell will produce. Within the T-region are the genes that control the transformed state of the plant, as well as the genes that cause it to synthesize the opines that will benefit the *Agrobacterium* that originally provided the T-DNA.

As a practical matter, the ability of *Agrobacterium* to transfer T-DNA to the plant

genome makes it possible to introduce new genes into plants. Because the transfer/integration and oncogenic functions are separate, it is possible to engineer new Ti plasmids in which the oncogenic functions have been replaced by other genes whose effect on the plant we wish to test. The existence of a natural system for delivering genes to the plant genome should greatly facilitate genetic engineering of plants.

## REARRANGEMENT OF DNA

### 4.18.16 DNA amplification generates extra gene copies

---

#### Key Terms

**Amplification** refers to the production of additional copies of a chromosomal sequence, found as intrachromosomal or extrachromosomal DNA.

**Methotrexate** is a drug that inhibits the enzyme DHFR (dihydrofolate reductase).

A **homogeneously staining region (HSR)** is produced by the tandem amplification of a chromosomal sequence. As a result, it does not have a banded pattern.

**Double-minute chromosomes** are extrachromosomal elements formed by amplification of DHFR genes in response to methotrexate treatment. They are large enough to be visible in the light microscope.

#### Key Concepts

- Eukaryotic cells acquire resistance to methotrexate by amplifying the number of *dhfr* genes.
- The initial step of amplification is the generation of extrachromosomal DNA molecules containing tandem repeats of the DHFR locus.
- The extrachromosomal DNA forms double minute chromosomes that are lost frequently at division.
- Stable resistant lines are generated by generation of amplified copies in the chromosome.
- It is not known whether stable lines arise by *de novo* amplification *in situ* or by insertion of extrachromosomal amplified sequences.

---

The eukaryotic genome has the capacity to accommodate additional sequences of either exogenous or endogenous origin. Endogenous sequences may be produced by **amplification** of an existing sequence. The additional sequences often take the form of a tandem array, containing many copies of a repeating unit. A gene that is contained within the repeating unit is not necessarily expressed in every copy, but expression tends to increase with the number of copies.

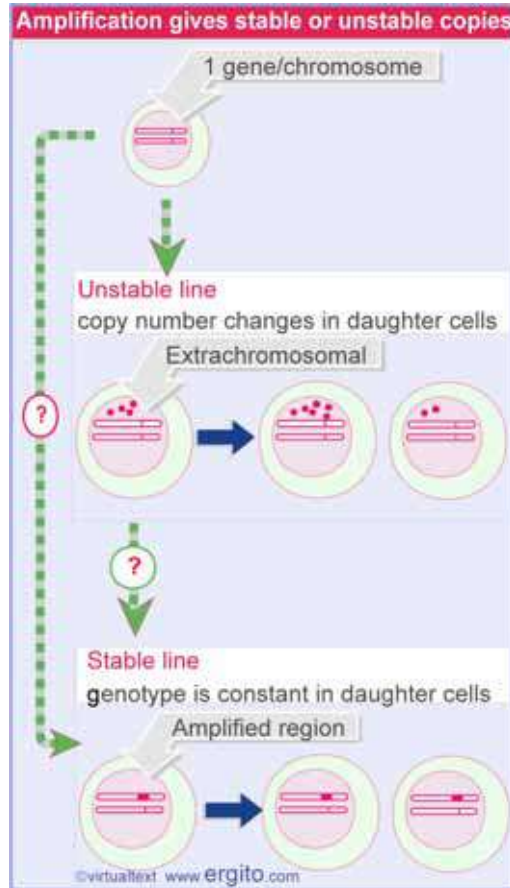

A tandem array of multiple copies may exist in either of two forms in a cell. If it takes the form of an extrachromosomal unit, it is inherited in an irregular manner: there is no equivalent in animal cells to the ability of a bacterial plasmid to be segregated evenly at cell division, so the entire unit is lost at a high frequency. If the array is integrated into the genome, however, it becomes a component of the genotype, and is inherited like any other genomic sequence.

Amplification of endogenous sequences is provoked by selecting cells for resistance to certain agents. The best-characterized example of amplification results from the

addition of **methotrexate** (mtx) to certain cultured cell lines. This reagent blocks folate metabolism. Resistance to it is conferred by mutations that change the activity of the enzyme dihydrofolate reductase (DHFR). As an alternative to change in the enzyme itself, the amount of enzyme may be increased. The cause of this increase is an amplification of the number of *dhfr* structural genes. Amplification occurs at a frequency greater than the spontaneous point mutation rate, generally ranging from  $10^{-4}$ - $10^{-6}$ . Similar events now have been observed in >20 other genes.

A common feature in most of these systems is that highly resistant cells are not obtained in a single step, but instead appear when the cells are adapted to gradually increasing doses of the toxic reagent. So gene amplification may require several stages. Amplification generally occurs at only one of the two *dhfr* alleles; and increased resistance to methotrexate is accomplished by further increases in the degree of amplification at this locus (for review see 184; 185).

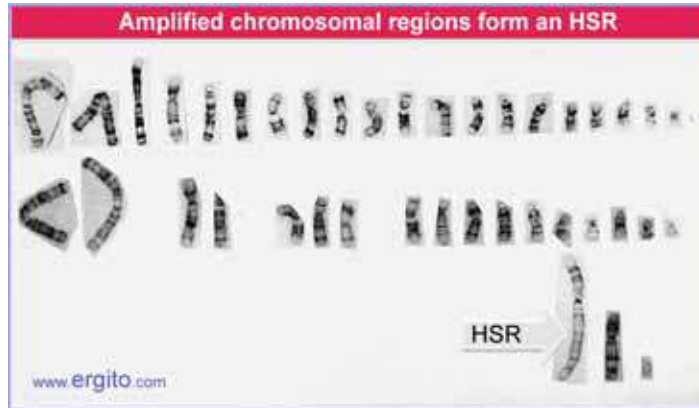

The number of *dhfr* genes in a cell line resistant to methotrexate varies from 40-400, depending on the stringency of the selection and the individual cell line. The *mtx<sup>r</sup>* lines fall into two classes, distinguished by their response when the selective pressure for high levels of DHFR activity is relieved by growth in the absence of methotrexate. The basis for the difference is illustrated in **Figure 18.31**.

**Figure 18.31** The *dhfr* gene can be amplified to give unstable copies that are extrachromosomal (double minutes) or stable (chromosomal). Extrachromosomal copies arise at early times.

- In *stable* lines, the amplified genes are retained, because they reside on the chromosome, at the site usually occupied by the single *dhfr* gene. Usually the other chromosome retains its normal single copy of *dhfr*.
- In *unstable* lines, the amplified genes are at least partially lost when the selective pressure is released, because the amplified genes exist as an extrachromosomal array.

Gene amplification has a visible effect on the chromosomes. In stable lines, the *dhfr* locus can be visualized in the form of a **homogeneously staining region (HSR)**. An example is shown in **Figure 18.32**. The HSR takes its name from the presence of an additional region that lacks any chromosome bands after treatments such as G-banding. This change suggests that some region of the chromosome between bands has undergone an expansion.

**Figure 18.32** Amplified copies of the *dhfr* gene produce a homogeneously staining region (*HSR*) in the chromosome. Photograph kindly provided by Robert Schimke.

In unstable cell lines, no change is seen in the chromosomes carrying *dhfr*. However, large numbers of elements called **double-minute chromosomes** are visible, as can be seen in **Figure 18.33**. In a typical cell line, each double-minute carries 2-4 *dhfr* genes. The double minutes appear to be self-replicating; but they lack centromeres. As a result, they do not attach to the mitotic spindle and therefore segregate erratically, frequently being lost from the daughter cells. Notwithstanding their name, the actual status of the double minutes is regarded as extrachromosomal.

**Figure 18.33** Amplified extrachromosomal *dhfr* genes take the form of double-minute chromosomes, as seen in the form of the small white dots. Photograph kindly provided by Robert Schimke.

The irregular inheritance of the double minutes explains the instability of methotrexate resistance in these lines. Double minutes are lost continuously during cell divisions; and in the presence of methotrexate, cells with reduced numbers of *dhfr* genes will die. Only those cells that have retained a sufficient number of double minutes will appear in the surviving population.

The presence of the double minutes reduces the rate at which the cells proliferate. So when the selective pressure is removed, cells lacking the amplified genes have an advantage; they generate progeny more rapidly and soon take over the population. This explains why the amplified state is retained in the cell line only so long as cells

are grown in the presence of methotrexate.

Because of the erratic segregation of the double minutes, increases in the copy number can occur relatively quickly as cells are selected at each division for progeny that have gained more than their fair share of the *dhfr* genes. Cells with greater numbers of copies are found in response to increased levels of methotrexate. The behavior of the double-minutes explains the stepwise evolution of the *mtx<sup>r</sup>* condition and the incessant fluctuation in the level of *dhfr* genes in unstable lines.

Both stable and unstable lines are found after long periods of selection for methotrexate resistance. What is the initial step in gene amplification? After short periods of selection, most or all of the resistant cells are unstable. The formation of extrachromosomal copies clearly is a more frequent event than amplification within the chromosome. At very early times in the process, amplified *dhfr* genes can be found as (small) extrachromosomal units before double minutes or any change in chromosomes can be detected. This suggests that the acquisition of resistance is most often due to generation of extrachromosomal repeats.

The amplified region is longer than the *dhfr* gene itself. The gene has a length of ~31 kb, but the average length of the repeated unit is 500-1000 kb in the chromosomal HSR. The extent of the amplified region is different in each cell line. The amount of DNA contained in a double minute seems to lie in a range of 100-1000 kb.

How do the extrachromosomal copies arise? We know that their generation occurs without loss of the original chromosomal copy. There are two general possibilities. Additional cycles of replication could be initiated in the vicinity of the *dhfr* gene, followed by nonhomologous recombination between the copies. Or the process could be initiated by nonhomologous recombination between alleles. The extra copies could be released from the chromosome, possibly by some recombination-like event. Depending on the nature of this event, it could generate an extrachromosomal DNA molecule containing one or several copies. If the double minutes contain circular DNA, recombination between them in any case is likely to generate multimeric molecules.

Some information about the events involved in perpetuating the double minutes is given by an unstable cell line whose amplified genes code for a mutant DHFR enzyme. The mutant enzyme is not present in the original (diploid) cell line (so the mutation must have arisen at some point during the amplification process). Despite variations in the number of amplified genes, these cells display only the mutant enzyme. So the wild-type chromosomal genes cannot be continuously generating large numbers of double minutes anew, because these amplified copies would produce normal enzyme.

Once amplified extrachromosomal genes have arisen, therefore, changes in the state of the cell are mediated through these genes and not through the original chromosomal copies. When methotrexate is removed, the cell line loses its double minutes in the usual way. On re-exposure to the reagent, normal genes are amplified to give a new population of double minutes. This shows that none of the extrachromosomal copies of the mutant gene had integrated into the chromosome.

Another striking implication of these results is that the double minutes of the mutant

line carried only mutant genes – so if there is more than one *dhfr* gene per double minute, all must be of the mutant type. This suggests that multicopy double minutes can be generated from individual extrachromosomal genes.

A major question has been whether amplified chromosomal copies arise by integration of the extrachromosomal copies or by an independent mechanism. We do not know whether intrachromosomal amplification simply proceeds less often as a *de novo* step or requires extrachromosomal amplification to occur as an intermediate step. The form taken by the amplified genes is influenced by the cell genotype; some cell lines tend to generate double minutes, while others more readily display the HSR configuration.

The type of amplification event also depends upon the particular locus that is involved. Another case of amplification is provided by resistance to an inhibitor of the enzyme transcarbamylase, which occurs by amplification of the CAD gene. (CAD is a protein which has the first three enzymatic activities of the pathway for UMP synthesis.) Amplified CAD DNA is always found within the chromosome. In this case, the amplified genes are found in the form of several dispersed amplified regions, often involving more than one chromosome.

## REARRANGEMENT OF DNA

### 4.18.17 Transfection introduces exogenous DNA into cells

---

#### Key Terms

**Transfection** of eukaryotic cells is the acquisition of new genetic markers by incorporation of added DNA.

**Transient transfectants** have foreign DNA in an unstable, i.e. extrachromosomal, form.

An **integrant (Stable transfectant)** is a cell line in which a gene introduced by transfection has become integrated into the genome.

#### Key Concepts

- DNA that is transfected into a eukaryotic cells forms a large repeating unit of many head to tail tandem repeats.
- The transfected unit is unstable unless it becomes integrated into a host chromosome.
- Genes carried by the transfected DNA can be expressed.

---

The procedure for introducing exogenous donor DNA into recipient cells is called **transfection**. Transfection experiments began with the addition of preparations of metaphase chromosomes to cell suspensions. The chromosomes are taken up rather inefficiently by the cells and give rise to unstable variants at a low frequency. Intact chromosomes rarely survive the procedure; the recipient cell usually gains a fragment of a donor chromosome (which is unstable because it lacks a centromere). Rare cases of stable lines may have resulted from integration of donor material into a resident chromosome.

Similar results are obtained when purified DNA is added to a recipient cell preparation. However, with purified DNA it is possible to add particular sequences instead of relying on random fragmentation of chromosomes. Transfection with DNA yields stable as well as unstable lines, with the former relatively predominant. (These experiments are directly analogous to those performed in bacterial transformation, but are described as transfection because of the historical use of "transformation" to describe changes that allow unrestrained growth of eukaryotic cells.)

Unstable transfectants (sometimes called **transient transfectants**) reflect the survival of the transfected DNA in extrachromosomal form; stable lines result from integration into the genome. The transfected DNA can be expressed in both cases. However, the low frequencies of transfection make it necessary to use donor markers whose presence in the recipient cells can be selected for. Most transfection experiments have used markers representing readily assayed enzymatic functions, but, in principle, any marker that can be selected can be assayed. This allows the

isolation of genes responsible for morphological phenomena. Most notably, transfected cells can be selected for acquisition of the transformed (tumorigenic) phenotype. This type of protocol has led to the isolation of several cellular *onc* genes (see *Molecular Biology* 6.30.9 *Ras oncogenes can be detected in a transfection assay*).

Cotransfection with more than one marker has proved informative about the events involved in transfection and extends the range of questions that we can ask with this technique. A common marker used in such experiments is the *tk* gene, coding for the enzyme thymidine kinase, which catalyzes an essential step in the provision of thymidine triphosphate as a precursor for DNA synthesis.

When *tk*<sup>-</sup> cells are transfected with a DNA preparation containing both a purified *tk*<sup>+</sup> gene and the  $\phi$ X174 genome, all the *tk*<sup>+</sup> transformants have both donor sequences. This is a useful observation, because it allows unselected markers to be introduced routinely by cotransfection with a selected marker.

The arrangement of *tk* and  $\phi$ X174 sequences is different in each transfected line, but remains the same during propagation of that line. Often multiple copies of the donor sequences are present, the number varying with the individual line. Revertants lose the  $\phi$ X174 sequences together with *tk* sequences. Amplification of transfected sequences under selective pressure results in the increase of copy number of all donor sequences *pari passu*. So the two types of donor sequence become physically linked during transfection and suffer the same fate thereafter.

To perform a transfection experiment, the mass of DNA added to the recipient cells is increased by including an excess of "carrier DNA," a preparation of some other DNA (often from salmon sperm). Transfected cells prove to have sequences of the carrier DNA flanking the selected sequences on either side. Transfection therefore appears to be mediated by a large unit, consisting of a linked array of all sequences present in the donor preparation.

Since revertants for the selected marker lose all of this material, it seems likely that the transfected cell gains only a single large unit. The unit is formed by a concatemeric linkage of donor sequences in a reaction that is rapid relative to the other events involved in transfection. This transfecting package is ~1000 kb in length.

Because of the size of the donor unit, we cannot tell from blotting experiments whether it is physically linked to recipient chromosomal DNA (the relevant end fragments are present in too small a relative proportion). It seems plausible that the first stage is the establishment of an unstable extrachromosomal unit, followed by the acquisition of stability via integration.

*In situ* hybridization can be used to show that transfected cells have donor material integrated into the resident chromosomes. Any given cell line has only a single site of integration; but the site is different in each line. Probably the selection of a site for integration is a random event; sometimes it is associated with a gross chromosomal rearrangement.

The sites at which exogenous material becomes integrated usually do not appear to

have any sequence relationship to the transfected DNA. The integration event involves a nonhomologous recombination between the mass of added DNA and a random site in the genome. The recombination event may be provoked by the introduction of a double-strand break into the chromosomal DNA, possibly by the action of DNA repair enzymes that are induced by the free ends of the exogenous DNA. **Integrants** produced by the integration event are stable, and are therefore more useful than transient transfectants for experiments that rely on the expression of the transfected gene (for review see 183).

## REARRANGEMENT OF DNA

### 4.18.18 Genes can be injected into animal eggs

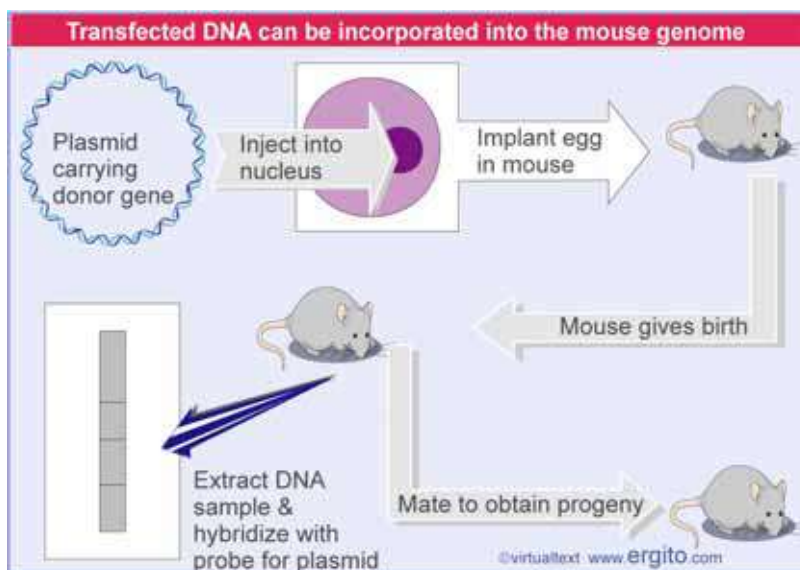

#### Key Terms

**Transgenic** animals are created by introducing DNA prepared in test tubes into the germline. The DNA may be inserted into the genome or exist in an extrachromosomal structure.

#### Key Concepts

- DNA that is injected into animal eggs can integrate into the genome.
- Usually a large array of tandem repeats integrates at a single site.
- Expression of the DNA is variable and may be affected by the site of integration and other epigenetic effects.

An exciting development of transfection techniques is their application to introduce genes into animals. An animal that gains new genetic information from the addition of foreign DNA is described as **transgenic**. The approach of directly injecting DNA can be used with mouse eggs, as shown in **Figure 18.34**. Plasmids carrying the gene of interest are injected into the germinal vesicle (nucleus) of the oocyte or into the pronucleus of the fertilized egg. The egg is implanted into a pseudopregnant mouse. After birth, the recipient mouse can be examined to see whether it has gained the foreign DNA, and, if so, whether it is expressed. (For a description of the technique see *Great Experiments 11.3 Transgenic mice: Expression of foreign genes in animals*.)

**Figure 18.34** Transfection can introduce DNA directly into the germ line of animals

The first questions we ask about any transgenic animal are how many copies it has of the foreign material, where these copies are located, and whether they are present in the germline and inherited in a Mendelian manner. The usual result of such experiments is that a reasonable minority (say ~15%) of the injected mice carry the transfected sequence. Usually, multiple copies of the plasmid appear to have been integrated in a tandem array into a single chromosomal site. The number of copies varies from 1-150. They are inherited by the progeny of the injected mouse as expected of a Mendelian locus.

An important issue that can be addressed by experiments with transgenic animals concerns the independence of genes and the effects of the region within which they reside. If we take a gene, including the flanking sequences that contain its known regulatory elements, can it be expressed independently of its location in the genome? In other words, do the regulatory elements function independently, or is gene expression in addition controlled by other effects, for example, location in an appropriate chromosomal domain?

Are transfected genes expressed with the proper developmental specificity? The general rule now appears to be that there is a reasonable facsimile of proper control: the transfected genes are generally expressed in appropriate cells and at the usual time. There are exceptions, however, in which a transfected gene is expressed in an inappropriate tissue.

In the progeny of the injected mice, expression of the donor gene is extremely variable; it may be extinguished entirely, reduced somewhat, or even increased. Even in the original parents, the level of gene expression does not correlate with the number of tandemly integrated genes. Probably only some of the genes are active. In addition to the question of how many of the gene copies are capable of being activated, a parameter influencing regulation could be the relationship between the gene number and the regulatory proteins: a large number of promoters could dilute out any regulator proteins present in limiting amounts.

What is responsible for the variation in gene expression? One possibility that has often been discussed for transfected genes (and which applies also to integrated retroviral genomes) is that the site of integration is important. Perhaps a gene is expressed if it integrates within an active domain, but not if it integrates in another area of chromatin. Another possibility is the occurrence of epigenetic modification; for example, changes in the pattern of methylation might be responsible for changes in activity. Alternatively, the genes that happened to be active in the parents may have been deleted or amplified in the progeny.

A particularly striking example of the effects of an injected gene is provided by a strain of transgenic mice derived from eggs injected with a fusion consisting of the MT promoter linked to the rat growth hormone structural gene. Growth hormone levels in some of the transgenic mice were several hundred times greater than normal. The mice grew to nearly twice the size of normal mice, as can be seen from **Figure 18.35**.

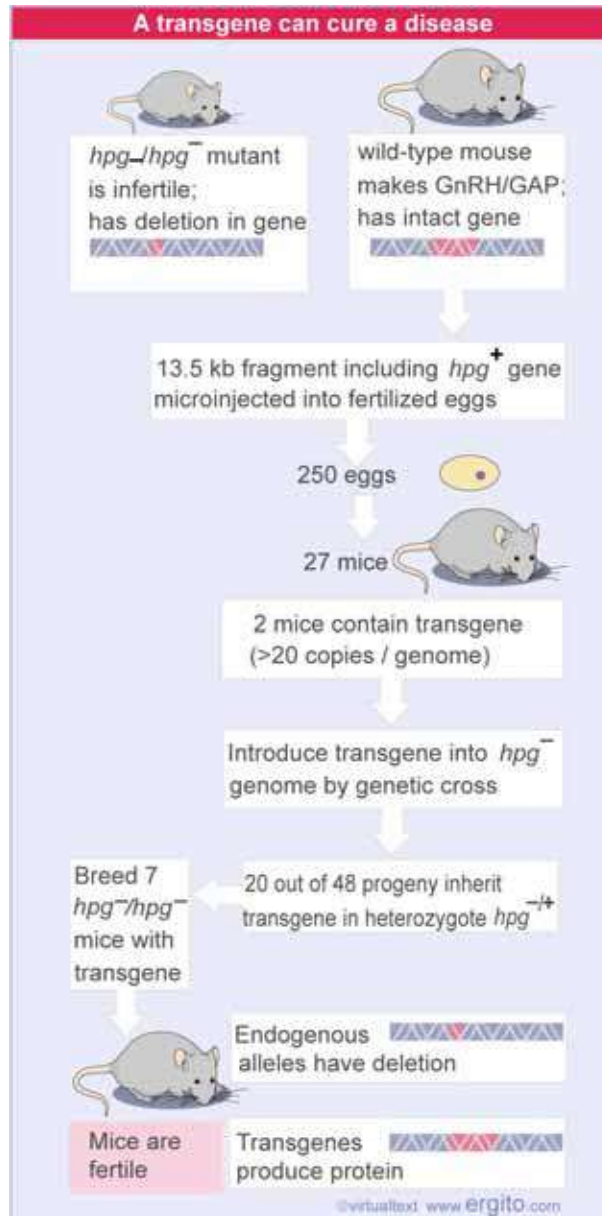

**Figure 18.35** A transgenic mouse with an active rat growth hormone gene (left) is twice the size of a normal mouse (right). Photograph kindly provided by Ralph Brinster.

The introduction of oncogene sequences can lead to tumor formation. Transgenic mice containing the SV40 early coding region and regulatory elements express the viral genes for large T and small t antigens only in some tissues, most often brain, thymus, and kidney. (The T/t antigens are alternatively spliced proteins coded by the early region of the virus; they have the ability to transform cultured cells to a tumorigenic phenotype; see *Molecular Biology 6.30.5 Early genes of DNA transforming viruses have multifunctional oncogenes.*) The transgenic mice usually die before reaching 6 months, as the result of developing tumors in the brain; sometimes tumors are found also in thymus and kidney. Different oncogenes may be used to generate mice developing various cancers, thus making possible a range of model systems. For example, introduction of the *myc* gene under control of an active promoter causes the appearance of adenocarcinomas and other tumors.

Can defective genes be replaced by functional genes in the germline using transgenic techniques? One successful case is represented by a cure of the defect in the hypogonadal mouse. The *hpg* mouse has a deletion that removes the distal part of the gene coding for the polyprotein precursor to GnRH (gonadotropin-releasing hormone) and GnRH-associated peptide (GAP). As a result, the mouse is infertile.

When an intact *hpg* gene is introduced into the mouse by transgenic techniques, it is expressed in the appropriate tissues. **Figure 18.36** summarizes experiments to introduce a transgene into *hpg/hpg* homozygous mutant mice. The resulting mice are normal. This provides a striking demonstration that expression of a transgene under normal regulatory control can be indistinguishable from the behavior of the normal allele.

**Figure 18.36** Hypogonadism of the *hpg* mouse can be cured by introducing a transgene that has the wild-type sequence.

Impediments to using such techniques to cure genetic defects at present are that the transgene must be introduced into the germline of the preceding generation, the ability to express a transgene is not predictable, and an adequate level of expression of a transgene may be obtained in only a small minority of the transgenic animals. Also, the large number of transgenes that may be introduced into the germline, and their erratic expression, could pose problems for the animal in cases in which overexpression of the transgene was harmful.

In the *hpg* murine experiments, for example, only 2 out of 250 eggs mice injected with intact *hpg* genes gave rise to transgenic mice. Each transgenic animal contained >20 copies of the transgene. Only 20 of the 48 offspring of the transgenic mice

retained the transgenic trait. When inherited by their offspring, however, the transgene(s) could substitute for the lack of endogenous *hpg* genes. Gene replacement via a transgene is therefore effective only under restricted conditions.

The disadvantage of direct injection of DNA is the introduction of multiple copies, their variable expression, and often difficulty in cloning the insertion site because sequence rearrangements may have been generated in the host DNA. An alternative procedure is to use a retroviral vector carrying the donor gene. A single proviral copy inserts at a chromosomal site, without inducing any rearrangement of the host DNA. It is possible also to treat cells at different stages of development, and thus to target a particular somatic tissue; however, it is difficult to infect germ cells.

## REARRANGEMENT OF DNA

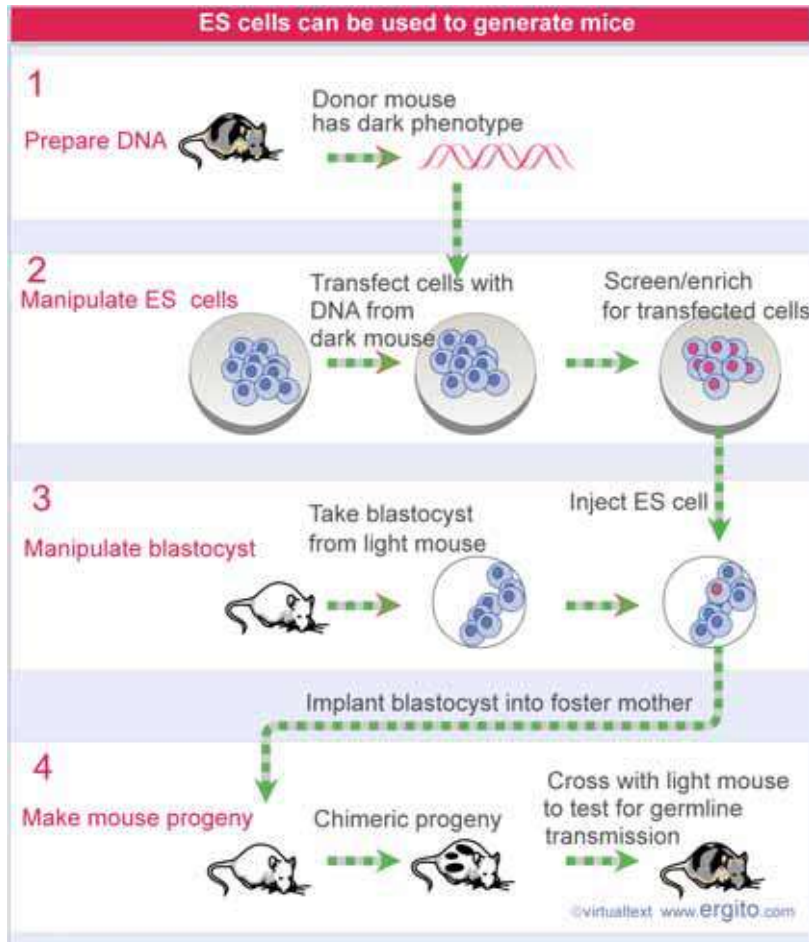

### 4.18.19 ES cells can be incorporated into embryonic mice

---

#### Key Concepts

- ES (embryonic carcinoma) cells that are injected into a mouse blastocyst generate descendant cells that become part of a chimeric adult mouse.
  - When the ES cells contribute to the germline, the next generation of mice may be derived from the ES cell.
  - Genes can be added to the mouse germline by transfecting them into ES cells before the cells are added to the blastocyst.
- 

A powerful technique for making transgenic mice takes advantage of embryonic stem (ES) cells, which are derived from the mouse blastocyst (an early stage of development, which precedes implantation of the egg in the uterus). **Figure 18.37** illustrates the principles of this technique.

**Figure 18.37** ES cells can be used to generate mouse chimeras, which breed true for the transfected DNA when the ES cell contributes to the germ line.

ES cells are transfected with DNA in the usual way (most often by microinjection or electroporation). By using a donor that carries an additional sequence such as a drug resistance marker or some particular enzyme, it is possible to select ES cells that have obtained an integrated transgene carrying any particular donor trait. An alternative is to use PCR technology to assay the transfected ES cells for successful integration of the donor DNA. By such means, a population of ES cells is obtained in which there is a high proportion carrying the marker.

These ES cells are then injected into a recipient blastocyst. The ability of the ES cells to participate in normal development of the blastocyst forms the basis of the technique. The blastocyst is implanted into a foster mother, and in due course develops into a *chimeric* mouse. Some of the tissues of the chimeric mice will be derived from the cells of the recipient blastocyst; other tissues will be derived from the injected ES cells. The proportion of tissues in the adult mouse that are derived from cells in the recipient blastocyst and from injected ES cells varies widely in individual progeny; if a visible marker (such as coat color gene) is used, areas of tissue representing each type of cell can be seen.

To determine whether the ES cells contributed to the germline, the chimeric mouse is

crossed with a mouse that lacks the donor trait. Any progeny that have the trait must be derived from germ cells that have descended from the injected ES cells. By this means, an entire mouse has been generated from an original ES cell (for review see 186)!

## REARRANGEMENT OF DNA

### 4.18.20 Gene targeting allows genes to be replaced or knocked out

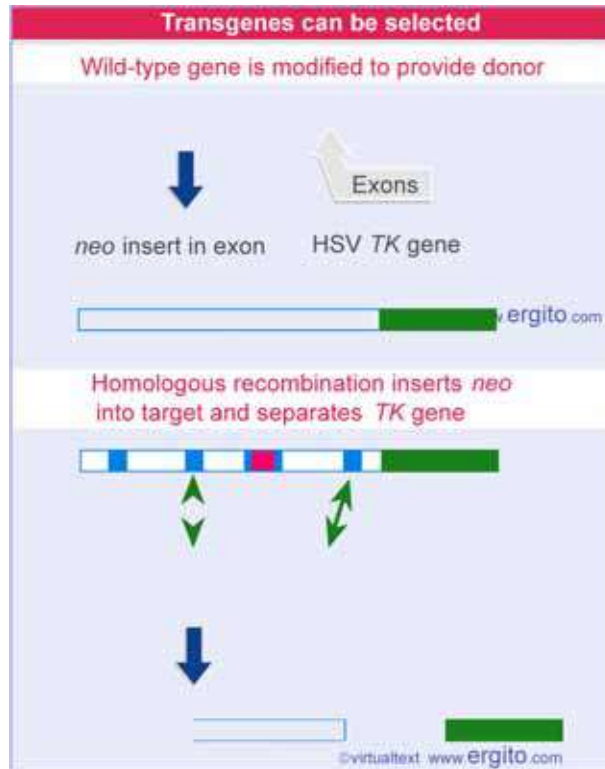

---

#### Key Concepts

- An endogenous gene can be replaced by a transfected gene using homologous recombination.
- The occurrence of a homologous recombination can be detected by using two selectable markers, one of which is incorporated with the integrated gene, the other of which is lost when recombination occurs.

---

A further development of these techniques makes it possible to obtain homologous recombinants (see *Great Experiments 3.4 Gene targeting: Altering the genome in mice*). A particular use of homologous recombination is to disrupt endogenous genes, as illustrated in **Figure 18.38**. A wild-type gene is modified by interrupting an exon with a marker sequence; most often the *neo* gene that confers resistance to the drug G418 is used. Also, another marker is added on one side of the gene; for example, the TK gene of the herpes virus. When this DNA is introduced into an ES cell, it may be inserted into the genome by either nonhomologous or homologous recombination. A nonhomologous recombination inserts the whole unit, including the flanking TK sequence. But a homologous recombination requires two exchanges, as a result of which the flanking TK sequence is lost. Cells in which a homologous recombination has occurred can therefore be selected by the gain of *neo* resistance and absence of TK activity (which can be selected because TK causes sensitivity to the drug gancyclovir). If it is not convenient to use a selectable marker such as TK, cells can simply be screened by PCR assays for the absence of flanking DNA. The frequency of homologous recombination is  $\sim 10^{-7}$ , and probably represents <1% of all recombination events (for review see 187).

**Figure 18.38** A transgene containing *neo* within an exon and TK downstream can be selected by resistance to G418 and loss of TK activity.

The presence of the *neo* gene in an exon disrupts transcription, and thereby creates a null allele. A particular target gene can therefore be "knocked out" by this means; and once a mouse with one null allele has been obtained, it can be bred to generate the homozygote. This is a powerful technique for investigating whether a particular gene is essential, and what functions in the animal are perturbed by its loss.

A sophisticated method for introducing new DNA sequences has been developed with *D. melanogaster* by taking advantage of the P element. The protocol is illustrated in **Figure 18.39**. A defective P element carrying the gene of interest is injected together with an intact P element into preblastoderm embryos. The intact P element provides a transposase that recognizes not only its own ends but also those of the defective element. As a result, either or both elements may be inserted into the genome (587).

**Figure 18.39** Transgenic flies that have a single, normally expressed copy of a gene can be obtained by injecting *D. melanogaster* embryos with an active P element plus foreign DNA flanked by P element ends.

Only the sequences between the ends of the P DNA are inserted; the sequences on either side are not part of the transposable element. An advantage of this technique is that only a single element is inserted in any one event, so the transgenic flies usually carry only one copy of the foreign gene, a great aid in analyzing its behavior.

Several genes that have been introduced in this way all show the same behavior. They are expressed only in the appropriate tissues and at the proper times during development, irrespective of the site of integration. So in *D. melanogaster*, all the information needed to regulate gene expression may be contained within the gene locus itself, and can be relatively impervious to external influence.

With these experiments, we see the possibility of extending from cultured cells to animals the option of examining the regulatory features. The ability to introduce DNA into the genotype allows us to make changes in it, to add new genes that have had particular modifications introduced *in vitro*, or to inactivate existing genes. So it

becomes possible to delineate the features responsible for tissue-specific gene expression. Ultimately we may expect routinely to replace defective genes in the genotype in a targeted manner.

## REARRANGEMENT OF DNA

### 4.18.21 Summary

---

Yeast mating type is determined by whether the *MAT* locus carries the *a* or  $\alpha$  sequence. Expression in haploid cells of the sequence at *MAT* leads to expression of genes specific for the mating type and to repression of genes specific for the other mating type. Both activation and repression are achieved by control of transcription, and require factors that are not specific for mating type as well as the products of *MAT*. The functions that are activated in either mating type include secretion of the appropriate pheromone and expression on the cell surface of the receptor for the opposite type of pheromone. Interaction between pheromone and receptor on cells of either mating type activates a G protein on the membrane, and sets in train a common pathway that prepares cells for sporulation. Diploid cells do not express mating-type functions.

Additional, silent copies of the mating-type sequences are carried at the loci *HML*  $\alpha$  and *HMRa*. They are repressed by the actions of the *sir* loci. Cells that carry the HO endonuclease display a unidirectional transfer process in which the sequence at *HML*  $\alpha$  replaces an *a* sequence at *MAT*, or the sequence at *HMRa* replaces an  $\alpha$  sequence at *MAT*. The endonuclease makes a double-strand break at *MAT*, and a free end invades either *HML*  $\alpha$  or *HMRa*. *MAT* initiates the transfer process, but is the recipient of the new sequence. The HO endonuclease is transcribed in mother cells but not daughter cells, and is under cell-cycle control. So switching is detected only in the products of a division, and the mating type has been switched in both daughter cells.

Trypanosomes carry >1000 sequences coding for varieties of the surface antigen. Only a single VSG is expressed in one cell, from an active site located near a telomere. The active site is localized in a special extranucleolar body, where the VSG gene is transcribed by RNA polymerase I. The VSG may be changed by substituting a new coding sequence at the active site via a gene conversion process, or by switching the site of expression to another telomere. Switches in expression occur every  $10^4$ - $10^6$  divisions.

*Agrobacterium* induce tumor formation in wounded plant cells. The wounded cells secrete phenolic compounds that activate *vir* genes carried by the Ti plasmid of the bacterium. The *vir* gene products cause a single strand of DNA from the T-DNA region of the plasmid to be transferred to the plant cell nucleus. Transfer is initiated at one boundary of T-DNA, but ends at variable sites. The single strand is converted into a double strand and integrated into the plant genome. Genes within the T-DNA transform the plant cell, and cause it to produce particular opines (derivatives of arginine). Genes in the Ti plasmid allow *Agrobacterium* to metabolize the opines produced by the transformed plant cell. T-DNA has been used to develop vectors for transferring genes into plant cells.

Endogenous sequences may become amplified in cultured cells. Exposure to methotrexate leads to the accumulation of cells that have additional copies of the *dhfr* gene. The copies may be carried as extrachromosomal arrays in the form of double-minute "chromosomes," or they may be integrated into the genome at the site

of one of the *dhfr* alleles. Double-minute chromosomes are unstable, and disappear from the cell line rapidly in the absence of selective pressure. The amplified copies may originate by additional cycles of replication that are associated with recombination events.

New sequences of DNA may be introduced into a cultured cell by transfection or into an animal egg by microinjection. The foreign sequences may become integrated into the genome, often as large tandem arrays. The array appears to be inherited as a unit in a cultured cell. The sites of integration appear to be random. A transgenic animal arises when the integration event occurs into a genome that enters the germ-cell lineage. A transgene or transgenic array is inherited in Mendelian manner, but the copy number and activity of the gene(s) may change in the progeny. Often a transgene responds to tissue- and temporal regulation in a manner that resembles the endogenous gene. Using conditions that promote homologous recombination, an inactive sequence can be used to replace a functional gene, thus creating a null locus. Transgenic mice can be obtained by injecting recipient blastocysts with ES cells that carry transfected DNA.

## CHROMOSOMES

### 5.19.1 Introduction

---

#### Key Terms

The **nucleoid** is the region in a prokaryotic cell that contains the genome. The DNA is bound to proteins and is not enclosed by a membrane.

**Chromatin** describes the state of nuclear DNA and its associated proteins during the interphase (between mitoses) of the eukaryotic cell cycle.

A **chromosome** is a discrete unit of the genome carrying many genes. Each chromosome consists of a very long molecule of duplex DNA and an approximately equal mass of proteins. It is visible as a morphological entity only during cell division.

The **packing ratio** is the ratio of the length of DNA to the unit length of the fiber containing it.

---

A general principle is evident in the organization of all cellular genetic material. It exists as a compact mass, confined to a limited volume; and its various activities, such as replication and transcription, must be accomplished within this space. The organization of this material must accommodate transitions between inactive and active states.

The condensed state of nucleic acid results from its binding to basic proteins. The positive charges of these proteins neutralize the negative charges of the nucleic acid. The structure of the nucleoprotein complex is determined by the interactions of the proteins with the DNA (or RNA).

A common problem is presented by the packaging of DNA into phages and viruses, into bacterial cells and eukaryotic nuclei. The length of the DNA as an extended molecule would vastly exceed the dimensions of the compartment that contains it. The DNA (or in the case of some viruses, the RNA) must be compressed exceedingly tightly to fit into the space available. *So in contrast with the customary picture of DNA as an extended double helix, structural deformation of DNA to bend or fold it into a more compact form is the rule rather than exception.*

The magnitude of the discrepancy between the length of the nucleic acid and the size of its compartment is evident from the examples summarized in **Figure 19.1**. For bacteriophages and for eukaryotic viruses, the nucleic acid genome, whether single-stranded or double-stranded DNA or RNA, effectively fills the container (which can be rod-like or spherical).

DNA is highly compressed in all types of genomes					
Compartment	Shape	Dimensions	Type of Nucleic Acid	Length	
TMV	filament	0.008 x 0.3 mm	1 single-stranded RNA	2 mm =	6.4 kb
Phage fd	filament	0.006 x 0.85 mm	1 single-stranded DNA	2 mm =	6.0 kb
Adenovirus	icosahedron	0.07 mm diameter	1 double-stranded DNA	11 mm =	35.0 kb
Phage T4	icosahedron	0.065 x 0.10 mm	1 double-stranded DNA	55 mm =	170.0 kb
<i>E. coli</i>	cylinder	1.7 x 0.65 mm	1 double-stranded DNA	1.3 mm =	$4.2 \times 10^3$ kb
Mitochondrion (human)	oblate spheroid	3.0 x 0.5 mm	~10 identical double-stranded DNAs	50 mm =	16.0 kb
Nucleus (human)	spheroid	6 mm diameter	46 chromosomes of double-stranded DNA	1.8 m =	$6 \times 10^6$ kb

©virtualtext www.ergito.com

**Figure 19.1** The length of nucleic acid is much greater than the dimensions of the surrounding compartment.

For bacteria or for eukaryotic cell compartments, the discrepancy is hard to calculate exactly, because the DNA is contained in a compact area that occupies only part of the compartment. The genetic material is seen in the form of the **nucleoid** in bacteria and as the mass of **chromatin** in eukaryotic nuclei at interphase (between divisions).

The density of DNA in these compartments is high. In a bacterium it is ~10 mg/ml, in a eukaryotic nucleus it is ~100 mg/ml., and in the phage T4 head it is >500 mg/ml. Such a concentration in solution would be equivalent to a gel of great viscosity. We do not entirely understand the physiological implications, for example, what effect this has upon the ability of proteins to find their binding sites on DNA.

The packaging of chromatin is flexible; it changes during the eukaryotic cell cycle. At the time of division (mitosis or meiosis), the genetic material becomes even more tightly packaged, and individual **chromosomes** become recognizable.

The overall compression of the DNA can be described by the **packing ratio**, the length of the DNA divided by the length of the unit that contains it. For example, the smallest human chromosome contains  $\sim 4.6 \times 10^7$  bp of DNA (~10 times the genome size of the bacterium *E. coli*). This is equivalent to 14,000  $\mu\text{m}$  (= 1.4 cm) of extended DNA. At the most condensed moment of mitosis, the chromosome is ~2  $\mu\text{m}$  long. So the packing ratio of DNA in the chromosome can be as great as 7000.

Packing ratios cannot be established with such certainty for the more amorphous overall structures of the bacterial nucleoid or eukaryotic chromatin. However, the usual reckoning is that mitotic chromosomes are likely to be 5-10 $\times$  more tightly packaged than interphase chromatin, which therefore has a typical packing ratio of 1000-2000.

A major unanswered question concerns the *specificity* of packaging. Is the DNA folded into a *particular* pattern, or is it different in each individual copy of the genome? How does the pattern of packaging change when a segment of DNA is replicated or transcribed?

## CHROMOSOMES

### 5.19.2 Viral genomes are packaged into their coats

---

#### Key Terms

A **capsid** is the external protein coat of a virus particle.

**Icosahedral symmetry** is typical of viruses that have capsids that are polyhedrons.

The **nucleation center** of TMV (tobacco mosaic virus) is a duplex hairpin where assembly of coat protein with RNA is initiated.

A **terminase** enzyme cleaves multimers of a viral genome and then uses hydrolysis of ATP to provide the energy to translocate the DNA into an empty viral capsid starting with the cleaved end.

**Monster** particles of bacteriophages form as the result of an assembly defect in which the capsid proteins form a head that is much longer than usual.

An **assembly factor** is a protein that is required for formation of a macromolecular structure but is not itself part of that structure.

#### Key Concepts

- The length of DNA that can be incorporated into a virus is limited by the structure of the head shell.
- Nucleic acid within the head shell is extremely condensed.
- Filamentous RNA viruses condense the RNA genome as they assemble the head shell around it.
- Spherical DNA viruses insert the DNA into a preassembled protein shell.

---

From the perspective of packaging the *individual* sequence, there is an important difference between a cellular genome and a virus. The cellular genome is essentially indefinite in size; the number and location of individual sequences can be changed by duplication, deletion, and rearrangement. So it requires a *generalized* method for packaging its DNA, insensitive to the total content or distribution of sequences. By contrast, two restrictions define the needs of a virus. The amount of nucleic acid to be packaged is *predetermined* by the size of the genome. And it must all fit within a coat assembled from a protein or proteins coded by the viral genes.

A virus particle is deceptively simple in its superficial appearance. The nucleic acid genome is contained within a **capsid**, a symmetrical or quasi-symmetrical structure assembled from one or only a few proteins. Attached to the capsid, or incorporated into it, are other structures, assembled from distinct proteins, and necessary for infection of the host cell.

The virus particle is tightly constructed. The internal volume of the capsid is rarely much greater than the volume of the nucleic acid it must hold. The difference is usually less than twofold, and often the internal volume is barely larger than the

nucleic acid.

In its most extreme form, the restriction that the capsid must be assembled from proteins coded by the virus means that the entire shell is constructed from a single type of subunit. The rules for assembly of identical subunits into closed structures restrict the capsid to one of two types. The protein subunits stack sequentially in a helical array to form a *filamentous* or rod-like shape. Or they form a pseudospherical shell, a type of structure that conforms to a polyhedron with **icosahedral symmetry**. Some viral capsids are assembled from more than a single type of protein subunit, but although this extends the exact types of structures that can be formed, viral capsids still all conform to the general classes of quasi-crystalline filaments or icosahedrons (590).

There are two types of solution to the problem of how to construct a capsid that contains nucleic acid:

- The protein shell can be assembled around the nucleic acid, condensing the DNA or RNA by protein-nucleic acid interactions during the process of assembly.
- Or the capsid can be constructed from its component(s) in the form of an empty shell, into which the nucleic acid must be inserted, being condensed as it enters.

The capsid is assembled around the genome for single-stranded RNA viruses. The principle of assembly is that *the position of the RNA within the capsid is determined directly by its binding to the proteins of the shell*. The best characterized example is TMV (tobacco mosaic virus). Assembly starts at a duplex hairpin that lies within the RNA sequence (3157; 3158). From this **nucleation center**, it proceeds bidirectionally along the RNA, until reaching the ends. The unit of the capsid is a two-layer disk, each layer containing 17 identical protein subunits. The disk is a circular structure, which forms a helix as it interacts with the RNA. At the nucleation center, the RNA hairpin inserts into the central hole in the disk, and the disk changes conformation into a helical structure that surrounds the RNA. Then further disks are added, each disk pulling a new stretch of RNA into its central hole. The RNA becomes coiled in a helical array on the inside of the protein shell, as illustrated in **Figure 19.2** (589; for review see 3159; 3160).

**Figure 19.2** A helical path for TMV RNA is created by the stacking of protein subunits in the virion.

The spherical capsids of DNA viruses are assembled in a different way, as best characterized for the phages lambda and T4. In each case, an empty headshell is assembled from a small set of proteins. *Then the duplex genome is inserted into the head*, accompanied by a structural change in the capsid.

**Figure 19.3** summarizes the assembly of lambda. It starts with a small headshell that contains a protein "core". This is converted to an empty headshell of more distinct shape. Then DNA packaging begins, the headshell expands in size though remaining the same shape, and finally the full head is sealed by addition of the tail.

**Figure 19.3** Maturation of phage lambda passes through several stages. The empty head changes shape and expands when it becomes filled with DNA. The electron micrographs show the particles at the start and end of the maturation pathway. Photographs kindly provided by A. F. Howatson.

Now a double-stranded DNA considered over short distances is a fairly rigid rod. Yet it must be compressed into a compact structure to fit within the capsid. We should like to know whether packaging involves a smooth coiling of the DNA into the head or requires abrupt bends.

Inserting DNA into a phage head involves two types of reaction: translocation and condensation. Both are energetically unfavorable.

Translocation is an active process in which the DNA is driven into the head by an ATP-dependent mechanism. A common mechanism is used for many viruses that replicate by a rolling circle mechanism to generate long tails that contain multimers of the viral genome. The best characterized example is phage lambda. The genome is packaged into the empty capsid by the **terminase** enzyme. **Figure 19.4** summarizes the process.

**Figure 19.4** Terminase protein binds to specific sites on a multimer of virus genomes generated by rolling circle replication. Terminase cuts the DNA and binds to an empty virus capsid. It uses energy from hydrolysis of ATP to insert the DNA into the capsid.

The terminase was first recognized for its role in generating the ends of the linear phage DNA by cleaving at *cos* sites. (The name *cos* reflects the fact that it generates cohesive ends that have complementary single-stranded tails.) The phage genome codes two subunits that make up the terminase. One subunit binds to a *cos* site; then it is joined by the other subunit, which cuts the DNA. The terminase assembles into a hetero-oligomer in a complex that also includes IHF (the integration host factor coded by the bacterial genome) (3161). It then binds to an empty capsid and uses ATP hydrolysis to power translocation along the DNA. The translocation drives the DNA into the empty capsid.

Another method of packaging uses a structural component of the phage. In the *B. subtilis* phage  $\phi 29$ , the motor that inserts the DNA into the phage head is the structure that connects the head to the tail. It functions as a rotary motor, where the motor action effects the linear translocation of the DNA into the phage head (3163; 3162). The same motor is used to eject the DNA from the phage head when it infects a bacterium.

---

Little is known about the mechanism of condensation into an empty capsid, except that the capsid contains "internal proteins" as well as DNA. One possibility is that they provide some sort of "scaffolding" onto which the DNA condenses. (This would be a counterpart to the use of the proteins of the shell in the plant RNA viruses.)

How specific is the packaging? It cannot depend on particular sequences, because deletions, insertions, and substitutions all fail to interfere with the assembly process. The relationship between DNA and the headshell has been investigated directly by determining which regions of the DNA can be chemically crosslinked to the proteins of the capsid. The surprising answer is that all regions of the DNA are more or less equally susceptible. This probably means that when DNA is inserted into the head, it follows a general rule for condensing, but the pattern is not determined by particular sequences (for review see 192).

These varying mechanisms of virus assembly all accomplish the same end: packaging a single DNA or RNA molecule into the capsid. However, some viruses have genomes that consist of multiple nucleic acid molecules. Reovirus contains ten double-stranded RNA segments, all of which must be packaged into the capsid. Specific sorting sequences in the segments may be required to ensure that the assembly process selects one copy of each different molecule in order to collect a complete set of genetic information. In the simpler case of phage  $\phi 6$ , which packages three different segments of double-stranded RNA into one capsid, the RNA segments must bind in a specific order; as each is incorporated into the capsid, it triggers a change in the conformation of the capsid that creates binding sites for the next segment (for review see 3164).

Some plant viruses are multipartite: their genomes consist of segments, each of which is packaged into a *different* capsid. An example is alfalfa mosaic virus (AMV), which has four different single-stranded RNAs, each packaged independently into a coat comprising the same protein subunit. A successful infection depends on the entry of one of each type into the cell.

The four components of AMV exist as particles of different sizes. This means that the same capsid protein can package each RNA into its own characteristic particle. This is a departure from the packaging of a unique length of nucleic acid into a capsid of fixed shape.

The assembly pathway of viruses whose capsids have only one authentic form may be diverted by mutations that cause the formation of aberrant **monster** particles in which the head is longer than usual. These mutations show that a capsid protein(s) has an intrinsic ability to assemble into a particular type of structure, but the exact size and shape may vary. Some of the mutations occur in genes that code for **assembly factors**, which are needed for head formation, but are not themselves part of the headshell. Such ancillary proteins limit the options of the capsid protein so that it assembles only along the desired pathway. Comparable proteins are employed in the assembly of cellular chromatin (see *Molecular Biology 5.20 Nucleosomes*).

**CHROMOSOMES****5.19.3 The bacterial genome is a nucleoid**

---

**Key Terms**

The **nucleoid** is the region in a prokaryotic cell that contains the genome. The DNA is bound to proteins and is not enclosed by a membrane.

**Key Concepts**

- The bacterial nucleoid is ~80% DNA by mass and can be unfolded by agents that act on RNA or protein.
  - The proteins that are responsible for condensing the DNA have not been identified.
- 

Although bacteria do not display structures with the distinct morphological features of eukaryotic chromosomes, their genomes nonetheless are organized into definite bodies. The genetic material can be seen as a fairly compact clump or series of clumps that occupies about a third of the volume of the cell. **Figure 19.5** displays a thin section through a bacterium in which this **nucleoid** is evident (for review see 191).

**Figure 19.5** A thin section shows the bacterial nucleoid as a compact mass in the center of the cell. Photograph kindly provided by Jack Griffith.

When *E. coli* cells are lysed, fibers are released in the form of loops attached to the broken envelope of the cell. As can be seen from **Figure 19.6**, the DNA of these loops is not found in the extended form of a free duplex, but is compacted by association with proteins.

**Figure 19.6** The nucleoid spills out of a lysed *E. coli* cell in the form of loops of a fiber. Photograph kindly provided by Jack Griffith.

Several DNA-binding proteins with a superficial resemblance to eukaryotic chromosomal proteins have been isolated in *E. coli*. What criteria should we apply for deciding whether a DNA-binding protein plays a structural role in the nucleoid? It should be present in sufficient quantities to bind throughout the genome. And mutations in its gene should cause some disruption of structure or of functions associated with genome survival (for example, segregation to daughter cells). None of the candidate proteins yet satisfies the genetic conditions (for review see 190).

Protein HU is a dimer that condenses DNA, possibly wrapping it into a bead-like structure. It is related to IHF (integration host factor), another dimer, which has a structural role in building a protein complex in specialized recombination reactions. Null mutations in either of the genes coding for the subunits of HU (*hupA, B*) have little effect, but loss of both functions causes a cold-sensitive phenotype and some loss of superhelicity in DNA. These results raise the possibility that HU plays some general role in nucleoid condensation.

Protein H1 (also known as H-NS) binds DNA, interacting preferentially with sequences that are bent. Mutations in its gene have turned up in a variety of guises (*osmZ, bglY, pilG*), each identified as an apparent regulator of a different system.

These results probably reflect the effect that H1 has on the local topology of DNA, with effects upon gene expression that depend upon the particular promoter.

We might expect that the absence of a protein required for nucleoid structure would have serious effects upon viability. Why then are the effects of deletions in the genes for proteins HU and H1 relatively restricted? One explanation is that these proteins are *redundant*, that any one can substitute for the others, so that deletions of *all* of them would be necessary to interfere seriously with nucleoid structure. Another possibility is that we have yet to identify the proteins responsible for the major features of nucleoid integrity.

The nucleoid can be isolated directly in the form of a very rapidly sedimenting complex, consisting of ~80% DNA by mass. (The analogous complexes in eukaryotes have ~50% DNA by mass; see *Molecular Biology 5.19.4 The bacterial genome is supercoiled.*) It can be unfolded by treatment with reagents that act on RNA or protein. The possible role of proteins in stabilizing its structure is evident. The role of RNA has been quite refractory to analysis.

## CHROMOSOMES

### 5.19.4 The bacterial genome is supercoiled

---

#### Key Terms

A **domain** of a chromosome may refer *either* to a discrete structural entity defined as a region within which supercoiling is independent of other domains; *or* to an extensive region including an expressed gene that has heightened sensitivity to degradation by the enzyme DNAase I.

#### Key Concepts

- The nucleoid has ~100 independently negatively supercoiled domains.
- The average density of supercoiling is ~1 turn/100 bp.

---

The DNA of the bacterial nucleoid isolated *in vitro* behaves as a closed duplex structure, as judged by its response to ethidium bromide. This small molecule intercalates between base pairs to generate *positive* superhelical turns in "closed" circular DNA molecules, that is, molecules in which both strands have covalent integrity. (In "open" circular molecules, which contain a nick in one strand, or with linear molecules, the DNA can rotate freely in response to the intercalation, thus relieving the tension.)

In a natural closed DNA that is *negatively* supercoiled, the intercalation of ethidium bromide first removes the negative supercoils and then introduces positive supercoils. The amount of ethidium bromide needed to achieve zero supercoiling is a measure of the original density of negative supercoils.

Some nicks occur in the compact nucleoid during its isolation; they can also be generated by limited treatment with DNAase. But this does not abolish the ability of ethidium bromide to introduce positive supercoils. This capacity of the genome to retain its response to ethidium bromide in the face of nicking means that it must have many independent chromosomal **domains**; *the supercoiling in each domain is not affected by events in the other domains.*

This autonomy suggests that the structure of the bacterial chromosome has the general organization depicted diagrammatically in **Figure 19.7**. Each domain consists of a loop of DNA, the ends of which are secured in some (unknown) way that does not allow rotational events to propagate from one domain to another. There are ~100 such domains per genome; each consists of ~40 kb (13  $\mu$ m) of DNA, organized into some more compact fiber whose structure has yet to be characterized.

**Figure 19.7** The bacterial genome consists of a large number of loops of duplex DNA (in the form of a fiber), each secured at the base to form an independent structural domain.

The existence of separate domains could permit different degrees of supercoiling to be maintained in different regions of the genome. This could be relevant in considering the different susceptibilities of particular bacterial promoters to supercoiling (see *Molecular Biology 3.9.15 Supercoiling is an important feature of transcription*).

Supercoiling in the genome can in principle take either of two forms, as summarized in in **Figure 19.8**:

**Figure 19.8** An unrestrained supercoil in the DNA path creates tension, but no tension is transmitted along DNA when a supercoil is restrained by protein binding.

- If a supercoiled DNA is free, its path is *unrestrained*, and negative supercoils generate a state of torsional tension that is transmitted freely along the DNA

within a domain. It can be relieved by unwinding the double helix, as described in *Molecular Biology 4.15.12 Supercoiling affects the structure of DNA*. The DNA is in a dynamic equilibrium between the states of tension and unwinding.

- Supercoiling can be *restrained* if proteins are bound to the DNA to hold it in a particular three-dimensional configuration. In this case, the supercoils are represented by the path the DNA follows in its fixed association with the proteins. The energy of interaction between the proteins and the supercoiled DNA stabilizes the nucleic acid, so that no tension is transmitted along the molecule.

Are the supercoils in *E. coli* DNA restrained *in vivo* or is the double helix subject to the torsional tension characteristic of free DNA? Measurements of supercoiling *in vitro* encounter the difficulty that restraining proteins may have been lost during isolation. Various approaches suggest that DNA is under torsional stress *in vivo*.

One approach is to measure the effect of nicking the DNA. Unrestrained supercoils are released by nicking, but restrained supercoils are unaffected. Nicking releases ~50% of the overall supercoiling, suggesting that about half of the supercoiling is transmitted as tension along DNA, but the other half is absorbed by protein binding (3245).

Another approach uses the crosslinking reagent psoralen, which binds more readily to DNA when it is under torsional tension. The reaction of psoralen with *E. coli* DNA *in vivo* corresponds to an average density of one negative superhelical turn / 200 bp ( $\sigma = -0.05$ ).

We can also examine the ability of cells to form alternative DNA structures; for example, to generate cruciforms at palindromic sequences. From the change in linking number that is required to drive such reactions, it is possible to calculate the original supercoiling density. This approach suggests an average density of  $\sigma = -0.025$ , or one negative superhelical turn / 100 base pairs.

So supercoils *do* create torsional tension *in vivo*. There may be variation about an average level, and although the precise range of densities is difficult to measure, it is clear that the level is sufficient to exert significant effects on DNA structure, for example, in assisting melting in particular regions such as origins or promoters (for review see 3235).

Many of the important features of the structure of the compact nucleoid remain to be established. What is the specificity with which domains are constructed – do the same sequences always lie at the same relative locations, or can the contents of individual domains shift? How is the integrity of the domain maintained? Biochemical analysis by itself is unable to answer these questions fully, but if it is possible to devise suitable selective techniques, the properties of structural mutants should lead to a molecular analysis of nucleoid construction.

## CHROMOSOMES

### 5.19.5 Eukaryotic DNA has loops and domains attached to a scaffold

---

#### Key Terms

A chromosome **scaffold** is a proteinaceous structure in the shape of a sister chromatid pair, generated when chromosomes are depleted of histones.

#### Key Concepts

- DNA of interphase chromatin is negatively supercoiled into independent domains of ~85 kb.
- Metaphase chromosomes have a protein scaffold to which the loops of supercoiled DNA are attached.

---

Interphase chromatin is a tangled mass occupying a large part of the nuclear volume, in contrast with the highly organized and reproducible ultrastructure of mitotic chromosomes. What controls the distribution of interphase chromatin within the nucleus?

Some indirect evidence on its nature is provided by the isolation of the genome as a single, compact body. Using the same technique that was developed for isolating the bacterial nucleoid (see *Molecular Biology 5.19.4 The bacterial genome is supercoiled*), nuclei can be lysed on top of a sucrose gradient. This releases the genome in a form that can be collected by centrifugation. As isolated from *D. melanogaster*, it can be visualized as a compactly folded fiber (10 nm in diameter), consisting of DNA bound to proteins.

Supercoiling measured by the response to ethidium bromide corresponds to about one negative supercoil / 200 bp. These supercoils can be removed by nicking with DNAase, although the DNA remains in the form of the 10 nm fiber. This suggests that the supercoiling is caused by the arrangement of the fiber in space, and represents the existing torsion.

Full relaxation of the supercoils requires one nick / 85 kb, identifying the average length of "closed" DNA. This region could comprise a loop or domain similar in nature to those identified in the bacterial genome. Loops can be seen directly when the majority of proteins are extracted from mitotic chromosomes. The resulting complex consists of the DNA associated with ~8% of the original protein content. As seen in **Figure 19.9**, the protein-depleted chromosomes take the form of a central **scaffold** surrounded by a halo of DNA.

**Figure 19.9** Histone-depleted chromosomes consist of a protein scaffold to which loops of DNA are anchored. Photograph kindly provided by Ulrich K. Laemmli.

The metaphase scaffold consists of a dense network of fibers. Threads of DNA emanate from the scaffold, apparently as loops of average length 10-30  $\mu\text{m}$  (30-90 kb). The DNA can be digested without affecting the integrity of the scaffold, which consists of a set of specific proteins. This suggests a form of organization in which loops of DNA of ~60 kb are anchored in a central proteinaceous scaffold.

The appearance of the scaffold resembles a mitotic pair of sister chromatids. The sister scaffolds usually are tightly connected, but sometimes are separate, joined only by a few fibers. Could this be the structure responsible for maintaining the shape of the mitotic chromosomes? Could it be generated by bringing together the protein components that usually secure the bases of loops in interphase chromatin?

*This content is available online at <http://www.ergito.com/main.jsp?bcs=MBIO.5.19.5>*

## CHROMOSOMES

### 5.19.6 Specific sequences attach DNA to an interphase matrix

---

#### Key Terms

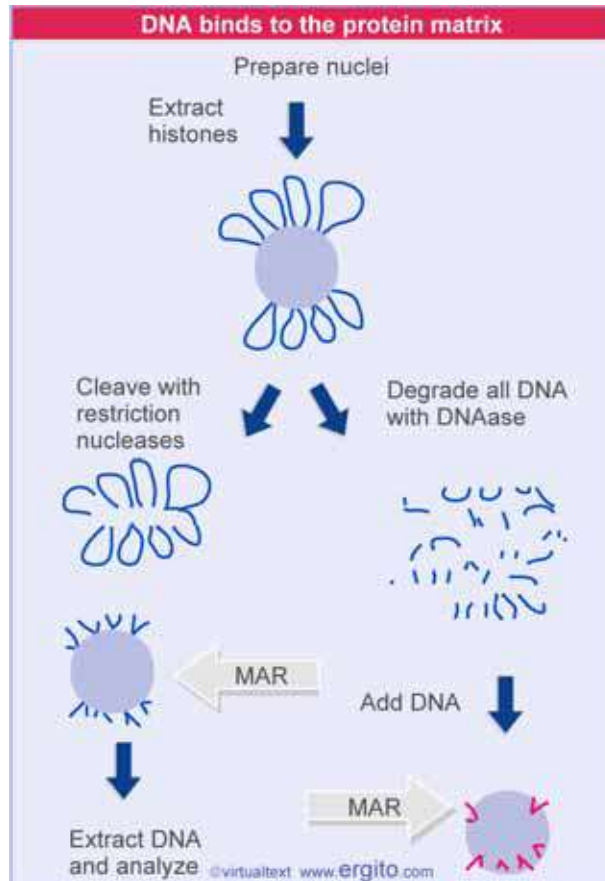

A **matrix attachment site (MAR)** is a region of DNA that attaches to the nuclear matrix. It is also known as a scaffold attachment site (SAR).

#### Key Concepts

- DNA is attached to the nuclear matrix at specific sequences called MARs or SARs.
  - The MARs are A·T-rich but do not have any specific consensus sequence.
- 

Is DNA attached to the scaffold via specific sequences? DNA sites attached to proteinaceous structures in interphase nuclei are called **MAR** (matrix attachment regions); they are sometimes also called *SAR* (scaffold attachment regions). The nature of the structure in interphase cells to which they are connected is not clear. Chromatin often appears to be attached to a matrix, and there have been many suggestions that this attachment is necessary for transcription or replication. When nuclei are depleted of proteins, the DNA extrudes as loops from a residual proteinaceous structure. However, attempts to relate the proteins found in this preparation to structural elements of intact cells have not been successful.

Are particular DNA regions associated with this matrix? *In vivo* and *in vitro* approaches are summarized in **Figure 19.10**. Both start by isolating the matrix as a crude nuclear preparation containing chromatin and nuclear proteins. Different treatments can then be used to characterize DNA in the matrix or to identify DNA able to attach to it.

**Figure 19.10** Matrix-associated regions may be identified by characterizing the DNA retained by the matrix isolated *in vivo* or by identifying the fragments that can bind to the matrix from which all DNA has been removed

To analyze the existing MAR, the chromosomal loops can be decondensed by extracting the proteins. Removal of the DNA loops by treatment with restriction nucleases leaves only the (presumptive) *in vivo* MAR sequences attached to the matrix.

The complementary approach is to remove *all* the DNA from the matrix by treatment with DNAase; then isolated fragments of DNA can be tested for their ability to bind to the matrix *in vitro*.

The same sequences should be associated with the matrix *in vivo* or *in vitro*. Once a potential MAR has been identified, the size of the minimal region needed for association *in vitro* can be determined by deletions. We can also then identify proteins that bind to the MAR sequences.

A surprising feature is the lack of conservation of sequence in MAR fragments. They are usually ~70% A·T-rich, but otherwise lack any consensus sequences. However, other interesting sequences often are in the DNA stretch containing the MAR. *Cis*-acting sites that regulate transcription are common. And a recognition site for topoisomerase II is usually present in the MAR. It is therefore possible that an MAR

serves more than one function, providing a site for attachment to the matrix, but also containing other sites at which topological changes in DNA are effected.

What is the relationship between the chromosome scaffold of dividing cells and the matrix of interphase cells? Are the same DNA sequences attached to both structures? In several cases, the same DNA fragments that are found with the nuclear matrix *in vivo* can be retrieved from the metaphase scaffold. And fragments that contain MAR sequences can bind to a metaphase scaffold. It therefore seems likely that DNA contains a single type of attachment site, which in interphase cells is connected to the nuclear matrix, and in mitotic cells is connected to the chromosome scaffold.

The nuclear matrix and chromosome scaffold consist of different proteins, although there are some common components. Topoisomerase II is a prominent component of the chromosome scaffold, and is a constituent of the nuclear matrix, suggesting that the control of topology is important in both cases.

---

## CHROMOSOMES

### 5.19.7 Chromatin is divided into euchromatin and heterochromatin

---

#### Key Terms

**Euchromatin** comprises all of the genome in the interphase nucleus except for the heterochromatin. The euchromatin is less tightly coiled than heterochromatin, and contains the active or potentially active genes.

**Heterochromatin** describes regions of the genome that are highly condensed, are not transcribed, and are late-replicating. Heterochromatin is divided into two types, which are called constitutive and facultative.

The **chromocenter** is an aggregate of heterochromatin from different chromosomes.

#### Key Concepts

- Individual chromosomes can be seen only during mitosis.
- During interphase, the general mass of chromatin is in the form of euchromatin, which is less tightly packed than mitotic chromosomes.
- Regions of heterochromatin remain densely packed throughout interphase.

---

Each chromosome contains a single, very long duplex of DNA. This explains why chromosome replication is semiconservative like the individual DNA molecule. (This would not necessarily be the case if a chromosome carried many independent molecules of DNA.) The single duplex of DNA is folded into a fiber that runs continuously throughout the chromosome. *So in accounting for interphase chromatin and mitotic chromosome structure, we have to explain the packaging of a single, exceedingly long molecule of DNA into a form in which it can be transcribed and replicated, and can become cyclically more and less compressed.*

Individual eukaryotic chromosomes come into the limelight for a brief period, during the act of cell division. Only then can each be seen as a compact unit. **Figure 19.11** is an electron micrograph of a sister chromatid pair, captured at metaphase. (The sister chromatids are daughter chromosomes produced by the previous replication event, still joined together at this stage of mitosis.) Each consists of a fiber with a diameter of ~30 nm and a nubby appearance. The DNA is 5–10× more condensed in chromosomes than in interphase chromatin.

**Figure 19.11** The sister chromatids of a mitotic pair each consist of a fiber (~30 nm in diameter) compactly folded into the chromosome. Photograph kindly provided by E. J. DuPraw.

During most of the life cycle of the eukaryotic cell, however, its genetic material occupies an area of the nucleus in which individual chromosomes cannot be distinguished. The structure of the interphase chromatin does not change visibly between divisions. No disruption is evident during the period of replication, when the amount of chromatin doubles. Chromatin is fibrillar, although the overall configuration of the fiber in space is hard to discern in detail. The fiber itself, however, is similar or identical to that of the mitotic chromosomes.

Chromatin can be divided into two types of material, which can be seen in the nuclear section of **Figure 19.12**:

**Figure 19.12** A thin section through a nucleus stained with Feulgen shows heterochromatin as compact regions clustered near the nucleolus and nuclear membrane. Photograph kindly provided by Edmund Puvion.

- In most regions, the fibers are much less densely packed than in the mitotic chromosome. This material is called **euchromatin**. It has a relatively dispersed appearance in the nucleus, and occupies most of the nuclear region in **Figure 19.12**.
- Some regions of chromatin are very densely packed with fibers, displaying a condition comparable to that of the chromosome at mitosis. This material is called **heterochromatin**. It is typically found at centromeres, but occurs at other locations also. It passes through the cell cycle with relatively little change in its degree of condensation. It forms a series of discrete clumps in **Figure 19.12**, but often the various heterochromatic regions aggregate into a densely staining **chromocenter**. (This description applies to regions that are always heterochromatic, called constitutive heterochromatin; in addition, there is another sort of heterochromatin, called facultative heterochromatin, in which regions of euchromatin are converted to a heterochromatic state).

The same fibers run continuously between euchromatin and heterochromatin, which implies that these states represent different degrees of condensation of the genetic material. In the same way, euchromatic regions exist in different states of condensation during interphase and during mitosis. So the genetic material is organized in a manner that permits alternative states to be maintained side by side in chromatin, and allows cyclical changes to occur in the packaging of euchromatin between interphase and division. We discuss the molecular basis for these states in *Molecular Biology 5.23 Controlling chromatin structure*.

The structural condition of the genetic material is correlated with its activity. The common features of constitutive heterochromatin are:

- It is permanently condensed.
- It often consists of multiple repeats of a few sequences of DNA that are not transcribed.

- The density of genes in this region is very much reduced compared with heterochromatin; and genes that are translocated into or near it are often inactivated.
- Probably resulting from the condensed state, it replicates late in S phase and has a reduced frequency of genetic recombination.

We have some molecular markers for changes in the properties of the DNA and protein components (see *Molecular Biology 5.23.15 Heterochromatin depends on interactions with histones*). They include reduced acetylation of histone proteins, increased methylation of one histone protein, and hypermethylation of cytidine bases in DNA. These molecular changes cause the condensation of the material, which is responsible for its inactivity.

Although active genes are contained within euchromatin, only a small minority of the sequences in euchromatin are transcribed at any time. So location in euchromatin is *necessary* for gene expression, but is not *sufficient* for it.

## CHROMOSOMES

### 5.19.8 Chromosomes have banding patterns

#### Key Terms

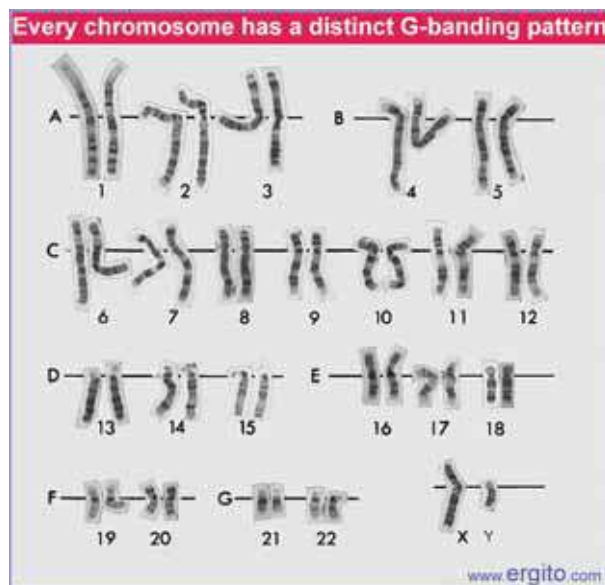

**G-bands** are generated on eukaryotic chromosomes by staining techniques and appear as a series of lateral striations. They are used for karyotyping (identifying chromosomal regions by the banding pattern).

#### Key Concepts

- Certain staining techniques cause the chromosomes to have the appearance of a series of striations called G-bands.
- The bands are lower in G-C content than the interbands.
- Genes are concentrated in the G-C-rich interbands.

Because of the diffuse state of chromatin, we cannot directly determine the specificity of its organization. But we can ask whether the structure of the (mitotic) chromosome is ordered. Do particular sequences always lie at particular sites, or is the folding of the fiber into the overall structure a more random event?

At the level of the chromosome, each member of the complement has a different and reproducible ultrastructure. When subjected to certain treatments and then stained with the chemical dye Giemsa, chromosomes generate a series of **G-bands**. **Figure 19.13** presents an example of the human set.

**Figure 19.13** G-banding generates a characteristic lateral series of bands in each member of the chromosome set. Photograph kindly provided by Lisa Shaffer.

Until the development of this technique, chromosomes could be distinguished only by their overall size and the relative location of the centromere. G-banding allows each chromosome to be identified by its characteristic banding pattern. This pattern allows translocations from one chromosome to another to be identified by comparison with the original diploid set. **Figure 19.14** shows a diagram of the bands of the human X chromosome. The bands are large structures, each  $\sim 10^7$  bp of DNA, which could include many hundreds of genes.

**Figure 19.14** The human X chromosome can be divided into distinct regions by its banding pattern. The short arm is *p* and the long arm is *q*; each arm is divided into larger regions that are further subdivided. This map shows a low resolution structure; at higher resolution, some bands are further subdivided into smaller bands and interbands, e.g. *p21* is divided into *p21.1*, *p21.2*, and *p21.3*.

The banding technique is of enormous practical use, but the mechanism of banding remains a mystery. All that is certain is that the dye stains untreated chromosomes more or less uniformly. So the generation of bands depends on a variety of treatments that change the response of the chromosome (presumably by extracting the component that binds the stain from the nonbanded regions). But similar bands can be generated by a variety of treatments.

The only known feature that distinguishes bands from interbands is that the bands have a lower G-C content than the interbands. This is a peculiar result. If there are  $\sim 10$  bands on a large chromosome with a total content of  $\sim 100$  Mb, this means that the chromosome is divided into regions of  $\sim 5$  Mb in length that alternate between low G-C (band) and high G-C (interband) content (1514). There is a tendency for genes (as identified by hybridization with mRNAs) to be located in the interband regions. All of this argues for some long-range sequence-dependent organization.

The human genome sequence confirms the basic observation (1439; 1440). **Figure 19.15** shows that there are distinct fluctuations in G-C content when the genome is divided into small tranches. The average of 41% G-C is common to mammalian genomes. There are regions as low as 30% or as high as 65%. When longer tranches are examined, there is less variation. The average length of regions with >43% G-C is 200-250 kb. This makes it clear that the band/interband structure does not represent homogeneous segments that alternate in G-C content, although the bands do contain a higher content of low G-C segments. Genes are concentrated in regions of higher G-C content. We have yet to understand how the G-C content affects chromosome structure.

**Figure 19.15** There are large fluctuations in G-C content over short distances. Each bar shows the per cent of 20 kb fragments with the given G-C content.

## CHROMOSOMES

### 5.19.9 Lampbrush chromosomes are extended

---

#### Key Terms

**Chromomeres** are densely staining granules visible in chromosomes under certain conditions, especially early in meiosis, when a chromosome may appear to consist of a series of chromomeres.

**Lampbrush chromosomes** are the extremely extended meiotic bivalents of certain amphibian oocytes.

#### Key Concepts

- Sites of gene expression on lampbrush chromosomes show loops that are extended from the chromosomal axis.

---

It would be extremely useful to visualize gene expression in its natural state, to see what structural changes are associated with transcription. The compression of DNA in chromatin, coupled with the difficulty of identifying particular genes within it, makes it impossible to visualize the transcription of individual active genes.

Gene expression can be visualized directly in certain unusual situations, in which the chromosomes are found in a highly extended form that allows individual loci (or groups of loci) to be distinguished. Lateral differentiation of structure is evident in many chromosomes when they first appear for meiosis. At this stage, the chromosomes resemble a series of beads on a string. The beads are densely staining granules, properly known as **chromomeres**. However, usually there is little gene expression at meiosis, and it is not practical to use this material to identify the activities of individual genes. But an exceptional situation that allows the material to be examined is presented by **lampbrush chromosomes**, which have been best characterized in certain amphibians.

Lampbrush chromosomes are formed during an unusually extended meiosis, which can last up to several months! During this period, the chromosomes are held in a stretched-out form in which they can be visualized in the light microscope. Later during meiosis, the chromosomes revert to their usual compact size. So the extended state essentially proffers an unfolded version of the normal condition of the chromosome.

The lampbrush chromosomes are meiotic bivalents, each consisting of two pairs of sister chromatids. **Figure 19.16** shows an example in which the sister chromatid pairs have mostly separated so that they are held together only by chiasmata. Each sister chromatid pair forms a series of ellipsoidal chromomeres, ~1-2  $\mu\text{m}$  in diameter, which are connected by a very fine thread. This thread contains the two sister duplexes of DNA, and runs continuously along the chromosome, through the chromomeres.

**Figure 19.16** A lampbrush chromosome is a meiotic bivalent in which the two pairs of sister chromatids are held together at chiasmata (indicated by arrows). Photograph kindly provided by Joe Gall.

The lengths of the individual lampbrush chromosomes in the newt *Notophthalmus viridescens* range from 400–800  $\mu\text{m}$ , compared with the range of 15–20  $\mu\text{m}$  seen later in meiosis. So the lampbrush chromosomes are  $\sim 30$  times less tightly packed. The total length of the entire lampbrush chromosome set is 5–6 mm, organized into  $\sim 5000$  chromomeres.

The lampbrush chromosomes take their name from the lateral loops that extrude from the chromomeres at certain positions. (These resemble a lampbrush, an extinct object.) The loops extend in pairs, one from each sister chromatid. The loops are continuous with the axial thread, which suggests that they represent chromosomal material extruded from its more compact organization in the chromomere.

The loops are surrounded by a matrix of ribonucleoproteins. These contain nascent RNA chains. Often a transcription unit can be defined by the increase in the length of the RNP moving around the loop. An example is shown in **Figure 19.17**.

**Figure 19.17** A lampbrush chromosome loop is surrounded by a matrix of ribonucleoprotein. Photograph kindly provided by Oscar Miller.

So the loop is an extruded segment of DNA that is being actively transcribed. In some cases, loops corresponding to particular genes have been identified. Then the structure of the transcribed gene, and the nature of the product, can be scrutinized *in situ*.

## CHROMOSOMES

### 5.19.10 Polytene chromosomes form bands

#### Key Terms

**Polytene chromosomes** are generated by successive replications of a chromosome set without separation of the replicas.

**Bands** of polytene chromosomes are visible as dense regions that contain the majority of DNA. They include active genes.

**Interbands** are the relatively dispersed regions of polytene chromosomes that lie between the bands.

**In situ hybridization (Cytological hybridization)** is performed by denaturing the DNA of cells squashed on a microscope slide so that reaction is possible with an added single-stranded RNA or DNA; the added preparation is radioactively labeled and its hybridization is followed by autoradiography.

#### Key Concepts

- Polytene chromosomes of Dipterans have a series of bands that can be used as a cytological map.

The interphase nuclei of some tissues of the larvae of Dipteran flies contain chromosomes that are greatly enlarged relative to their usual condition. They possess both increased diameter and greater length. **Figure 19.18** shows an example of a chromosome set from the salivary gland of *D. melanogaster*. They are called **polytene** chromosomes.

**Figure 19.18** The polytene chromosomes of *D. melanogaster* form an alternating series of bands and interbands. Photograph kindly provided by Jose Bonner.

Each member of the polytene set consists of a visible series of **bands** (more properly, but rarely, described as chromomeres). The bands range in size from the largest with a breadth of  $\sim 0.5 \mu\text{m}$  to the smallest of  $\sim 0.05 \mu\text{m}$ . (The smallest can be distinguished

only under the electron microscope.) The bands contain most of the mass of DNA and stain intensely with appropriate reagents. The regions between them stain more lightly and are called **interbands**. There are ~5000 bands in the *D. melanogaster* set.

The centromeres of all four chromosomes of *D. melanogaster* aggregate to form a chromocenter that consists largely of heterochromatin (in the male it includes the entire Y chromosome). Allowing for this, ~75% of the haploid DNA set is organized into alternating bands and interbands. The length of the chromosome set is ~2000  $\mu\text{m}$ . The DNA in extended form would stretch for ~40,000  $\mu\text{m}$ , so the packing ratio is ~20. This demonstrates vividly the extension of the genetic material relative to the usual states of interphase chromatin or mitotic chromosomes.

What is the structure of these giant chromosomes? Each is produced by the successive replications of a synapsed diploid pair. The replicas do not separate, but remain attached to each other in their extended state. At the start of the process, each synapsed pair has a DNA content of  $2C$  (where  $C$  represents the DNA content of the individual chromosome). Then this doubles up to 9 times, at its maximum giving a content of  $1024C$ . The number of doublings is different in the various tissues of the *D. melanogaster* larva.

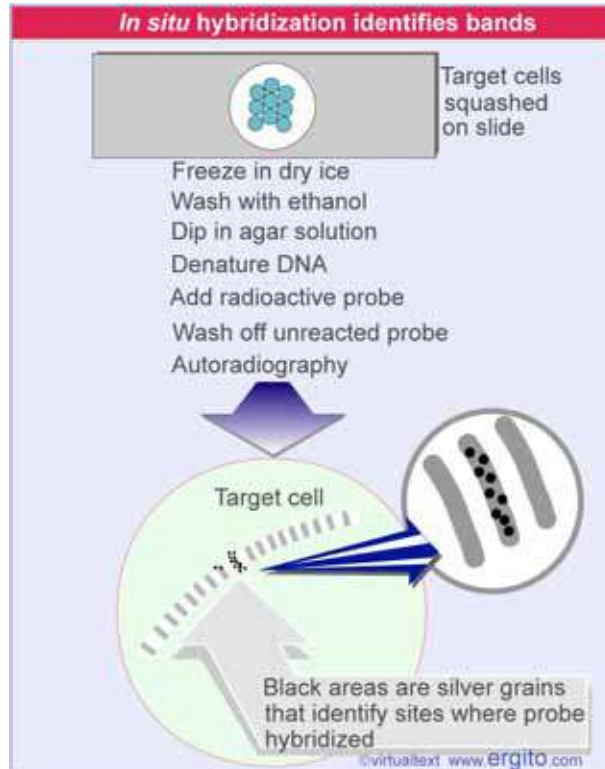

Each chromosome can be visualized as a large number of parallel fibers running longitudinally, tightly condensed in the bands, less condensed in the interbands. Probably each fiber represents a single ( $C$ ) haploid chromosome. This gives rise to the name polytene. The degree of polyteny is the number of haploid chromosomes contained in the giant chromosome.

The banding pattern is characteristic for each strain of *Drosophila*. The constant number and linear arrangement of the bands was first noted in the 1930s, when it was realized that they form a *cytological map* of the chromosomes. Rearrangements – such as deletions, inversions, or duplications – result in alterations of the order of bands.

The linear array of bands can be equated with the linear array of genes. So genetic rearrangements, as seen in a linkage map, can be correlated with structural rearrangements of the cytological map. Ultimately, a particular mutation can be located in a particular band. Since the total number of genes in *D. melanogaster* exceeds the number of bands, there are probably multiple genes in most or all bands.

The positions of particular genes on the cytological map can be determined directly by the technique of *in situ* hybridization. The protocol is summarized in **Figure 19.19**. A radioactive probe representing a gene (most often a labeled cDNA clone derived from the mRNA) is hybridized with the denatured DNA of the polytene chromosomes *in situ*. Autoradiography identifies the position or positions of the corresponding genes by the superimposition of grains at a particular band or bands. An example is shown in **Figure 19.20**. With this type of technique at hand, it is possible to determine directly the band within which a particular sequence lies.

**Figure 19.19** Individual bands containing particular genes can be identified by *in situ* hybridization.

**Figure 19.20** A magnified view of bands 87A and 87C shows their hybridization *in situ* with labeled RNA extracted from heat-shocked cells. Photograph kindly provided by Jose Bonner.

## CHROMOSOMES

### 5.19.11 Polytene chromosomes expand at sites of gene expression

#### Key Terms

A **puff** is an expansion of a band of a polytene chromosome associated with the synthesis of RNA at some locus in the band.

#### Key Concepts

- Bands that are sites of gene expression on polytene chromosomes expand to give "puffs".

One of the intriguing features of the polytene chromosomes is that active sites can be visualized. Some of the bands pass transiently through an expanded state in which they appear like a **puff** on the chromosome, when chromosomal material is extruded from the axis. An example of some very large puffs (called Balbiani rings) is shown in **Figure 19.21**.

**Figure 19.21** Chromosome IV of the insect *C. tentans* has three Balbiani rings in the salivary gland. Photograph kindly provided by Bertil Daneholt.

What is the nature of the puff? It consists of a region in which the chromosome fibers unwind from their usual state of packing in the band. The fibers remain continuous with those in the chromosome axis. Puffs usually emanate from single bands, although when they are very large, as typified by the Balbiani rings, the swelling may be so extensive as to obscure the underlying array of bands.

The pattern of puffs is related to gene expression. During larval development, puffs appear and regress in a definite, tissue-specific pattern. A characteristic pattern of puffs is found in each tissue at any given time. Puffs are induced by the hormone

ecdysone that controls *Drosophila* development. Some puffs are induced directly by the hormone; others are induced indirectly by the products of earlier puffs.

The puffs are *sites where RNA is being synthesized*. The accepted view of puffing has been that expansion of the band is a consequence of the need to relax its structure in order to synthesize RNA. Puffing has therefore been viewed as a consequence of transcription. A puff can be generated by a single active gene. The sites of puffing differ from ordinary bands in accumulating additional proteins, which include RNA polymerase II and other proteins associated with transcription.

The features displayed by lampbrush and polytene chromosomes suggest a general conclusion. In order to be transcribed, the genetic material is dispersed from its usual more tightly packed state. The question to keep in mind is whether this dispersion at the gross level of the chromosome mimics the events that occur at the molecular level within the mass of ordinary interphase euchromatin.

Do the bands of a polytene chromosome have a functional significance, that is, does each band correspond to some type of genetic unit? You might think that the answer would be immediately evident from the sequence of the fly genome, since by mapping interbands to the sequence it should be possible to determine whether a band has any fixed type of identity. However, so far, no pattern has been found that identifies a functional significance for the bands.

## CHROMOSOMES

### 5.19.12 The eukaryotic chromosome is a segregation device

---

#### Key Terms

A **microtubule organizing center (MTOC)** is a region from which microtubules emanate. The major MTOCs in a mitotic cell are the centrosomes.

The **centromere** is a constricted region of a chromosome that includes the site of attachment (the kinetochore) to the mitotic or meiotic spindle.

An **acentric fragment** of a chromosome (generated by breakage) lacks a centromere and is lost at cell division.

**C-bands** are generated by staining techniques that react with centromeres. The centromere appears as a darkly-staining dot.

The **kinetochore** is the structural feature of the chromosome to which microtubules of the mitotic spindle attach. Its location determines the centromeric region.

#### Key Concepts

- A eukaryotic chromosome is held on the mitotic spindle by the attachment of microtubules to the kinetochore that forms in its centromeric region.
- Centromeres often have heterochromatin that is rich in satellite DNA sequences.

---

During mitosis, the sister chromatids move to opposite poles of the cell. Their movement depends on the attachment of the chromosome to microtubules, which are connected at their other end to the poles. (The microtubules comprise a cellular filamentous system, reorganized at mitosis so that they connect the chromosomes to the poles of the cell.) The sites in the two regions where microtubule ends are organized – in the vicinity of the centrioles at the poles and at the chromosomes – are called **MTOCs** (microtubule organizing centers).

**Figure 19.22** illustrates the separation of sister chromatids as mitosis proceeds from metaphase to telophase. The region of the chromosome that is responsible for its segregation at mitosis and meiosis is called the **centromere**. The centromeric region on each sister chromatid is pulled by microtubules to the opposite pole. Opposing this motive force, "glue" proteins called cohesins hold the sister chromatids together. Initially the sister chromatids separate at their centromeres, and then they are released completely from one another during anaphase when the cohesins are degraded (the cohesins are discussed in more detail in *Molecular Biology 6.29.19 Cohesins hold sister chromatids together*).

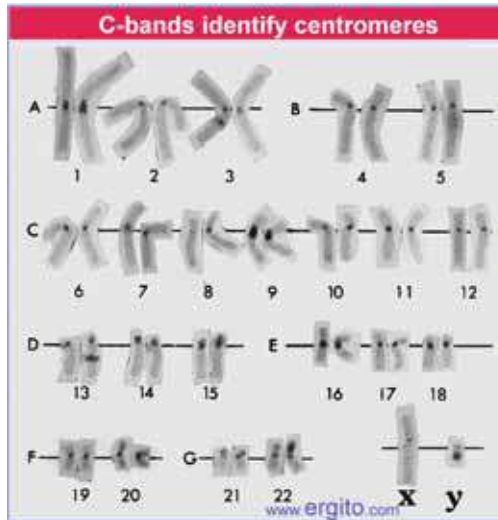

**Figure 19.22** Chromosomes are pulled to the poles via microtubules that attach at the centromeres. The sister chromatids are held together until anaphase by glue proteins (cohesins). The centromere is shown here in the middle of the chromosome (metacentric), but can be located anywhere along its length, including close to the end (acrocentric) and at the end (telocentric).

The centromere is pulled toward the pole during mitosis, and the attached chromosome is dragged along behind, as it were. The chromosome therefore provides a device for attaching a large number of genes to the apparatus for division. It contains the site at which the sister chromatids are held together prior to the separation of the individual chromosomes. This shows as a constricted region connecting all four chromosome arms, as in the photograph of **Figure 19.11**, which shows the sister chromatids at the metaphase stage of mitosis.

The centromere is essential for segregation, as shown by the behavior of chromosomes that have been broken. A single break generates one piece that retains the centromere, and another, an **acentric fragment**, that lacks it. The acentric fragment does not become attached to the mitotic spindle; and as a result it fails to be included in either of the daughter nuclei.

(When chromosome movement relies on discrete centromeres, there can be *only* one centromere per chromosome. When translocations generate chromosomes with more than one centromere, aberrant structures form at mitosis, since the two centromeres on the *same* sister chromatid can be pulled toward different poles, breaking the chromosome. However, in some species the centromeres are "diffuse," which creates a different situation. Only discrete centromeres have been analyzed at the molecular level.)

The regions flanking the centromere often are rich in satellite DNA sequences and display a considerable amount of heterochromatin. Because the entire chromosome is condensed, centromeric heterochromatin is not immediately evident in mitotic chromosomes. However, it can be visualized by a technique that generates **C-bands**. In the example of **Figure 19.23**, all the centromeres show as darkly staining regions. Although it is common, heterochromatin cannot be identified around *every* known centromere, which suggests that it is unlikely to be essential for the division mechanism.

**Figure 19.23** C-banding generates intense staining at the centromeres of all chromosomes. Photograph kindly provided by Lisa Shaffer.

The region of the chromosome at which the centromere forms is defined by DNA sequences (although the sequences have been defined in only a very small number of cases). The centromeric DNA binds specific proteins that are responsible for establishing the structure that attaches the chromosome to the microtubules. This structure is called the **kinetochore**. It is a darkly staining fibrous object of diameter or length ~400 nm. The kinetochore provides the MTOC on a chromosome (for review see 197). **Figure 19.24** shows the hierarchy of organization that connects centromeric DNA to the microtubules. Proteins bound to the centromeric DNA bind other proteins that bind to microtubules (see *Molecular Biology 5.19.14 The centromere binds a protein complex*).

**Figure 19.24** The centromere is identified by a DNA sequence that binds specific proteins. These proteins do not themselves bind to microtubules, but establish the site at which the microtubule-binding proteins in turn bind.

## CHROMOSOMES

### 5.19.13 Centromeres have short DNA sequences in *S. cerevisiae*

---

#### Key Concepts

- CEN elements are identified in *S. cerevisiae* by the ability to allow a plasmid to segregate accurately at mitosis.
  - CEN elements consists of short conserved sequences CDE-I and CDE-III that flank the A·T-rich region CDE-II.
- 

If a centromeric sequence of DNA is responsible for segregation, any molecule of DNA possessing this sequence should move properly at cell division, while any DNA lacking it will fail to segregate. This prediction has been used to isolate centromeric DNA in the yeast, *S. cerevisiae*. Yeast chromosomes do not display visible kinetochores comparable to those of higher eukaryotes, but otherwise divide at mitosis and segregate at meiosis by the same mechanisms.

Genetic engineering has produced plasmids of yeast that are replicated like chromosomal sequences (see *Molecular Biology 4.13.6 Replication origins can be isolated in yeast*). However, they are unstable at mitosis and meiosis, disappearing from a majority of the cells because they segregate erratically. Fragments of chromosomal DNA containing centromeres have been isolated by their ability to confer mitotic stability on these plasmids.

A *CEN* fragment is identified as the minimal sequence that can confer stability upon such a plasmid. Another way to characterize the function of such sequences is to modify them *in vitro* and then reintroduce them into the yeast cell, where they replace the corresponding centromere on the chromosome. This allows the sequences required for *CEN* function to be defined directly in the context of the chromosome (for review see 188).

A *CEN* fragment derived from one chromosome can replace the centromere of another chromosome with no apparent consequence. This result suggests that centromeres are interchangeable. *They are used simply to attach the chromosome to the spindle, and play no role in distinguishing one chromosome from another.*

The sequences required for centromeric function fall within a stretch of ~120 bp. The centromeric region is packaged into a nuclease-resistant structure, and it binds a single microtubule. We may therefore look to the *S. cerevisiae* centromeric region to identify proteins that bind centromeric DNA and proteins that connect the chromosome to the spindle.

Three types of sequence element may be distinguished in the *CEN* region, as summarized in **Figure 19.25** (3174):

**Figure 19.25** Three conserved regions can be identified by the sequence homologies between yeast *CEN* elements.

- CDE-I is a sequence of 9 bp that is conserved with minor variations at the left boundary of all centromeres.
- CDE-II is a >90% A-T-rich sequence of 80-90 bp found in all centromeres; its function could depend on its length rather than exact sequence. Its constitution is reminiscent of some short tandemly repeated (satellite) DNAs (see *Molecular Biology 1.4.12 Arthropod satellites have very short identical repeats*). Its base composition may cause some characteristic distortions of the DNA double helical structure.
- CDE-III is an 11 bp sequence highly conserved at the right boundary of all centromeres. Sequences on either side of the element are less well conserved, and may also be needed for centromeric function. (CDE-III could be longer than 11 bp if it turns out that the flanking sequences are essential.)

Mutations in CDE-I or CDE-II reduce but do not inactivate centromere function, but point mutations in the central CCG of CDE-III completely inactivate the centromere (for review see 189).

**CHROMOSOMES****5.19.14 The centromere binds a protein complex****Key Concepts**

- A specialized protein complex that is an alternative to the usual chromatin structure is formed at CDE-II.
- The CBF3 protein complex that binds to CDE-III is essential for centromeric function.
- The proteins that connect these two complexes may provide the connection to microtubules.

Can we identify proteins that are necessary for the function of CEN sequences? There are several genes in which mutations affect chromosome segregation, and whose proteins are localized at centromeres. The contributions of these proteins to the centromeric structure are summarized in **Figure 19.26**.

**Figure 19.26** The DNA at CDE-II is wound around a protein aggregate including Cse4p, CDE-III is bound to CBF3, and CDE-I is bound to CBF1. These proteins are connected by the group of Ctf19, Mcm21, and Okp1.

A specialized chromatin structure is built by binding the CDE-II region to a protein called Cse4p, which resembles one of the histone proteins that comprise the basic subunits of chromatin (see *Molecular Biology 5.23.15 Heterochromatin depends on interactions with histones*) (624). A protein called Mif2p may also be part of this complex or connected to it (3169). Cse4p and Mif2p have counterparts that are localized at higher eukaryotic centromeres, called CENP-A and CENP-C, which suggests that this interaction may be a universal aspect of centromere construction. The basic interaction consists of bending the DNA of the CDE-II region around a protein aggregate; the reaction is probably assisted by the occurrence of intrinsic bending in the CDE-II sequence.

CDE-I is bound by the homodimer CBF1; this interaction is not essential for centromere function, but in its absence the fidelity of chromosome segregation is reduced  $\sim 10\times$ . A 240 kD complex of four proteins, called CBF3, binds to CDE-III.

This interaction is essential for centromeric function (3175).

The proteins bound at CDE-I and CDE-III are connected to each other and also to the protein structure bound at CDE-II by another group of proteins (Ctf19, Mcm21, Okp1) (3170). The connection to the microtubule may be made by this complex.

The overall model suggests that the complex is localized at the centromere by a protein structure that resembles the normal building block of chromatin (the nucleosome). The bending of DNA at this structure allows proteins bound to the flanking elements to become part of a single complex. Some components of the complex (possibly not those that bind directly to DNA) link the centromere to the microtubule. The construction of kinetochores probably follows a similar pattern, and uses related components, in a wide variety of organisms (for review see 3425).

## CHROMOSOMES

### 5.19.15 Centromeres may contain repetitious DNA

---

#### Key Concepts

- Centromeres in higher eukaryotic chromosomes contain large amounts of repetitious DNA.
  - The function of the repetitious DNA is not known.
- 

The length of DNA required for centromeric function is often quite long. (The short, discrete, elements of *S. cerevisiae* may be an exception to the general rule.) In those cases where we can equate specific DNA sequences with the centromeric region, they usually include repetitive sequences.

*S. cerevisiae* is the only case so far in which centromeric DNA can be identified by its ability to confer stability on plasmids. However, a related approach has been used with the yeast *S. pombe*. This has only 3 chromosomes, and the region containing each centromere has been identified by deleting most of the sequences of each chromosome to create a stable minichromosome. This approach locates the centromeres within regions of 40-100 kb that consist largely or entirely of repetitious DNA. It is not clear how much of each of these rather long regions is required for chromosome segregation at mitosis and meiosis.

Attempts to localize centromeric functions in *Drosophila* chromosomes suggest that they are dispersed in a large region, consisting of 200-600 kb. The large size of this type of centromere suggests that it is likely to contain several separate specialized functions, including sequences required for kinetochore assembly, sister chromatid pairing, etc. (3177).

The size of the centromere in *Arabidopsis* is comparable (922). Each of the 5 chromosomes has a centromeric region in which recombination is very largely suppressed. This region occupies >500 kb. Clearly it includes the centromere, but we have no direct information as to how much of it is required. There are expressed genes within these regions, which casts some doubt on whether the entire region is part of the centromere. At the center of the region is a series of 180 bp repeats; this is the type of structure generally associated with centromeres. It is too early to say how these structures relate to centromeric function.

The primary motif comprising the heterochromatin of primate centromeres is the  $\alpha$  satellite DNA, which consists of tandem arrays of a 170 bp repeating unit. There is significant variation between individual repeats, although those at any centromere tend to be better related to one another than to members of the family in other locations. It is clear that the sequences required for centromeric function reside within the blocks of  $\alpha$  satellite DNA, but it is not clear whether the  $\alpha$  satellite sequences themselves provide this function, or whether other sequences are embedded within the  $\alpha$  satellite arrays (3178; 3179).

## CHROMOSOMES

### 5.19.16 Telomeres have simple repeating sequences

#### Key Terms

A **telomere** is the natural end of a chromosome; the DNA sequence consists of a simple repeating unit with a protruding single-stranded end that may fold into a hairpin.

#### Key Concepts

- The telomere is required for the stability of the chromosome end.
- A telomere consists of a simple repeat where a C+A-rich strand has the sequence  $C_n(A/T)_{1-4}$ .

Another essential feature in all chromosomes is the **telomere**, which "seals" the end. We know that the telomere must be a special structure, because chromosome ends generated by breakage are "sticky" and tend to react with other chromosomes, whereas natural ends are stable.

We can apply two criteria in identifying a telomeric sequence:

- It must lie at the end of a chromosome (or, at least, at the end of an authentic linear DNA molecule).
- It must confer stability on a linear molecule.

The problem of finding a system that offers an assay for function again has been brought to the molecular level by using yeast. All the plasmids that survive in yeast (by virtue of possessing *ARS* and *CEN* elements) are circular DNA molecules. Linear plasmids are unstable (because they are degraded). Could an authentic telomeric DNA sequence confer stability on a linear plasmid? Fragments from yeast DNA that prove to be located at chromosome ends can be identified by such an assay. And a region from the end of a known natural linear DNA molecule – the extrachromosomal rDNA of *Tetrahymena* – is able to render a yeast plasmid stable in linear form.

Telomeric sequences have been characterized from a wide range of lower and higher eukaryotes. The same type of sequence is found in plants and man, so the construction of the telomere seems to follow a universal principle. Each telomere consists of a long series of short, tandemly repeated sequences. There may be 100-1000 repeats, depending on the organism.

All telomeric sequences can be written in the general form  $C_n(A/T)_m$ , where  $n > 1$  and  $m$  is 1-4. **Figure 19.27** shows a generic example. One unusual property of the telomeric sequence is the extension of the G-T-rich strand, usually for 14-16 bases as

a single strand. The G-tail is probably generated because there is a specific limited degradation of the C-A-rich strand (2000).

**Figure 19.27** A typical telomere has a simple repeating structure with a G-T-rich strand that extends beyond the C-A-rich strand. The G-tail is generated by a limited degradation of the C-A-rich strand.

Some indications about how a telomere functions are given by some unusual properties of the ends of linear DNA molecules. In a trypanosome population, the ends are variable in length. When an individual cell clone is followed, the telomere grows longer by 7-10 bp (1-2 repeats) per generation. Even more revealing is the fate of ciliate telomeres introduced into yeast. After replication in yeast, *yeast telomeric repeats are added onto the ends of the Tetrahymena repeats*.

Addition of telomeric repeats to the end of the chromosome in every replication cycle could solve the difficulty of replicating linear DNA molecules discussed in *Molecular Biology 4.13.8 The ends of linear DNA are a problem for replication*. The addition of repeats by *de novo* synthesis would counteract the loss of repeats resulting from failure to replicate up to the end of the chromosome. Extension and shortening would be in dynamic equilibrium (for review see 188; 193).

If telomeres are continually being lengthened (and shortened), their exact sequence may be irrelevant. All that is required is for the end to be recognized as a suitable substrate for addition. This explains how the ciliate telomere functions in yeast.

**CHROMOSOMES****5.19.17 Telomeres seal the chromosome ends****Key Concepts**

- The protein TRF2 catalyzes a reaction in which the 3' repeating unit of the G+T-rich strand forms a loop by displacing its homologue in an upstream region of the telomere.

Isolated telomeric fragments do not behave as though they contain single-stranded DNA; instead they show aberrant electrophoretic mobility and other properties.

Guanine bases have an unusual capacity to associate with one another. The single-stranded G-rich tail of the telomere can form "quartets" of G residues (594; 595). Each quartet contains 4 guanines that hydrogen bond with one another to form a planar structure. Each guanine comes from the corresponding position in a successive TTAGGG repeating unit. **Figure 19.28** shows an organization based on a recent crystal structure (2861). The quartet that is illustrated represents an association between the first guanine in each repeating unit. It is stacked on top of another quartet that has the same organization, but is formed from the second guanine in each repeating unit. A series of quartets could be stacked like this in a helical manner. While the formation of this structure attests to the unusual properties of the G-rich sequence *in vitro*, it does not of course demonstrate whether the quartet forms *in vivo*.

**Figure 19.28** The crystal structure of a short repeating sequence from the human telomere forms 3 stacked G quartets. The top quartet contains the first G from each repeating unit. This is stacked above quartets that contains the second G (G3, G9, G15, G21) and the third G (G4, G10, G16, G22).

What feature of the telomere is responsible for the stability of the chromosome end?

**Figure 19.29** shows that a loop of DNA forms at the telomere. The absence of any free end may be the crucial feature that stabilizes the end of the chromosome. The average length of the loop in animal cells is 5-10 kb.

**Figure 19.29** A loop forms at the end of chromosomal DNA. Photograph kindly provided by Jack Griffith.

**Figure 19.30** shows that the loop is formed when the 3' single-stranded end of the telomere (TTAGGG)<sub>n</sub> displaces the same sequence in an upstream region of the telomere. This converts the duplex region into a structure like a D-loop, where a series of TTAGGG repeats are displaced to form a single-stranded region, and the tail of the telomere is paired with the homologous strand (597).

**Figure 19.30** The 3' single-stranded end of the telomere (TTAGGG)<sub>n</sub> displaces the homologous repeats from duplex DNA to form a t-loop. The reaction is catalyzed by TRF2.

The reaction is catalyzed by the telomere-binding protein TRF2, which together with other proteins forms a complex that stabilizes the chromosome ends. Its importance in protecting the ends is indicated by the fact the deletion of TRF2 causes chromosome rearrangements to occur (1997; 1998).

## CHROMOSOMES

### 5.19.18 Telomeres are synthesized by a ribonucleoprotein enzyme

---

#### Key Terms

**Telomerase** is the ribonucleoprotein enzyme that creates repeating units of one strand at the telomere, by adding individual bases to the DNA 3' end, as directed by an RNA sequence in the RNA component of the enzyme.

#### Key Concepts

- Telomerase uses the 3' -OH of the G+T telomeric strand to prime synthesis of tandem TTGGGG repeats.
- The RNA component of telomerase has a sequence that pairs with the C+A-rich repeats.
- One of the protein subunits is a reverse transcriptase that uses the RNA as template to synthesis the G+T-rich sequence.

---

The telomere has two functions:

- One is to protect the chromosome end. Any other DNA end – for example, the end generated by a double strand break – becomes a target for repair systems. The cell has to be able to distinguish the telomere.
- The second is to allow the telomere to be extended. Otherwise it would become shorter with each replication cycle (because replication cannot start at the very end).

Proteins that bind to the telomere provide the solution for both problems. In yeast, different sets of proteins solve each problem, but both are bound to the telomere via the same protein, Cdc13 (1999):

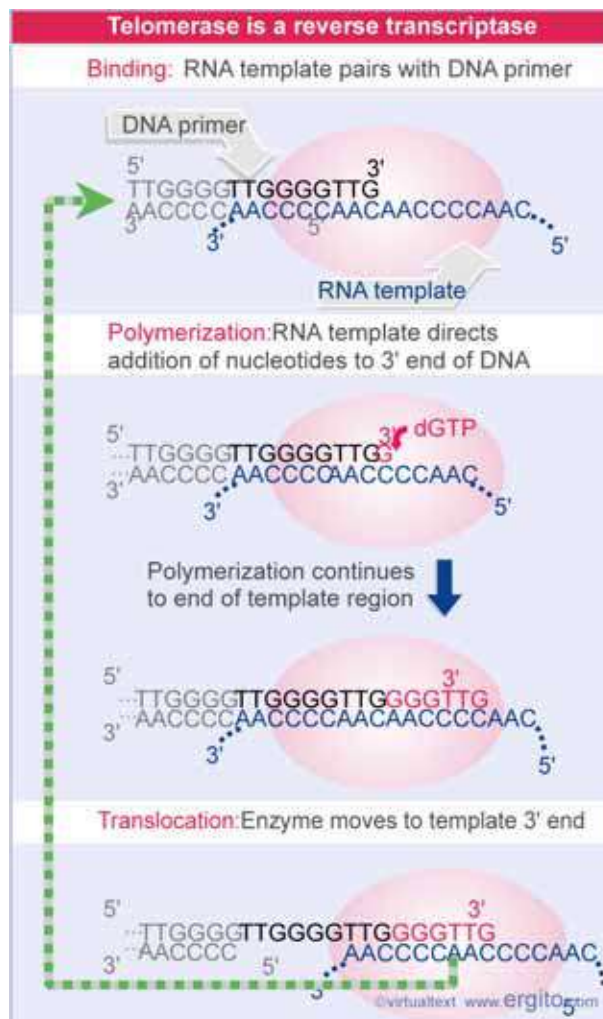

- The Stn1 protein protects against degradation (specifically against any extension of the degradation of the C-A-strand that generates the G-tail).
- A **telomerase** enzyme extends the C-A-rich strand. Its activity is influenced by two proteins that have ancillary roles, such as controlling the length of the extension.

The telomerase uses the 3' -OH of the G+T telomeric strand as a primer for synthesis of tandem TTGGGG repeats. Only dGTP and dTTP are needed for the activity. The telomerase is a large ribonucleoprotein that consists of a templating RNA (coded by *TLC1*) and a protein with catalytic activity (*EST2*). The short RNA component (159 bases long in *Tetrahymena*, 192 bases long in *Euplotes*) includes a

sequence of 15-22 bases that is identical to two repeats of the C-rich repeating sequence. This RNA provides the template for synthesizing the G-rich repeating sequence. The protein component of the telomerase is a catalytic subunit that can act only upon the RNA template provided by the nucleic acid component (for review see 195; 196; 593; 596; 986).

**Figure 19.31** shows the action of telomerase. The enzyme progresses discontinuously: the template RNA is positioned on the DNA primer, several nucleotides are added to the primer, and then the enzyme translocates to begin again. The telomerase is a specialized example of a reverse transcriptase, an enzyme that synthesizes a DNA sequence using an RNA template (see *Molecular Biology 4.17.4 Viral DNA is generated by reverse transcription*). We do not know how the complementary (C-A-rich) strand of the telomere is assembled, but we may speculate that it could be synthesized by using the 3' -OH of a terminal G-T hairpin as a primer for DNA synthesis.

**Figure 19.31** Telomerase positions itself by base pairing between the RNA template and the protruding single-stranded DNA primer. It adds G and T bases one at a time to the primer, as directed by the template. The cycle starts again when one repeating unit has been added.

Telomerase synthesizes the individual repeats that are added to the chromosome ends, but does not itself control the number of repeats. Other proteins are involved in determining the length of the telomere. They can be identified by the *EST1* and *EST3* mutants in yeast that have altered telomere lengths. These proteins may bind telomerase, and influence the length of the telomere by controlling the access of telomerase to its substrate. Proteins that bind telomeres in mammalian cells have been found similarly, but less is known about their functions (for review see 198; 199).

The minimum features required for existence as a chromosome are:

- Telomeres to ensure survival.
- A centromere to support segregation.
- An origin to initiate replication.

All of these elements have been put together to construct a yeast artificial chromosome (YAC). This is a useful method for perpetuating foreign sequences. It turns out that the synthetic chromosome is stable only if it is longer than 20-50 kb. We do not know the basis for this effect, but the ability to construct a synthetic chromosome allows us to investigate the nature of the segregation device in a controlled environment (592).

## CHROMOSOMES

### 5.19.19 Telomeres are essential for survival

Telomerase activity is found in all dividing cells and is generally turned off in terminally differentiated cells that do not divide. **Figure 19.32** shows that if telomerase is mutated in a dividing cell, the telomeres become gradually shorter with each cell division. An example of the effects of such a mutation in yeast are shown in **Figure 19.33**, where the telomere length shortens over ~120 generations from 400 bp to zero (1384).

**Figure 19.32** Mutation in telomerase causes telomeres to shorten in each cell division. Eventual loss of the telomere causes chromosome breaks and rearrangements.

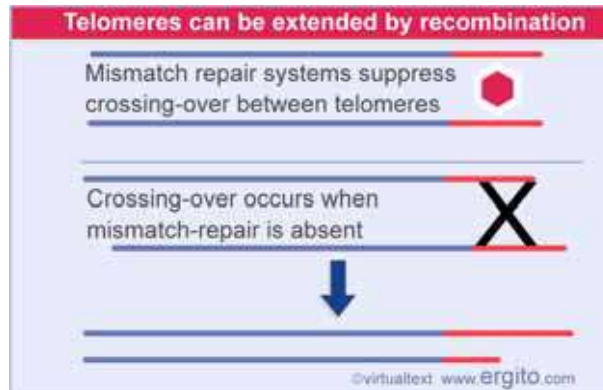

**Figure 19.33** Telomere length is maintained at ~350 bp in wild-type yeast, but a mutant in the *trt1* gene coding for the RNA component of telomerase rapidly shortens its telomeres to zero length. Data kindly provided by Tom Cech and Toru Nakamura (from 1384).

Loss of telomeres has very bad effects. When the telomere length reaches zero, it becomes difficult for the cells to divide successfully. Attempts to divide typically generate chromosome breaks and translocations. This causes an increased rate of mutation (1952). In yeast this is associated with a loss of viability and the culture becomes predominantly occupied by senescent cells (elongated and nondividing, which eventually die; see 1384).

But some cells grow out of the senescing culture. They have acquired the ability to extend their telomeres by an alternative to telomerase activity. The survivors fall into groups (1929). One group have circularized their chromosomes – since they now have no telomeres, they have become independent of telomerase. The other group use unequal crossing-over to extend their telomeres (see **Figure 19.34**). Because the telomere is a repeating structure, it is possible for two telomeres to misalign when chromosomes pair. Recombination between the mispaired regions generates an unequal crossing-over, as shown previously in **Figure 4.1**, when the length of one recombinant chromosome increases, and the length of the other recombinant chromosome decreases.

Cells usually suppress unequal crossing-over because of its potentially deleterious consequences. Two systems are responsible for suppressing crossing-over between telomeres. One is provided by telomere-binding proteins. In yeast, the frequency of recombination between telomeres is increased by deletion of the gene *taz1*, which

codes for a protein that regulates telomerase activity (1929). The second is a general system that undertakes mismatch repair (see *Molecular Biology 4.15 Recombination and repair*). In addition to correcting mismatched base pairs that may arise in DNA, this system suppresses recombination between mispaired regions. As shown in **Figure 19.34**, this includes telomeres. When it is mutated, a greater proportion of telomerase-deficient yeast survive the loss of telomeres because recombination between telomeres generates some chromosomes with longer telomeres (1930).

**Figure 19.34** Crossing-over in telomeric regions is usually suppressed by mismatch-repair systems, but can occur when they are mutated. An unequal crossing-over event extends the telomere of one of the products, allowing the chromosome to survive in the absence of telomerase.

When eukaryotic cells are placed in culture, they usually divide for a fixed number of generations and then enter senescence. The reason appears to be a decline in telomere length because of the absence of telomerase expression (see *Molecular Biology 6.30.24 Telomere shortening causes cell senescence*). Cells enter a crisis from which some emerge, but typically with chromosome rearrangements that have resulted from lack of protection of chromosome ends. These rearrangements may cause mutations that contribute to the tumorigenic state. The absence of telomerase expression in this situation is due to failure to express the gene, and reactivation of telomerase is one of the mechanisms by which these cells then survive continued culture (this of course was not an option in the yeast experiments in which the gene had been deleted).

## CHROMOSOMES

### 5.19.20 Summary

---

The genetic material of all organisms and viruses takes the form of tightly packaged nucleoprotein. Some virus genomes are inserted into preformed virions, while others assemble a protein coat around the nucleic acid. The bacterial genome forms a dense nucleoid, with ~20% protein by mass, but details of the interaction of the proteins with DNA are not known. The DNA is organized into ~100 domains that maintain independent supercoiling, with a density of unrestrained supercoils corresponding to ~1 / 100-200 bp. Interphase chromatin and metaphase chromosomes both appear to be organized into large loops. Each loop may be an independently supercoiled domain. The bases of the loops are connected to a metaphase scaffold or to the nuclear matrix by specific DNA sites.

Transcriptionally active sequences reside within the euchromatin that comprises the majority of interphase chromatin. The regions of heterochromatin are packaged ~5-10× more compactly, and are transcriptionally inert. All chromatin becomes densely packaged during cell division, when the individual chromosomes can be distinguished. The existence of a reproducible ultrastructure in chromosomes is indicated by the production of G-bands by treatment with Giemsa stain. The bands are very large regions, ~10<sup>7</sup> bp, that can be used to map chromosomal translocations or other large changes in structure.

Lampbrush chromosomes of amphibians and polytene chromosomes of insects have unusually extended structures, with packing ratios <100. Polytene chromosomes of *D. melanogaster* are divided into ~5000 bands, varying in size by an order of magnitude, with an average of ~25 kb. Transcriptionally active regions can be visualized in even more unfolded ("puffed") structures, in which material is extruded from the axis of the chromosome. This may resemble the changes that occur on a smaller scale when a sequence in euchromatin is transcribed.

The centromeric region contains the kinetochore, which is responsible for attaching a chromosome to the mitotic spindle. The centromere often is surrounded by heterochromatin. Centromeric sequences have been identified only in yeast *S. cerevisiae*, where they consist of short conserved elements, CDE-I and CDE-III that binds CBF1 and the CBF3 complex, respectively, and a long A·T-rich region called CDE-II that binds Cse4p to form a specialized structure in chromatin. Another group of proteins that binds to this assembly provides the connection to microtubules.

Telomeres make the ends of chromosomes stable. Almost all known telomeres consist of multiple repeats in which one strand has the general sequence C (A/T)<sub>n</sub>, where n>1 and m = 1-4. The other strand, G (T/A)<sub>m</sub>, has a single protruding "end" that provides a template for addition of individual "bases" in defined order. The enzyme telomere transferase is a ribonucleoprotein, whose RNA component provides the template for synthesizing the G-rich strand. This overcomes the problem of the inability to replicate at the very end of a duplex. The telomere stabilizes the chromosome end because the overhanging single strand G (T/A)<sub>m</sub> displaces its homologue in earlier repeating units in the telomere to form a "loop", so there are no free ends.

## NUCLEOSOMES

### 5.20.1 Introduction

---

#### Key Terms

The **nucleosome** is the basic structural subunit of chromatin, consisting of ~200 bp of DNA and an octamer of histone proteins.

**Histones** are conserved DNA-binding proteins that form the basic subunit of chromatin in eukaryotes. Histones H2A, H2B, H3, H4 form an octameric core around which DNA coils to form a nucleosome. Histone H1 is external to the nucleosome.

A **nonhistone** is any structural protein found in a chromosome except one of the histones.

---

Chromatin has a compact organization in which most DNA sequences are structurally inaccessible and functionally inactive. Within this mass is the minority of active sequences. What is the general structure of chromatin, and what is the difference between active and inactive sequences? The high overall packing ratio of the genetic material immediately suggests that DNA cannot be directly packaged into the final structure of chromatin. There must be *hierarchies* of organization.

*The fundamental subunit of chromatin has the same type of design in all eukaryotes.* The **nucleosome** contains ~200 bp of DNA, organized by an octamer of small, basic proteins into a bead-like structure. The protein components are **histones**. They form an interior core; the DNA lies on the surface of the particle. Nucleosomes are an invariant component of euchromatin and heterochromatin in the interphase nucleus, and of mitotic chromosomes. The nucleosome provides the first level of organization, giving a packing ratio of ~6. Its components and structure are well characterized.

The second level of organization is the coiling of the series of nucleosomes into a helical array to constitute the fiber of diameter ~30 nm that is found in both interphase chromatin and mitotic chromosomes (see **Figure 19.11**). In chromatin this brings the packing ratio of DNA to ~40. The structure of this fiber requires additional proteins, but is not well defined.

The final packing ratio is determined by the third level of organization, the packaging of the 30 nm fiber itself. This gives an overall packing ratio of ~1000 in euchromatin, cyclically interchangeable with packing into mitotic chromosomes to achieve an overall ratio of ~10,000. Heterochromatin generally has a packing ratio ~10,000 in both interphase and mitosis.

We need to work through these levels of organization to characterize the events involved in cyclical packaging, replication, and transcription. We assume that association with additional proteins, or modifications of existing chromosomal proteins, are involved in changing the structure of chromatin. We do not know the individual targets for controlling cyclical packaging. Both replication and

transcription require unwinding of DNA, and thus must involve an unfolding of the structure that allows the relevant enzymes to manipulate the DNA. This is likely to involve changes in all levels of organization.

When chromatin is replicated, the nucleosomes must be reproduced on both daughter duplex molecules. As well as asking how the nucleosome itself is assembled, we must inquire what happens to other proteins present in chromatin. Since replication disrupts the structure of chromatin, it both poses a problem for maintaining regions with specific structure and offers an opportunity to change the structure.

The mass of chromatin contains up to twice as much protein as DNA. Approximately half of the protein mass is accounted for by the nucleosomes. The mass of RNA is < 10% of the mass of DNA. Much of the RNA consists of nascent transcripts still associated with the template DNA.

The **nonhistones** include all the proteins of chromatin except the histones. They are more variable between tissues and species, and they comprise a smaller proportion of the mass than the histones. They also comprise a much larger number of proteins, so that any individual protein is present in amounts much smaller than any histone.

The functions of nonhistone proteins include control of gene expression and higher-order structure. So RNA polymerase may be considered to be a prominent nonhistone. The HMG (high-mobility group) proteins comprise a discrete and well-defined subclass of nonhistones (at least some of which are transcription factors). A major problem in working with other nonhistones is that they tend to be contaminated with other nuclear proteins, and so far it has proved difficult to obtain those nonhistone proteins responsible for higher-order structures.

## NUCLEOSOMES

### 5.20.2 The nucleosome is the subunit of all chromatin

---

#### Key Terms

**Micrococcal nuclease** is an endonuclease that cleaves DNA; in chromatin, DNA is cleaved preferentially between nucleosomes.

A **core histone** is one of the four types (H2A, H2B, H3, H4) found in the core particle derived from the nucleosome (this excludes histone H1).

#### Key Concepts

- Micrococcal nuclease releases individual nucleosomes from chromatin as 11S particles.
  - A nucleosome contains ~200 bp of DNA, 2 copies of each core histone (H2A, H2B, H3, H4), and 1 copy of H1.
  - DNA is wrapped around the outside surface of the protein octamer.
- 

When interphase nuclei are suspended in a solution of low ionic strength, they swell and rupture to release fibers of chromatin. **Figure 20.1** shows a lysed nucleus in which fibers are streaming out. In some regions, the fibers consist of tightly packed material, but in regions that have become stretched, they can be seen to consist of discrete particles. These are the nucleosomes. In especially extended regions, individual nucleosomes are connected by a fine thread, a free duplex of DNA. A *continuous duplex thread of DNA runs through the series of particles.*

**Figure 20.1** Chromatin spilling out of lysed nuclei consists of a compactly organized series of particles. The bar is 100 nm. Photograph kindly provided by Pierre Chambon.

Individual nucleosomes can be obtained by treating chromatin with the endonuclease **micrococcal nuclease**. It cuts the DNA thread at the junction between nucleosomes. First, it releases groups of particles; finally, it releases single nucleosomes. Individual nucleosomes can be seen in **Figure 20.2** as compact particles. They sediment at ~11S.

**Figure 20.2** Individual nucleosomes are released by digestion of chromatin with micrococcal nuclease. The bar is 100 nm. Photograph kindly provided by Pierre Chambon.

*The nucleosome contains ~200 bp of DNA associated with a histone octamer that*

consists of two copies each of H2A, H2B, H3, and H4. These are known as the **core histones**. Their association is illustrated diagrammatically in **Figure 20.3**. This model explains the stoichiometry of the core histones in chromatin: H2A, H2B, H3, and H4 are present in equimolar amounts, with 2 molecules of each per ~200 bp of DNA (598; for review see 200).

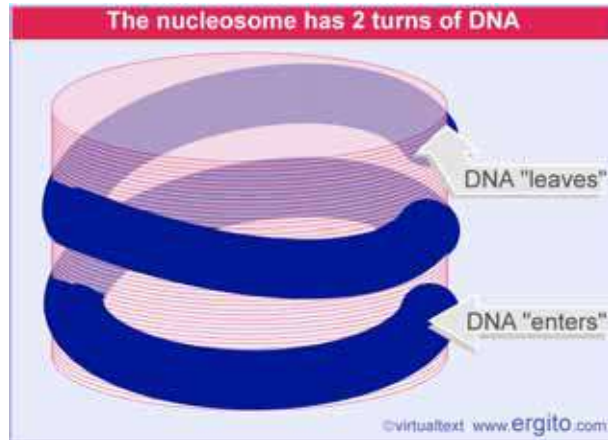

**Figure 20.3** The nucleosome consists of approximately equal masses of DNA and histones (including H1). The predicted mass of the nucleosome is 262 kD.

Histones H3 and H4 are among the most conserved proteins known. This suggests that their functions are identical in all eukaryotes. The types of H2A and H2B can be recognized in all eukaryotes, but show appreciable species-specific variation in sequence.

Histone H1 comprises a set of closely related proteins that show appreciable variation between tissues and between species (and are absent from yeast). The role of H1 is different from the core histones. It is present in half the amount of a core histone and can be extracted more readily from chromatin (typically with dilute salt [0.5 M] solution). *The H1 can be removed without affecting the structure of the nucleosome, which suggests that its location is external to the particle.*

The shape of the nucleosome corresponds to a flat disk or cylinder, of diameter 11 nm and height 6 nm. The length of the DNA is roughly twice the ~34 nm circumference of the particle. The DNA follows a symmetrical path around the octamer. **Figure 20.4** shows the DNA path diagrammatically as a helical coil that makes two turns around the cylindrical octamer. Note that the DNA "enters" and "leaves" the nucleosome at points close to one another. Histone H1 may be located in this region (see *Molecular Biology 5.20.4 Nucleosomes have a common structure*) (600).

**Figure 20.4** The nucleosome may be a cylinder with DNA organized into two turns around the surface.

Considering this model in terms of a cross-section through the nucleosome, in **Figure 20.5** we see that the two circumferences made by the DNA lie close to one another. The height of the cylinder is 6 nm, of which 4 nm is occupied by the two turns of DNA (each of diameter 2 nm).

**Figure 20.5** The two turns of DNA on the nucleosome lie close together.

The pattern of the two turns has a possible functional consequence. Since one turn around the nucleosome takes ~80 bp of DNA, two points separated by 80 bp in the free double helix may actually be close on the nucleosome surface, as illustrated in **Figure 20.6** (for review see 201).

**Figure 20.6** Sequences on the DNA that lie on different turns around the nucleosome may be close together.

**NUCLEOSOMES****5.20.3 DNA is coiled in arrays of nucleosomes****Key Concepts**

- >95% of the DNA is recovered in nucleosomes or multimers when micrococcal nuclease cleaves DNA of chromatin.
- The length of DNA per nucleosome varies for individual tissues in a range from 154-260 bp.

When chromatin is digested with the enzyme micrococcal nuclease, the DNA is cleaved into integral multiples of a unit length. Fractionation by gel electrophoresis reveals the "ladder" presented in **Figure 20.7**. Such ladders extend for ~10 steps, and the unit length, determined by the increments between successive steps, is ~200 bp.

**Figure 20.7** Micrococcal nuclease digests chromatin in nuclei into a multimeric series of DNA bands that can be separated by gel electrophoresis. Photograph kindly provided by Markus Noll.

**Figure 20.8** shows that the ladder is generated by groups of nucleosomes. When nucleosomes are fractionated on a sucrose gradient, they give a series of discrete peaks that correspond to monomers, dimers, trimers, etc. When the DNA is extracted from the individual fractions and electrophoresed, each fraction yields a band of DNA whose size corresponds with a step on the micrococcal nuclease ladder. The monomeric nucleosome contains DNA of the unit length, the nucleosome dimer contains DNA of twice the unit length, and so on (599).

**Figure 20.8** Each multimer of nucleosomes contains the appropriate number of unit lengths of DNA. Photograph kindly provided by John Finch.

So each step on the ladder represents the DNA derived from a discrete number of nucleosomes. *We therefore take the existence of the 200 bp ladder in any chromatin to indicate that the DNA is organized into nucleosomes.* The micrococcal ladder is generated when only ~2% of the DNA in the nucleus is rendered acid-soluble (degraded to small fragments) by the enzyme. *So a small proportion of the DNA is specifically attacked; it must represent especially susceptible regions.*

When chromatin is spilled out of nuclei, we often see a series of nucleosomes connected by a thread of free DNA (the beads on a string). However, the need for tight packaging of DNA *in vivo* suggests that probably there is usually little (if any)

free DNA.

This view is confirmed by the fact that *>95% of the DNA of chromatin can be recovered in the form of the 200 bp ladder*. Almost all DNA must therefore be organized in nucleosomes. In their natural state, nucleosomes are likely to be closely packed, with DNA passing directly from one to the next. Free DNA is probably generated by the loss of some histone octamers during isolation.

The length of DNA present in the nucleosome varies somewhat from the "typical" value of 200 bp. The chromatin of any particular cell type has a characteristic average value ( $\pm 5$  bp). The average most often is between 180 and 200, but there are extremes as low as 154 bp (in a fungus) or as high as 260 bp (in a sea urchin sperm). The average value may be different in individual tissues of the adult organism. And there can be differences between different parts of the genome in a single cell type. Variations from the genome average include tandemly repeated sequences, such as clusters of 5S RNA genes.

## NUCLEOSOMES

### 5.20.4 Nucleosomes have a common structure

---

#### Key Concepts

- Nucleosomal DNA is divided into the core DNA and linker DNA depending on its susceptibility to micrococcal nuclease.
- The core DNA is the length of 146 bp that is found on the core particles produced by prolonged digestion with micrococcal nuclease.
- Linker DNA is the region of 8-114 bp that is susceptible to early cleavage by the enzyme.
- Changes in the length of linker DNA account for the variation in total length of nucleosomal DNA.
- H1 is associated with linker DNA and may lie at the point where DNA enters and leaves the nucleosome.

---

A common structure underlies the varying amount of DNA that is contained in nucleosomes of different sources. The association of DNA with the histone octamer forms a core particle containing 146 bp of DNA, irrespective of the total length of DNA in the nucleosome. The variation in total length of DNA per nucleosome is superimposed on this basic core structure.

The core particle is defined by the effects of micrococcal nuclease on the nucleosome monomer. The initial reaction of the enzyme is to cut between nucleosomes, but if it is allowed to continue after monomers have been generated, then it proceeds to digest some of the DNA of the individual nucleosome. This occurs by a reaction in which DNA is "trimmed" from the ends of the nucleosome.

The length of the DNA is reduced in discrete steps, as shown in **Figure 20.9**. With rat liver nuclei, the nucleosome monomers initially have 205 bp of DNA. Then some monomers are found in which the length of DNA has been reduced to ~165 bp. Finally this is reduced to the length of the DNA of the core particle, 146 bp. (The core is reasonably stable, but continued digestion generates a "limit digest", in which the longest fragments are the 146 bp DNA of the core, while the shortest are as small as 20 bp.)

**Figure 20.9** Micrococcal nuclease reduces the length of nucleosome monomers in discrete steps. Photograph kindly provided by Roger Kornberg.

This analysis suggests that the nucleosomal DNA can be divided into two regions:

- Core DNA has an invariant length of 146 bp, and is relatively resistant to digestion by nucleases.
- Linker DNA comprises the rest of the repeating unit. Its length varies from as little as 8 bp to as much as 114 bp per nucleosome.

The sharp size of the band of DNA generated by the initial cleavage with micrococcal nuclease suggests that the region immediately available to the enzyme is restricted. It represents only part of each linker. (If the entire linker DNA were susceptible, the band would range from 146 bp to >200 bp.) But once a cut has been made in the linker DNA, the rest of this region becomes susceptible, and it can be removed relatively rapidly by further enzyme action. The connection between nucleosomes is represented in **Figure 20.10**.

**Figure 20.10** Micrococcal nuclease initially cleaves between nucleosomes. Mononucleosomes typically have ~200 bp DNA. End-trimming reduces the length of DNA first to ~165 bp, and then generates core particles with 146 bp.

Core particles have properties similar to those of the nucleosomes themselves, although they are smaller. Their shape and size are similar to nucleosomes, which suggests that the essential geometry of the particle is established by the interactions between DNA and the protein octamer in the core particle. Because core particles are more readily obtained as a homogeneous population, they are often used for structural studies in preference to nucleosome preparations. (Nucleosomes tend to vary because it is difficult to obtain a preparation in which there has been no end-trimming of the DNA.)

What is the physical nature of the core and the linker regions? *These terms were introduced as operational definitions that describe the regions in terms of their relative susceptibility to nuclease treatment.* This description does not make any implication about their actual structure. However, it turns out that the major part of the core DNA is tightly curved on the nucleosome, whereas the terminal regions of the core and the linker regions are more extended (see *Molecular Biology 5.20.5 DNA structure varies on the nucleosomal surface*).

The existence of linker DNA depends on factors extraneous to the four core histones. Reconstitution experiments *in vitro* show that histones have an intrinsic ability to organize DNA into core particles, but do not form nucleosomes with the proper unit length. The degree of supercoiling of the DNA is an important factor. Histone H1 and/or nonhistone proteins influence the length of linker DNA associated with the histone octamer in a natural series of nucleosomes. And "assembly proteins" that are not part of the nucleosome structure are involved *in vivo* in constructing nucleosomes from histones and DNA (see *Molecular Biology 5.20.10 Reproduction of chromatin requires assembly of nucleosomes*).

Where is histone H1 located? The H1 is lost during the degradation of nucleosome monomers. It can be retained on monomers that still have 165 bp of DNA; but is always lost with the final reduction to the 146 bp core particle. This suggests that H1 could be located in the region of the linker DNA immediately adjacent to the core DNA.

If H1 is located at the linker, it could "seal" the DNA in the nucleosome by binding at the point where the nucleic acid enters and leaves (see **Figure 20.4**). The idea that

H1 lies in the region joining adjacent nucleosomes is consistent with old results that H1 is removed the most readily from chromatin, and that H1-depleted chromatin is more readily "solubilized". And it is easier to obtain a stretched-out fiber of beads on a string when the H1 has been removed (618).

**NUCLEOSOMES****5.20.5 DNA structure varies on the nucleosomal surface****Key Concepts**

- 1.65 turns of DNA are wound round the histone octamer.
- The structure of the DNA is altered so that it has an increased number of base pairs/turn in the middle, but a decreased number at the ends.

The exposure of DNA on the surface of the nucleosome explains why it is accessible to cleavage by certain nucleases. The reaction with nucleases that attack single strands has been especially informative. The enzymes DNAase I and DNAase II make single-strand nicks in DNA; they cleave a bond in one strand, but the other strand remains intact at this point. So no effect is visible in the double-stranded DNA. But upon denaturation, short fragments are released instead of full-length single strands. If the DNA has been labeled at its ends, the end fragments can be identified by autoradiography as summarized in **Figure 20.11**. (This is exactly analogous to the restriction mapping technique shown in **Figure S 37**.)

**Figure 20.11** Nicks in double-stranded DNA are revealed by fragments when the DNA is denatured to give single strands. If the DNA is labeled at (say) 5' ends, only the 5' fragments are visible by autoradiography. The size of the fragment identifies the distance of the nick from the labeled end.

When DNA is free in solution, it is nicked (relatively) at random. The DNA on nucleosomes also can be nicked by the enzymes, *but only at regular intervals*. When the points of cutting are determined by using radioactively end-labeled DNA and then DNA is denatured and electrophoresed, a ladder of the sort displayed in **Figure 20.12** is obtained.

**Figure 20.12** Sites for nicking lie at regular intervals along core DNA, as seen in a DNAase I digest of nuclei. Photograph kindly provided by Leonard Lutter.

The interval between successive steps on the ladder is 10-11 bases. The ladder extends for the full distance of core DNA. The cleavage sites are numbered as S1 through S13 (where S1 is ~10 bases from the labeled 5' end, S2 is ~20 bases from it, and so on). Their positions relative to the DNA superhelix are illustrated in **Figure 20.13**.

**Figure 20.13** Two numbering schemes divide core particle DNA into 10 bp segments. Sites may be numbered S1 to S13 from one end; or taking S7 to identify coordinate 0 of the dyad symmetry, they may be numbered -7 to +7.

Not all sites are cut with equal frequency: some are cut rather efficiently, others are cut scarcely at all. The enzymes DNAase I and DNAase II generate the same ladder, although with some differences in the intensities of the bands. This shows that the pattern of cutting represents a unique series of targets in DNA, determined by its organization, with only some slight preference for particular sites imposed by the individual enzyme. The same cutting pattern is obtained by cleaving with a hydroxyl radical, which argues that the pattern reflects the structure of the DNA itself, rather than any sequence preference.

The sensitivity of nucleosomal DNA to nucleases is analogous to a footprinting experiment. So we can assign the lack of reaction at particular target sites to the structure of the nucleosome, in which certain positions on DNA are rendered inaccessible.

Since there are two strands of DNA in the core particle, in an end-labeling experiment both 5' (or both 3') ends are labeled, one on each strand. So the cutting pattern includes fragments derived from both strands. This is implied in **Figure 20.11**, where each labeled fragment is derived from a different strand. The corollary is that, in an experiment, each labeled band in fact represents two fragments, generated by cutting the *same* distance from *either* of the labeled ends.

How then should we interpret discrete preferences at particular sites? One view is that the path of DNA on the particle is symmetrical (about a horizontal axis through the nucleosome drawn in **Figure 20.4**). So if (for example) no 80-base fragment is generated by DNAase I, this must mean that the position at 80 bases from the 5' end of *either* strand is not susceptible to the enzyme. The second numbering scheme used in **Figure 20.13** reflects this view, and identifies  $S_7 = \text{site } 0$  as the center of symmetry.

When DNA is immobilized on a flat surface, sites are cut with a regular separation. **Figure 20.14** suggests that this reflects the recurrence of the exposed site with the helical periodicity of B-form DNA. The cutting periodicity (the spacing between cleavage points) coincides with, indeed, is a reflection of, the structural periodicity (the number of base pairs per turn of the double helix). So the distance between the sites corresponds to the number of base pairs per turn. Measurements of this type suggest that the average value for double-helical B-type DNA is 10.5 bp/turn.

**Figure 20.14** The most exposed positions on DNA recur with a periodicity that reflects the structure of the double helix. (For clarity, sites are shown for only one strand.)

What is the nature of the target sites on the nucleosome? **Figure 20.15** shows that each site has 3-4 positions at which cutting occurs; that is, the cutting site is defined  $\pm 2$  bp. So a cutting site represents a short stretch of bonds on both strands, exposed to nuclease action over 3-4 base pairs. The relative intensities indicate that some sites

are preferred to others.

**Figure 20.15** High resolution analysis shows that each site for DNAase I consists of several adjacent susceptible phosphodiester bonds as seen in this example of sites S4 and S5 analyzed in end-labeled core particles. Photograph kindly provided by Leonard Lutter.

From this pattern, we can calculate the "average" point that is cut. At the ends of the DNA, pairs of sites from S1 to S4 or from S10 to S13 lie apart a distance of 10.0 bases each. In the center of the particle, the separation from sites S4 to S10 is 10.7 bases. (Because this analysis deals with *average* positions, sites need not lie an integral number of bases apart.)

The variation in cutting periodicity along the core DNA (10.0 at the ends, 10.7 in the middle) means that there is variation in the structural periodicity of core DNA. The DNA has more bp/turn than its solution value in the middle, but has fewer bp/turn at the ends. The average periodicity over the nucleosome is only 10.17 bp/turn, which is significantly less than the 10.5 bp/turn of DNA in solution.

The crystal structure of the core particle suggests that DNA is organized as a flat superhelix, with 1.65 turns wound around the histone octamer. The pitch of the superhelix varies, with a discontinuity in the middle. Regions of high curvature are arranged symmetrically, and occur at positions  $\pm 1$  and  $\pm 4$ . These correspond to S6 and S8, and to S3 and S11, which are the sites least sensitive to DNAase I (for review see 204).

A high resolution structure of the nucleosome core shows in detail how the structure of DNA is distorted (4003). Most of the supercoiling occurs in the central 129 bp, which are coiled into 1.59 left-handed superhelical turns with a diameter of 80

(only 4 Å the diameter of the DNA duplex itself). The terminal sequences on either end make only a very small contribution to the overall curvature.

The central 129 bp are in the form of B-DNA, but with a substantial curvature that is needed to form the superhelix. The major groove is smoothly bent, but the minor groove has abrupt kinks. These conformational changes may explain why the central part of nucleosomal DNA is not usually a target for binding by regulatory proteins, which typically bind to the terminal parts of the core DNA or to the linker sequences.

## NUCLEOSOMES

### 5.20.6 The periodicity of DNA changes on the nucleosome

---

#### Key Concepts

- ~0.6 negative turns of DNA are absorbed by the change in bp/turn from 10.5 in solution to an average of 10.2 on the nucleosomal surface, explaining the linking number paradox.
- 

Some insights into the structure of nucleosomal DNA emerge when we compare predictions for supercoiling in the path that DNA follows with actual measurements of supercoiling of nucleosomal DNA. Much work on the structure of sets of nucleosomes has been carried out with the virus SV40. The DNA of SV40 is a circular molecule of 5200 bp, with a contour length ~1500 nm. In both the virion and infected nucleus, it is packaged into a series of nucleosomes, called a minichromosome.

As usually isolated, the contour length of the minichromosome is ~210 nm, corresponding to a packing ratio of ~7 (essentially the same as the ~6 of the nucleosome itself). Changes in the salt concentration can convert it to a flexible string of beads with a much lower overall packing ratio. This emphasizes the point that nucleosome strings can take more than one form *in vitro*, depending on the conditions.

The degree of supercoiling on the individual nucleosomes of the minichromosome can be measured as illustrated in **Figure 20.16**. First, the free supercoils of the minichromosome itself are relaxed, so that the nucleosomes form a circular string with a superhelical density of 0. Then the histone octamers are extracted. This releases the DNA to follow a free path. Every supercoil that was present but restrained in the minichromosome will appear in the deproteinized DNA as -1 turn. So now the total number of supercoils in the SV40 DNA is measured.

**Figure 20.16** The supercoils of the SV40 minichromosome can be relaxed to generate a circular structure, whose loss of histones then generates supercoils in the free DNA.

The observed value is close to the number of nucleosomes. The reverse result is seen when nucleosomes are assembled *in vitro* on to a supercoiled SV40 DNA: the formation of each nucleosome removes  $\sim 1$  negative supercoil.

So the DNA follows a path on the nucleosomal surface that generates  $\sim 1$  negative supercoiled turn when the restraining protein is removed. But the path that DNA follows on the nucleosome corresponds to  $-1.67$  superhelical turns (see **Figure 20.4**). This discrepancy is sometimes called the linking number paradox .

The discrepancy is explained by the difference between the 10.17 average bp/turn of nucleosomal DNA and the 10.5 bp/turn of free DNA. In a nucleosome of 200 bp, there are  $200/10.17 = 19.67$  turns. When DNA is released from the nucleosome, it now has  $200/10.5 = 19.0$  turns. The path of the less tightly wound DNA on the nucleosome absorbs  $-0.67$  turns, and this explains the discrepancy between the physical path of  $-1.67$  and the measurement of  $-1.0$  superhelical turns. In effect, some of the torsional strain in nucleosomal DNA goes into increasing the number of bp/turn; only the rest is left to be measured as a supercoil (for review see 206).

## NUCLEOSOMES

### 5.20.7 The path of nucleosomes in the chromatin fiber

---

#### Key Terms

The **10 nm fiber** is a linear array of nucleosomes, generated by unfolding from the natural condition of chromatin.

The **30 nm fiber** is a coiled coil of nucleosomes. It is the basic level of organization of nucleosomes in chromatin.

#### Key Concepts

- 10 nm chromatin fibers are unfolded from 30 nm fibers and consist of a string of nucleosomes.
- 30 nm fibers have 6 nucleosomes/turn, organized into a solenoid.
- Histone H1 is required for formation of the 30 nm fiber.

---

When chromatin is examined in the electron microscope, two types of fibers are seen: the 10 nm fiber and 30 nm fiber. They are described by the approximate diameter of the thread (that of the 30 nm fiber actually varies from ~25–30 nm).

The **10 nm fiber** is essentially a continuous string of nucleosomes. Sometimes, indeed, it runs continuously into a more stretched-out region in which nucleosomes are seen as a string of beads, as indicated in the example of **Figure 20.17**. The 10 nm fibril structure is obtained under conditions of low ionic strength and does not require the presence of histone H1. This means that it is a function strictly of the nucleosomes themselves. It may be visualized essentially as a continuous series of nucleosomes, as in **Figure 20.18**. It is not clear whether such a structure exists *in vivo* or is simply a consequence of unfolding during extraction *in vitro*.

**Figure 20.17** The 10 nm fiber in partially unwound state can be seen to consist of a string of nucleosomes. Photograph kindly provided by Barbara Hamkalo.

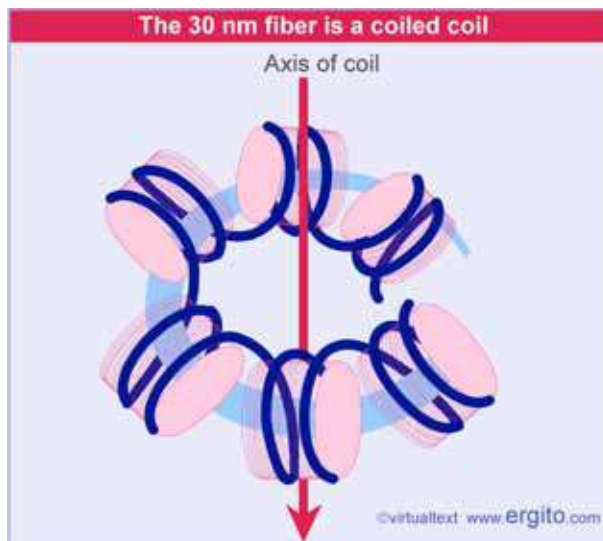

**Figure 20.18** The 10 nm fiber is a continuous string of nucleosomes.

When chromatin is visualized in conditions of greater ionic strength the **30 nm fiber** is obtained. An example is given in **Figure 20.19**. The fiber can be seen to have an underlying coiled structure. It has ~6 nucleosomes for every turn, which corresponds to a packing ratio of 40 (that is, each  $\mu\text{m}$  along the axis of the fiber contains 40  $\mu\text{m}$  of DNA). The presence of H1 is required. This fiber is the basic constituent of both interphase chromatin and mitotic chromosomes.

**Figure 20.19** The 30 nm fiber has a coiled structure. Photograph kindly provided by Barbara Hamkalo.

The most likely arrangement for packing nucleosomes into the fiber is a solenoid, illustrated in **Figure 20.20**. The nucleosomes turn in a helical array, with an angle of  $\sim 60^\circ$  between the faces of adjacent nucleosomes (for review see 205).

**Figure 20.20** The 30 nm fiber may have a helical coil of 6 nucleosomes per turn, organized radially.

The 30 nm and 10 nm fibers can be reversibly converted by changing the ionic strength. This suggests that the linear array of nucleosomes in the 10 nm fiber is coiled into the 30 nm structure at higher ionic strength and in the presence of H1.

Although the presence of H1 is necessary for the formation of the 30 nm fiber, information about its location is conflicting. Its relative ease of extraction from chromatin seems to argue that it is present on the outside of the superhelical fiber axis. But diffraction data, and the fact that it is harder to find in 30 nm fibers than in 10 nm fibers that retain it, would argue for an interior location.

How do we get from the 30 nm fiber to the specific structures displayed in mitotic chromosomes? And is there any further specificity in the arrangement of interphase chromatin; do particular regions of 30 nm fibers bear a fixed relationship to one another or is their arrangement random?

## NUCLEOSOMES

### 5.20.8 Organization of the histone octamer

---

#### Key Terms

The **histone fold** is a motif found in all four core histones in which three  $\alpha$ -helices are connected by two loops.

#### Key Concepts

- The histone octamer has a kernel of a  $H3_2 \cdot H4_2$  tetramer associated with two  $H2A \cdot H2B$  dimers.
- Each histone is extensively interdigitated with its partner.
- All core histones have the structural motif of the histone fold. N-terminal tails extend out of the nucleosome.

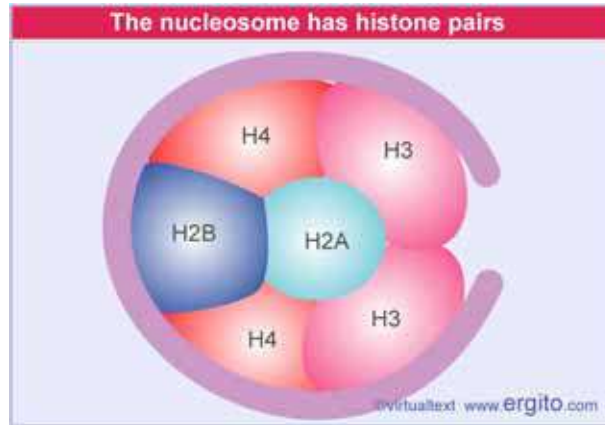

---

So far we have considered the construction of the nucleosome from the perspective of how the DNA is organized on the surface. From the perspective of protein, we need to know how the histones interact with each other and with DNA. Do histones react properly only in the presence of DNA, or do they possess an independent ability to form octamers? Most of the evidence about histone-histone interactions is provided by their abilities to form stable complexes, and by crosslinking experiments with the nucleosome.

The core histones form two types of complexes. H3 and H4 form a tetramer ( $H3_2 \cdot H4_2$ ). Various complexes are formed by H2A and H2B, in particular a dimer ( $H2A \cdot H2B$ ).

Intact histone octamers can be obtained either by extraction from chromatin or (with more difficulty) by letting histones associate *in vitro* under conditions of high-salt and high-protein concentration. The octamer can dissociate to generate a hexamer of histones that has lost an  $H2A \cdot H2B$  dimer. Then the other  $H2A \cdot H2B$  dimer is lost separately, leaving the  $H3_2 \cdot H4_2$  tetramer. This argues for a form of organization in which the nucleosome has a central "kernel" consisting of the  $H3_2 \cdot H4_2$  tetramer. The tetramer can organize DNA *in vitro* into particles that display some of the properties of the core particle.

Crosslinking studies extend these relationships to show which pairs of histones lie near each other in the nucleosome. (A difficulty with such data is that usually only a small proportion of the proteins becomes crosslinked, so it is necessary to be cautious in deciding whether the results typify the major interactions.) From these data, a model has been constructed for the organization of the nucleosome. It is shown in diagrammatic form in **Figure 20.21**.

**Figure 20.21** In a symmetrical model for the nucleosome, the  $H3_2 \cdot H4_2$  tetramer provides a kernel for the shape. One  $H2A \cdot H2B$  dimer can be seen in the top view; the other is underneath.

Structural studies show that the overall shape of the isolated histone octamer is similar to that of the core particle. This suggests that the histone-histone interactions establish the general structure. The positions of the individual histones have been assigned to regions of the octameric structure on the basis of their interaction behavior and response to crosslinking.

The crystal structure (at 3.1 Å resolution) suggests the model for the histone octamer shown in **Figure 20.22**. Tracing the paths of the individual polypeptide backbones in the crystal structure suggests that the histones are not organized as individual globular proteins, but that each is interdigitated with its partner, H3 with H4, and H2A with H2B. So the model distinguishes the  $H3_2 \cdot H4_2$  tetramer (white) from the  $H2A \cdot H2B$  dimers (blue), but does not show individual histones.

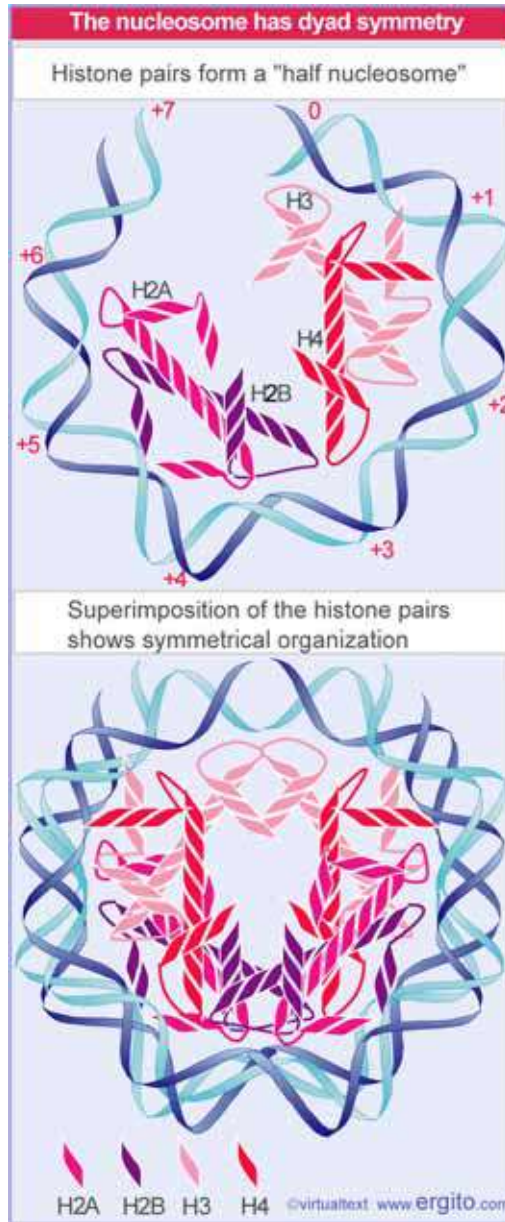

**Figure 20.22** The crystal structure of the histone core octamer is represented in a space-filling model with the H3<sub>2</sub>-H4<sub>2</sub> tetramer shown in white and the H2A-H2B dimers shown in blue. Only one of the H2A-H2B dimers is visible in the top view, because the other is hidden underneath. The potential path of the DNA is shown in the top view as a narrow tube (one quarter the diameter of DNA), and in the side view by the parallel lines in a 20 Å wide bundle. Photographs kindly provided by Evangelos Moudrianakis.

The top view represents the same perspective that was illustrated schematically in **Figure 20.21**. The H3<sub>2</sub>-H4<sub>2</sub> tetramer accounts for the diameter of the octamer. It forms the shape of a horseshoe. The H2A-H2B pairs fit in as two dimers, but only one can be seen in this view. The side view represents the same perspective that was illustrated in **Figure 20.4**. Here the responsibilities of the H3<sub>2</sub>-H4<sub>2</sub> tetramer and of the separate H2A-H2B dimers can be distinguished. The protein forms a sort of spool, with a superhelical path that could correspond to the binding site for DNA, which would be wound in almost two full turns in a nucleosome. The model displays two fold symmetry about an axis that would run perpendicular through the side view (601).

A more detailed view of the positions of the histones (based on a crystal structure at 2.8Å) is summarized in **Figure 20.23**. The upper view shows the position of one histone of each type relative to one turn around the nucleosome (numbered from 0 to +7). All four core histones show a similar type of structure in which three  $\alpha$ -helices are connected by two loops: this is called the **histone fold**. These regions interact to form crescent-shaped heterodimers; each heterodimer binds 2.5 turns of the DNA

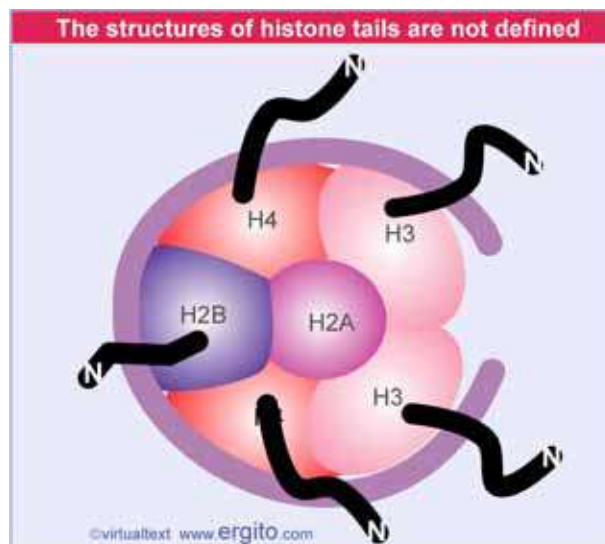

double helix (H2A-H2B binds at +3.5 - +6; H3-H4 binds at +0.5 - +3 for the circumference that is illustrated). Binding is mostly to the phosphodiester backbones (consistent with the need to package any DNA irrespective of sequence). The H<sub>3</sub><sub>2</sub>·H<sub>4</sub><sub>2</sub> tetramer is formed by interactions between the two H3 subunits, as can be seen in the lower part of the figure (602).

**Figure 20.23** Histone positions in a top view show H3-H4 and H2A-H2B pairs in a half nucleosome; the symmetrical organization can be seen in the superimposition of both halves.

Each of the core histones has a globular body that contributes to the central protein mass of the nucleosome. Each histone also has a flexible N-terminal tail, which has sites for modification that may be important in chromatin function. The positions of

the tails, which account for about one quarter of the protein mass, are not so well defined, as indicated in **Figure 20.24**. However, the tails of both H3 and H2B can be seen to pass between the turns of the DNA superhelix and extend out of the nucleosome, as seen in **Figure 20.25**. When histone tails are crosslinked to DNA by UV irradiation, more products are obtained with nucleosomes compared to core particles, which could mean that the tails contact the linker DNA (2205). The tail of H4 appears to contact an H2A-H2B dimer in an adjacent nucleosome; this could be an important feature in the overall structure.

**Figure 20.24** The globular bodies of the histones are localized in the histone octamer of the core particle, but the locations of the N-terminal tails, which carry the sites for modification, are not known, and could be more flexible.

**Figure 20.25** The N-terminal histone tails are disordered and exit from the nucleosome between turns of the DNA.

## NUCLEOSOMES

## 5.20.9 The N-terminal tails of histones are modified

## Key Concepts

- Histones are modified by methylation, acetylation, and phosphorylation.

All of the histones are modified by covalently linking extra moieties to the free groups of certain amino acids. The sites that are modified are concentrated in the N-terminal tails. These modifications have important effects on the structure of chromatin and in controlling gene expression (see *Molecular Biology 5.23.5 Histone modification is a key event*).

Acetylation and methylation occur on the free ( $\epsilon$ ) amino group of lysine. As seen in **Figure 20.26**, this removes the positive charge that resides on the  $\text{NH}_3^+$  form of the group. Methylation also occurs on arginine and histidine. Phosphorylation occurs on the hydroxyl group of serine and also on histidine. This introduces a negative charge in the form of the phosphate group.

**Figure 20.26** Acetylation of lysine or phosphorylation of serine reduces the overall positive charge of a protein.

These modifications are transient. Because they change the charge of the protein molecule, they are potentially able to change the functional properties of the octamers. Modification of histones is associated with structural changes that occur in chromatin at replication and transcription. Phosphorylations on specific positions and on different histones may be required for particular processes, for example, the Ser<sup>10</sup> position of H3 is phosphorylated when chromosomes condense at mitosis.

In synchronized cells in culture, both the pre-existing and newly synthesized core histones appear to be acetylated and methylated during S phase (when DNA is replicated and the histones also are synthesized). During the cell cycle, the modifying groups are later removed.

The coincidence of modification and replication suggests that acetylation (and methylation) could be connected with nucleosome assembly. One speculation has been that the reduction of positive charges on histones might lower their affinity for DNA, allowing the reaction to be better controlled. The idea has lost some ground in view of the observation that nucleosomes can be reconstituted, at least *in vitro*, with unmodified histones. Histone acetylation is essential for nucleosome assembly in yeast, and is probably required for some of the protein-protein interactions that occur during later stages of the reaction (see *Molecular Biology 5.23.6 Histone acetylation occurs in two circumstances*).

A cycle of phosphorylation and dephosphorylation occurs with H1, but its timing is different from the modification cycle of the other histones. With cultured mammalian cells, one or two phosphate groups are introduced at S phase. But the major phosphorylation event is the later addition of more groups at mitosis, to bring the total number up to as many as six. All the phosphate groups are removed at the end of the process of division. The phosphorylation of H1 is catalyzed by the M-phase kinase that provides an essential trigger for mitosis (see *Molecular Biology 6.29 Cell cycle and growth regulation*). In fact, this enzyme is now often assayed in terms of its H1 kinase activity. Not much is known about phosphatase(s) that remove the groups later.

The timing of the major H1 phosphorylation has prompted speculation that it is involved in mitotic condensation. However, in *Tetrahymena* (a protozoan) it is possible to delete all the genes for H1 without significantly affecting the overall properties of chromatin. There is a relatively small effect on the ability of chromatin to condense at mitosis. Some genes are activated and others are repressed by this change, suggesting that there alterations in local structure. Mutations that eliminate sites of phosphorylation in H1 have no effect, but mutations that mimic the effects of phosphorylation produce a phenotype that resembles the deletion. This suggests that the effect of phosphorylating H1 is to eliminate its effects on local chromatin structure.

## NUCLEOSOMES

### 5.20.10 Reproduction of chromatin requires assembly of nucleosomes

---

#### Key Concepts

- Histone octamers are not conserved during replication, but H2A·H2B dimers and H3<sub>2</sub>·H4<sub>2</sub> tetramers are conserved.
- There are different pathways for the assembly of nucleosomes during replication and independently of replication.
- Accessory proteins are required to assist the assembly of nucleosomes.
- CAF-1 is an assembly protein that is linked to the PCNA subunit of the replisome; it is required for deposition of H3<sub>2</sub>·H4<sub>2</sub> tetramers following replication.
- A different assembly protein and a variant of histone H3 may be used for replication-independent assembly.

---

Replication separates the strands of DNA and therefore must inevitably disrupt the structure of the nucleosome. The transience of the replication event is a major difficulty in analyzing the structure of a particular region while it is being replicated. The structure of the replication fork is distinctive. It is more resistant to micrococcal nuclease and is digested into bands that differ in size from nucleosomal DNA. The region that shows this altered structure is confined to the immediate vicinity of the replication fork. This suggests that a large protein complex is engaged in replicating the DNA, but the nucleosomes reform more or less immediately behind as it moves along.

Reproduction of chromatin does not involve any protracted period during which the DNA is free of histones. Once DNA has been replicated, nucleosomes are quickly generated on both the duplicates. This point is illustrated by the electron micrograph of **Figure 20.27**, which shows a recently replicated stretch of DNA, already packaged into nucleosomes on both daughter duplex segments.

**Figure 20.27** Replicated DNA is immediately incorporated into nucleosomes. Photograph kindly provided by S. MacKnight.

Both biochemical analysis and visualization of the replication fork therefore suggest that the disruption of nucleosome structure is limited to a short region immediately around the fork. Progress of the fork disrupts nucleosomes, but they form very rapidly on the daughter duplexes as the fork moves forward. In fact, the assembly of nucleosomes is directly linked to the replisome that is replicating DNA (for review see 1978).

How do histones associate with DNA to generate nucleosomes? Do the histones *preform* a protein octamer around which the DNA is subsequently wrapped? Or does the histone octamer assemble on DNA from free histones? **Figure 20.28** shows that two pathways can be used *in vitro* to assemble nucleosomes, depending on the conditions that are employed. In one pathway, a preformed octamer binds to DNA. In the other pathway, a tetramer of H3<sub>2</sub>·H4<sub>2</sub> binds first, and then two H2A·H2B dimers are added. Both these pathways are related to reactions that occur *in vivo*. The first reflects the capacity of chromatin to be remodeled by moving histone octamers along DNA (see *Molecular Biology 5.23.3 Chromatin remodeling is an active process*). The second represents the pathway that is used in replication.

**Figure 20.28** *In vitro*, DNA can either interact directly with an intact (crosslinked) histone octamer or can assemble with the H<sub>3</sub>-H<sub>4</sub><sub>2</sub> tetramer, after which two H<sub>2</sub>A-H<sub>2</sub>B dimers are added.

Accessory proteins are involved in assisting histones to associate with DNA. Candidates for this role can be identified by using extracts that assemble histones and exogenous DNA into nucleosomes. Accessory proteins may act as "molecular chaperones" that bind to the histones in order to release either individual histones or complexes (H<sub>3</sub><sub>2</sub>-H<sub>4</sub><sub>2</sub> or H<sub>2</sub>A-H<sub>2</sub>B) to the DNA in a controlled manner. This could be necessary because the histones, as basic proteins, have a general high affinity for DNA. *Such interactions allow histones to form nucleosomes without becoming trapped in other kinetic intermediates (that is, other complexes resulting from indiscreet binding of histones to DNA).*

Attempts to produce nucleosomes *in vitro* began by considering a process of assembly between free DNA and histones. But nucleosomes form *in vivo* only when DNA is replicated. A system that mimics this requirement has been developed by using extracts of human cells that replicate SV40 DNA and assemble the products into chromatin. The assembly reaction occurs preferentially on replicating DNA. It requires an ancillary factor, CAF-1, that consists of >5 subunits, with a total mass of

---

238 kD (3198; 3199). CAF-1 is recruited to the replication fork by PCNA, the processivity factor for DNA polymerase. This provides the link between replication and nucleosome assembly, ensuring that nucleosomes are assembled as soon as DNA has been replicated (609).

CAF-1 acts stoichiometrically, and functions by binding to newly synthesized H3 and H4. This suggests that new nucleosomes form by assembling first the H3<sub>2</sub>·H4<sub>2</sub> tetramer, and then adding the H2A·H2B dimers. The nucleosomes that are formed *in vitro* have a repeat length of 200 bp, although they do not have any H1 histone, which suggests that proper spacing can be accomplished without H1.

When chromatin is reproduced, a stretch of DNA *already associated with nucleosomes* is replicated, giving rise to two daughter duplexes. What happens to the pre-existing nucleosomes at this point? Are the histone octamers dissociated into free histones for reuse, or do they remain assembled? The integrity of the octamer can be tested by crosslinking the histones. The next two figures compare the possible outcomes from an experiment in which cells are grown in the presence of heavy amino acids to identify the histones before replication. Then replication is allowed to occur in the presence of light amino acids. At this point the histone octamers are crosslinked and centrifuged on a density gradient. **Figure 20.29** shows that if the original octamers have been conserved, they will be found at a position of high density, and new octamers will occupy a low density position. However, this does not happen. Little material is found at the high density position, which suggests that histone octamers are not conserved. The octamers have an intermediate density, and **Figure 20.30** shows that this is the expected result if the old histones have been released and then reassembled with newly synthesized histones.

**Figure 20.29** If histone octamers were conserved, old and new octamers would band at different densities when replication of heavy octamers occurs in light amino acids.

**Figure 20.30** When heavy octamers are replicated in light amino acids, the new octamers band diffusely between heavy and light densities, suggesting that disassembly and reassembly has occurred.

The pattern of disassembly and reassembly has been difficult to characterize in detail, but our working model is illustrated in **Figure 20.31**. The replication fork displaces histone octamers, which then dissociate into  $H3_2 \cdot H4_2$  tetramers and  $H2A \cdot H2B$  dimers (3197). These "old" tetramers and dimers enter a pool that also includes "new" tetramers and dimers, assembled from newly synthesized histones. Nucleosomes assemble ~600 bp behind the replication fork. Assembly is initiated when  $H3_2 \cdot H4_2$  tetramers bind to each of the daughter duplexes, assisted by CAF-1.

Then two H2A·H2B dimers bind to each H3<sub>2</sub>·H4<sub>2</sub> tetramer to complete the histone octamer. The assembly of tetramers and dimers is random with respect to "old" and "new" subunits, explaining the results of **Figure 20.30**. The "old" H3<sub>2</sub>·H4<sub>2</sub> tetramer could have an ability to be transiently associated with a single strand of DNA during replication; it may in fact have an increased chance of remaining with the leading strand for reuse. It is possible that nucleosomes are disrupted and reassembled in a similar way during transcription (see *Molecular Biology 5.20.12 Are transcribed genes organized in nucleosomes?*).

**Figure 20.31** Replication fork passage displaces histone octamers from DNA. They disassemble into H3-H4 tetramers and H2A-H2B dimers. Newly synthesized histones are assembled into H3-H4 tetramers and H2A-H2B dimers. The old and new tetramers and dimers are assembled with the aid of CAF-1 at random into new nucleosomes immediately behind the replication fork

During S phase (the period of DNA replication) in a eukaryotic cell, the duplication of chromatin requires synthesis of sufficient histone proteins to package an entire genome – basically the same quantity of histones must be synthesized that are already contained in nucleosomes. The synthesis of histone mRNAs is controlled as part of the cell cycle, and increases enormously in S phase (for review see 3200). The pathway for assembling chromatin from this equal mix of old and new histones during S phase is called the replication-coupled (RC) pathway.

Another pathway, called the replication-independent (RI) pathway exists for assembling nucleosomes during other phases of cell cycle, when DNA is not being synthesized. This may become necessary as the result of damage to DNA or because nucleosomes are displaced during transcription. The assembly process must necessarily have some differences from the replication-coupled pathway, because it cannot be linked to the replication apparatus. One of the most interesting features of the replication-independent pathway is that it uses different variants of some of the histones from those used during replication.

The histone H3.3 variant differs from the highly conserved H3 histone at 4 amino acid positions. H3.3 slowly replaces H3 in differentiating cells that do not have replication cycles. This happens as the result of assembly of new histone octamers to replace those that have been displaced from DNA for whatever reason. The mechanism that is used to ensure the use of H3.3 in the replication-independent pathway is different in two cases that have been investigated.

In the protozoan *Tetrahymena*, histone usage is determined exclusively by availability. Histone H3 is synthesized only during the cell cycle; the variant replacement histone is synthesized only in nonreplicating cells (3201). In *Drosophila*, however, there is an active pathway that ensures the usage of H3.3 by the replication-independent pathway. New nucleosomes containing H3.3 assemble at sites of transcription, presumably replacing nucleosome that were displaced by RNA polymerase. The assembly process discriminates between H3 and H3.3 on the basis of their sequences, specifically excluding H3 from being utilized (3185). By contrast, replication-coupled assembly uses both types of H3 (although H3.3 is available at much lower levels than H3, and therefore enters only a small proportion of nucleosomes).

CAF-1 is probably not involved in replication-independent assembly. (And there are organisms such as yeast and *Arabidopsis* where its gene is not essential, implying that alternative assembly processes may be used in replication-coupled assembly). A protein that may be involved in replication-independent assembly is called HIRA. Depletion of HIRA from *in vitro* systems for nucleosome assembly inhibits the formation of nucleosomes on nonreplicated DNA, but not on replicating DNA, indicating that the pathways do indeed use different assembly mechanisms (3190).

Assembly of nucleosomes containing an alternative to H3 also occurs at centromeres (see *Molecular Biology* 5.23.15 *Heterochromatin depends on interactions with histones*). Centromeric DNA replicates early during the replication phase of the cell cycle (in contrast with the surrounding heterochromatic sequences that replicate later; see *Molecular Biology* 4.13.5 *Each eukaryotic chromosome contains many replicons*). The incorporation of H3 at the centromeres is inhibited, and instead a protein called CENP-A is incorporated in higher eukaryotic cells (in *Drosophila* it is called Cid, and in yeast it is called Cse4p). This occurs by the

replication-independent assembly pathway, apparently because the replication-coupled pathway is inhibited for a brief period of time while centromeric DNA replicates (3188).

## NUCLEOSOMES

### 5.20.11 Do nucleosomes lie at specific positions?

---

#### Key Terms

**Nucleosome positioning** describes the placement of nucleosomes at defined sequences of DNA instead of at random locations with regards to sequence.

**Indirect end labeling** is a technique for examining the organization of DNA by making a cut at a specific site and isolating all fragments containing the sequence adjacent to one side of the cut; it reveals the distance from the cut to the next break(s) in DNA.

**Translational positioning** describes the location of a histone octamer at successive turns of the double helix, which determines which sequences are located in linker regions.

**Rotational positioning** describes the location of the histone octamer relative to turns of the double helix, which determines which face of DNA is exposed on the nucleosome surface.

#### Key Concepts

- Nucleosomes may form at specific positions as the result either of the local structure of DNA or of proteins that interact with specific sequences.
- The most common cause of nucleosome positioning is when proteins binding to DNA establish a boundary.
- Positioning may affect which regions of DNA are in the linker and which face of DNA is exposed on the nucleosome surface.

---

We know that nucleosomes can be reconstituted *in vitro* without regard to DNA sequence, but this does not mean that their formation *in vivo* is independent of sequence. Does a particular DNA sequence always lie in a certain position *in vivo* with regard to the topography of the nucleosome? Or are nucleosomes arranged randomly on DNA, so that a particular sequence may occur at any location, for example, in the core region in one copy of the genome and in the linker region in another?

To investigate this question, it is necessary to use a defined sequence of DNA; more precisely, we need to determine the position relative to the nucleosome of a defined point in the DNA. **Figure 20.32** illustrates the principle of a procedure used to achieve this.

**Figure 20.32** Nucleosome positioning places restriction sites at unique positions relative to the linker sites cleaved by micrococcal nuclease.

Suppose that the DNA sequence is organized into nucleosomes in only one particular configuration, so that each site on the DNA always is located at a particular position on the nucleosome. This type of organization is called **nucleosome positioning** (or sometimes nucleosome phasing). In a series of positioned nucleosomes, the linker regions of DNA comprise unique sites.

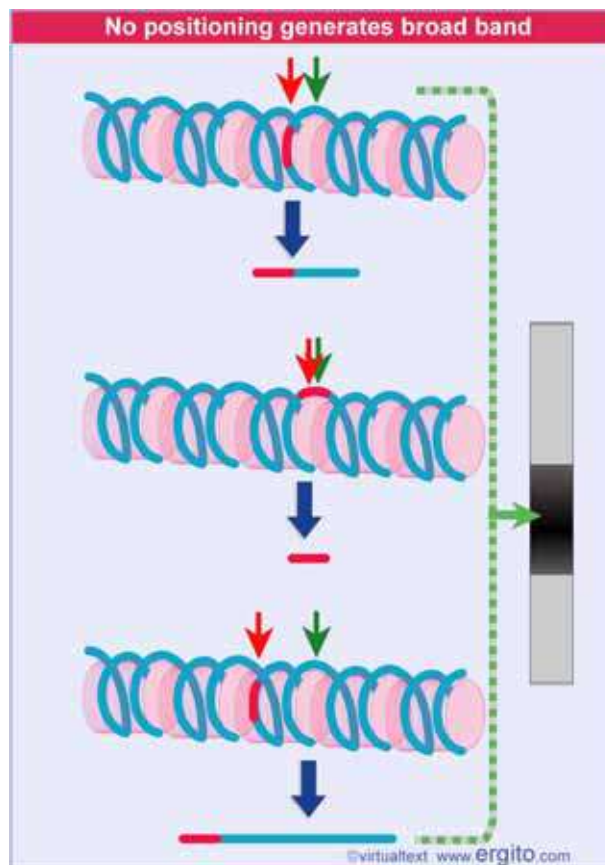

Consider the consequences for just a single nucleosome. Cleavage with micrococcal nuclease generates a monomeric fragment that constitutes a *specific sequence*. If the DNA is isolated and cleaved with a restriction enzyme that has only one target site in

this fragment, it should be cut at a unique point. This produces two fragments, each of unique size.

The products of the micrococcal/restriction double digest are separated by gel electrophoresis. A probe representing the sequence on one side of the restriction site is used to identify the corresponding fragment in the double digest. This technique is called **indirect end labeling**.

Reversing the argument, the identification of a single sharp band demonstrates that the position of the restriction site is uniquely defined with respect to the end of the nucleosomal DNA (as defined by the micrococcal nuclease cut). So the nucleosome has a unique sequence of DNA.

What happens if the nucleosomes do *not* lie at a single position? Now the linkers consist of *different* DNA sequences in each copy of the genome. So the restriction site lies at a different position each time; in fact, it lies at all possible locations relative to the ends of the monomeric nucleosomal DNA. **Figure 20.33** shows that the double cleavage then generates a broad smear, ranging from the smallest detectable fragment (~20 bases) to the length of the monomeric DNA.

**Figure 20.33** In the absence of nucleosome positioning, a restriction site lies at all possible locations in different copies of the genome. Fragments of all possible sizes are produced when a restriction enzyme cuts at a target site (red) and micrococcal nuclease cuts at the junctions between nucleosomes (green).

In discussing these experiments, we have treated micrococcal nuclease as an enzyme that cleaves DNA at the exposed linker regions without any sort of sequence specificity. However, the enzyme actually does have some sequence specificity (biased toward selection of A·T-rich sequences). So we cannot assume that the existence of a specific band in the indirect end-labeling technique represents the distance from a restriction cut to the linker region. It could instead represent the distance from the restriction cut to a preferred micrococcal nuclease cleavage site!

This possibility is controlled by treating the naked DNA in exactly the same way as the chromatin. If there are preferred sites for micrococcal nuclease in the particular region, specific bands are found. Then this pattern of bands can be compared with the pattern generated from chromatin.

A *difference* between the control DNA band pattern and the chromatin pattern provides evidence for nucleosome positioning. Some of the bands present in the control DNA digest may disappear from the nucleosome digest, indicating that preferentially cleaved positions are unavailable. New bands may appear in the nucleosome digest when new sites are rendered preferentially accessible by the nucleosomal organization.

Nucleosome positioning might be accomplished in either of two ways:

- It is intrinsic: *every nucleosome is deposited specifically at a particular DNA sequence*. This modifies our view of the nucleosome as a subunit able to form between any sequence of DNA and a histone octamer.
- It is extrinsic: *the first nucleosome in a region is preferentially assembled at a particular site*. A preferential starting point for nucleosome positioning results from the presence of a region from which nucleosomes are excluded. The excluded region provides a *boundary* that restricts the positions available to the adjacent nucleosome. Then a series of nucleosomes may be assembled sequentially, with a defined repeat length.

It is now clear that the deposition of histone octamers on DNA is not random with regard to sequence. The pattern is intrinsic in some cases, in which it is determined by structural features in DNA. It is extrinsic in other cases, in which it results from the interactions of other proteins with the DNA and/or histones.

Certain structural features of DNA affect placement of histone octamers. DNA has intrinsic tendencies to bend in one direction rather than another; thus A·T-rich regions locate so that the minor groove faces in towards the octamer, whereas G·C-rich regions are arranged so that the minor groove points out. Long runs of dA·dT (>8 bp) avoid positioning in the central superhelical turn of the core. It is not yet possible to sum all of the relevant structural effects and thus entirely to predict the location of a particular DNA sequence with regard to the nucleosome. Sequences that cause DNA to take up more extreme structures may have effects such as the exclusion of nucleosomes, and thus could cause boundary effects.

Positioning of nucleosomes near boundaries is common. If there is some variability in the construction of nucleosomes – for example, if the length of the linker can vary

by, say, 10 bp – the specificity of location would decline proceeding away from the first, defined nucleosome at the boundary. In this case, we might expect the positioning to be maintained rigorously only relatively near the boundary.

The location of DNA on nucleosomes can be described in two ways. **Figure 20.34** shows that **translational positioning** describes the position of DNA with regard to the boundaries of the nucleosome. In particular, it determines which sequences are found in the linker regions. Shifting the DNA by 10 bp brings the next turn into a linker region. So translational positioning determines which regions are more accessible (at least as judged by sensitivity to micrococcal nuclease).

**Figure 20.34** Translational positioning describes the linear position of DNA relative to the histone octamer. Displacement of the DNA by 10 bp changes the sequences that are in the more exposed linker regions, but does not alter which face of DNA is protected by the histone surface and which is exposed to the exterior. DNA is really coiled around the nucleosomes, and is shown in linear form only for convenience.

Because DNA lies on the outside of the histone octamer, one face of any particular sequence is obscured by the histones, but the other face is accessible. Depending upon its positioning with regard to the nucleosome, a site in DNA that must be recognized by a regulator protein could be inaccessible or available. The exact position of the histone octamer with respect to DNA sequence may therefore be important. **Figure 20.35** shows the effect of **rotational positioning** of the double helix with regard to the octamer surface. If the DNA is moved by a partial number of turns (imagine the DNA as rotating relative to the protein surface), there is a change in the exposure of sequence to the outside.

**Figure 20.35** Rotational positioning describes the exposure of DNA on the surface of the nucleosome. Any movement that differs from the helical repeat ( $\sim 10.2$  bp/turn) displaces DNA with reference to the histone surface. Nucleotides on the inside are more protected against nucleases than nucleotides on the outside.

Both translational and rotational positioning can be important in controlling access to DNA. The best characterized cases of positioning involve the specific placement of nucleosomes at promoters. Translational positioning and/or the exclusion of nucleosomes from a particular sequence may be necessary to allow a transcription complex to form. Some regulatory factors can bind to DNA only if a nucleosome is excluded to make the DNA freely accessible, and this creates a boundary for translational positioning. In other cases, regulatory factors can bind to DNA on the surface of the nucleosome, but rotational positioning is important to ensure that the face of DNA with the appropriate contact points is exposed. We discuss the connection between nucleosomal organization and transcription in *Molecular Biology 5.23.4 Nucleosome organization may be changed at the promoter.*

**NUCLEOSOMES****5.20.12 Are transcribed genes organized in nucleosomes?**

---

**Key Concepts**

- Nucleosomes are found at the same frequency when transcribed genes or nontranscribed genes are digested with micrococcal nuclease.
  - Some heavily transcribed genes appear to be exceptional cases that are devoid of nucleosomes.
- 

Attempts to visualize genes during transcription have produced conflicting results. The next two figures show each extreme.

Heavily transcribed chromatin can be seen to be rather extended (too extended to be covered in nucleosomes). In the intensively transcribed genes coding for rRNA, shown in **Figure 20.36**, the extreme packing of RNA polymerases makes it hard to see the DNA. We cannot directly measure the lengths of the rRNA transcripts because the RNA is compacted by proteins, but we know (from the sequence of the rRNA) how long the transcript must be. The length of the transcribed DNA segment, measured by the length of the axis of the "Christmas tree," is ~85% of the length of the rRNA. This means that the DNA is almost completely extended.

**Figure 20.36** The extended axis of an rDNA transcription unit alternates with the only slightly less extended non-transcribed spacer. Photograph kindly provided by Charles Laird.

On the other hand, transcription complexes of SV40 minichromosomes can be extracted from infected cells. They contain the usual complement of histones and display a beaded structure. Chains of RNA can be seen to extend from the minichromosome, as in the example of **Figure 20.37**. This argues that transcription can proceed while the SV40 DNA is organized into nucleosomes. Of course, the SV40 minichromosome is transcribed less intensively than the rRNA genes.

**Figure 20.37** An SV40 minichromosome can be transcribed. Photograph kindly provided by Pierre Chambon.

Transcription involves the unwinding of DNA, and may require the fiber to unfold in restricted regions of chromatin. A simple-minded view suggests that some "elbow-room" must be needed for the process. The features of polytene and

lampbrush chromosomes described in *Molecular Biology 5.19 Chromosomes* offer hints that a more expansive structural organization is associated with gene expression.

In thinking about transcription, we must bear in mind the relative sizes of RNA polymerase and the nucleosome. The eukaryotic enzymes are large multisubunit proteins, typically >500 kD. Compare this with the ~260 kD of the nucleosome. **Figure 20.38** illustrates the approach of RNA polymerase to nucleosomal DNA. Even without detailed knowledge of the interaction, it is evident that it involves the approach of two comparable bodies.

**Figure 20.38** RNA polymerase is comparable in size to the nucleosome and might encounter difficulties in following the DNA around the histone octamer.

Consider the two turns that DNA makes around the nucleosome. Would RNA polymerase have sufficient access to DNA if the nucleic acid were confined to this path? During transcription, as RNA polymerase moves along the template, it binds tightly to a region of ~50 bp, including a locally unwound segment of ~12 bp. The need to unwind DNA makes it seem unlikely that the segment engaged by RNA polymerase could remain on the surface of the histone octamer.

It therefore seems inevitable that transcription must involve a structural change. So the first question to ask about the structure of active genes is whether DNA being transcribed remains organized in nucleosomes. If the histone octamers are displaced, do they remain attached in some way to the transcribed DNA (for review see 208)?

One experimental approach is to digest chromatin with micrococcal nuclease, and then to use a probe to some specific gene or genes to determine whether the corresponding fragments are present in the usual 200 bp ladder at the expected concentration. The conclusions that we can draw from these experiments are limited but important. *Genes that are being transcribed contain nucleosomes at the same frequency as nontranscribed sequences.* So genes do not necessarily enter an alternative form of organization in order to be transcribed.

*But since the average transcribed gene probably only has a single RNA polymerase at any given moment, this does not reveal what is happening at sites actually engaged by the enzyme.* Perhaps they retain their nucleosomes; more likely the nucleosomes are temporarily displaced as RNA polymerase passes through, but reform immediately afterward.

**NUCLEOSOMES****5.20.13 Histone octamers are displaced by transcription****Key Concepts**

- RNA polymerase displaces histone octamers during transcription in a model system, but octamers reassociate with DNA as soon as the polymerase has passed.
- Nucleosomes are reorganized when transcription passes through a gene.

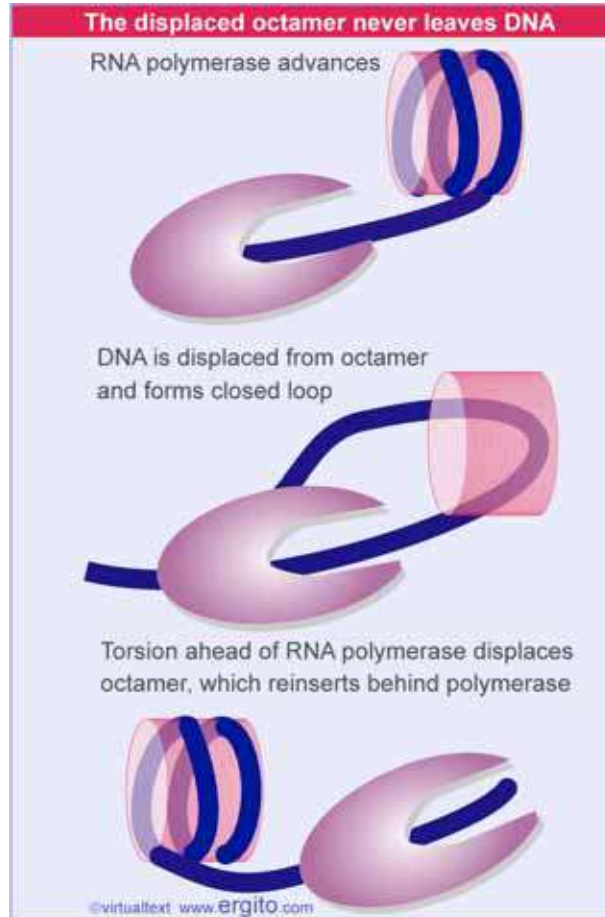

Experiments to test whether an RNA polymerase can transcribe directly through a nucleosome suggest that the histone octamer is displaced by the act of transcription. **Figure 20.39** shows what happens when the phage T7 RNA polymerase transcribes a short piece of DNA containing a single octamer core *in vitro*. The core remains associated with the DNA, but is found in a different location. The core is most likely to rebind to the same DNA molecule from which it was displaced (608).

**Figure 20.39** A protocol to test the effect of transcription on nucleosomes shows that the histone octamer is displaced from DNA and rebinds at a new position.

**Figure 20.40** shows a model for polymerase progression. DNA is displaced as the polymerase enters the nucleosome, but the polymerase reaches a point at which the

DNA loops back and reattaches, forming a closed region. As polymerase advances further, unwinding the DNA, it creates positive supercoils in this loop; the effect could be dramatic, because the closed loop is only ~80 bp, so each base pair through which the polymerase advances makes a significant addition to the supercoiling. In fact, the polymerase progresses easily for the first 30 bp into the nucleosome. Then it proceeds more slowly, as though encountering increasing difficulty in progressing. Pauses occur every 10 bp, suggesting that the structure of the loop imposes a constraint related to rotation around each turn of DNA. When the polymerase reaches the midpoint of the nucleosome (the next bases to be added are essentially at the axis of dyad symmetry), pausing ceases, and the polymerase advances rapidly. This suggests that the midpoint of the nucleosome marks the point at which the octamer is displaced (possibly because positive supercoiling has reached some critical level that expels the octamer from DNA). This releases tension ahead of the polymerase and allows it to proceed. The octamer then binds to the DNA behind the polymerase and no longer presents an obstacle to progress. Probably the octamer changes position without ever completely losing contact with the DNA.

**Figure 20.40** RNA polymerase displaces DNA from the histone octamer as it advances. The DNA loops back and attaches (to polymerase or to the octamer) to form a closed loop. As the polymerase proceeds, it generates positive supercoiling ahead. This displaces the octamer, which keeps contact with DNA and/or polymerase, and is inserted behind the RNA polymerase.

*This is a static version of an interactive figure; see <http://www.ergito.com/main.jsp?bcs=MBIO.5.20.13> to view properly.*

Is the octamer released as an intact unit? Crosslinking the proteins of the octamer does not create an obstacle to transcription. Transcription can continue even when crosslinking is extensive enough to ensure that the central regions of the core histones have been linked. This implies that transcription does not require dissociation of the octamer into its component histones, nor is it likely to require any major unfolding of the central structure. However, addition of histone H1 to this system causes a rapid decline in transcription. This suggests two conclusions: the histone octamer (whether remaining present or displaced) functions as an intact unit; and it may be necessary to remove H1 from active chromatin or to modify its interactions in some way.

So a small RNA polymerase can displace a single nucleosome, which reforms behind it, during transcription. Of course, the situation is more complex in a eukaryotic

nucleus. RNA polymerase is very much larger, and the impediment to progress is a string of connected nucleosomes. Overcoming this obstacle requires additional factors that act on chromatin (see *Molecular Biology 5.23 Controlling chromatin structure*).

The organization of nucleosomes may be changed by transcription. **Figure 20.41** shows what happens to the yeast *URA3* gene when it transcribed under control of an inducible promoter (606). Positioning is examined by using micrococcal nuclease to examine cleavage sites relative to a restriction site at the 5' end of the gene. Initially the gene displays a pattern of nucleosomes that are organized from the promoter for a significant distance across the gene; positioning is lost in the 3' regions. When the gene is expressed, a general smear replaces the positioned pattern of nucleosomes. So, nucleosomes are present at the same density but are no longer organized in phase. This suggests that transcription destroys the nucleosomal positioning. When repression is reestablished, positioning appears within 10 min (although it is not complete). This result makes the interesting point that the positions of the nucleosomes can be adjusted without replication.

**Figure 20.41** The *URA3* gene has positioned nucleosomes before transcription. When transcription is induced, nucleosome positions are randomized. When transcription is repressed, the nucleosomes resume their particular positions. Photograph kindly provided by Fritz Thoma.

The unifying model is to suppose that RNA polymerase displaces histone octamers as it progresses. If the DNA behind the polymerase is available, the octamer reattaches there (possibly or probably never having ever totally lost contact with the DNA. It remains a puzzle how an octamer could retain contact with DNA, without

unfolding or losing components, as an object of even larger size than itself proceeds along the DNA. Perhaps the octamer is "passed back" by making contacts with RNA polymerase). If the DNA is not available, for example, because another polymerase continues immediately behind the first, then the octamer may be permanently displaced, and the DNA may persist in an extended form.

## NUCLEOSOMES

### 5.20.14 Nucleosome displacement and reassembly require special factors

---

#### Key Concepts

- Ancillary factors are required both for RNA polymerase to displace octamers during transcription and for the histones to reassemble into nucleosomes after transcription.
- 

Displacing nucleosomes from DNA is a key requirement for all stages of transcription. The process has been characterized best at initiation. Active promoters are marked by sites that are hypersensitive to DNAase, because histone octamers have been displaced from DNA (see *Molecular Biology 5.20.15 DNAase hypersensitive sites change chromatin structure*). The removal of the octamers requires remodeling complexes that are recruited by transcription factors and which use energy generated by hydrolysis of ATP to change chromatin structure (see *Molecular Biology 5.23.4 Nucleosome organization may be changed at the promoter*). This means that RNA polymerase starts DNA synthesis on a short stretch of DNA unimpeded by nucleosomes. For it to continue advancing during elongation, the histone octamers ahead of it must be displaced. And then, to avoid leaving naked DNA behind it, the octamers must reform following transcription.

Transcription *in vitro* by RNA polymerase II requires a protein called FACT that behaves like a transcription elongation factor (it is not part of RNA polymerase, but associates with it specifically during the elongation phase of transcription. FACT (an abbreviation for Facilitates Chromatin Transcription) consists of two subunits that are well conserved in all eukaryotes. It is associated with the chromatin of active genes (4108).

When FACT is added to isolated nucleosomes, it causes them to lose H2A·H2B dimers. During transcription *in vitro*, it converts nucleosomes to "hexasomes" that have lost H2A·H2B dimers (4107). This suggests that FACT is part of a mechanism for displacing octamers during transcription. FACT may also be involved in the reassembly of nucleosomes after transcription, because it assists formation of nucleosomes from core histones.

This suggests the model shown in **Figure 20.42**, in which FACT detaches H2A·H2B from a nucleosome in front of RNA polymerase, and then helps to add it to a nucleosome that is reassembling behind the enzyme. Other factors must be required to complete the process. FACT is also required for other reactions in which nucleosomes may be displaced, including DNA replication and repair.

**Figure 20.42** Histone octamers are disassembled ahead of transcription to remove nucleosomes. They reform following transcription. Release of H2A.H2B dimers probably initiates the disassembly process.

Other factors are required to maintain the integrity of chromatin in regions that are being transcribed, probably because they are also involved in the disassembly and reassembly of nucleosomes, but we do not yet have detailed information about their functions.

## NUCLEOSOMES

### 5.20.15 DNAase hypersensitive sites change chromatin structure

---

#### Key Terms

A **hypersensitive site** is a short region of chromatin detected by its extreme sensitivity to cleavage by DNAase I and other nucleases; it comprises an area from which nucleosomes are excluded.

#### Key Concepts

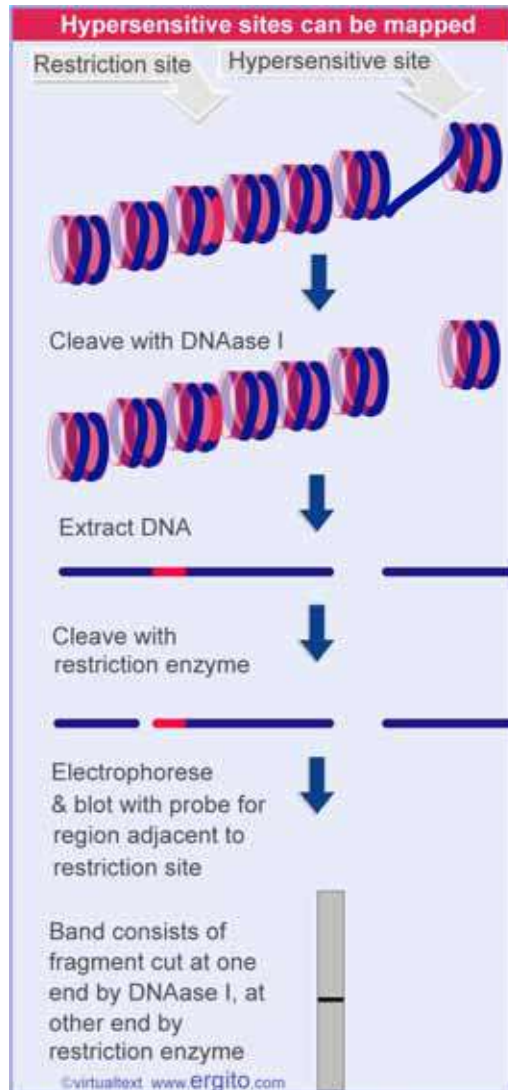

- Hypersensitive sites are found at the promoters of expressed genes.
- They are generated by the binding of transcription factors that displace histone octamers.

---

In addition to the general changes that occur in active or potentially active regions, structural changes occur at specific sites associated with initiation of transcription or with certain structural features in DNA. These changes were first detected by the effects of digestion with very low concentrations of the enzyme DNAase I.

When chromatin is digested with DNAase I, the first effect is the introduction of breaks in the duplex at specific, **hypersensitive sites**. Since susceptibility to DNAase I reflects the availability of DNA in chromatin, we take these sites to represent chromatin regions in which the DNA is particularly exposed because it is not organized in the usual nucleosomal structure. A typical hypersensitive site is 100× more sensitive to enzyme attack than bulk chromatin. These sites are also hypersensitive to other nucleases and to chemical agents (for review see 207).

Hypersensitive sites are created by the (tissue-specific) structure of chromatin. Their locations can be determined by the technique of indirect end labeling that we introduced earlier in the context of nucleosome positioning. This application of the technique is recapitulated in **Figure 20.43**. In this case, cleavage at the hypersensitive site by DNAase I is used to generate one end of the fragment, and its distance is measured from the other end that is generated by cleavage with a restriction enzyme.

**Figure 20.43** Indirect end-labeling identifies the distance of a DNAase hypersensitive site from a restriction cleavage site. The existence of a particular cutting site for DNAase I generates a discrete cutting site for DNAase I, whose size indicates the distance of the DNAase I hypersensitive site from the restriction site.

Many of the hypersensitive sites are related to gene expression. Every active gene has a site, or sometimes more than one site, in the region of the promoter. *Most hypersensitive sites are found only in chromatin of cells in which the associated gene is being expressed; they do not occur when the gene is inactive.* The 5' hypersensitive site(s) appear before transcription begins; and the DNA sequences contained within the hypersensitive sites are required for gene expression, as seen by mutational analysis.

A particularly well-characterized nuclease-sensitive region lies on the SV40 minichromosome. A short segment near the origin of replication, just upstream of the promoter for the late transcription unit, is cleaved preferentially by DNAase I,

micrococcal nuclease, and other nucleases (including restriction enzymes) (610; 611).

The state of the SV40 minichromosome can be visualized by electron microscopy. In up to 20% of the samples, a "gap" is visible in the nucleosomal organization, as evident in **Figure 20.44**. The gap is a region of ~120 nm in length (about 350 bp), surrounded on either side by nucleosomes. The visible gap corresponds with the nuclease-sensitive region. This shows directly that increased sensitivity to nucleases is associated with the exclusion of nucleosomes (3202).

**Figure 20.44** The SV40 minichromosome has a nucleosome gap. Photograph kindly provided by Moshe Yaniv.

A hypersensitive site is not necessarily uniformly sensitive to nucleases. **Figure 20.45** shows the maps of two hypersensitive sites.

**Figure 20.45** The SV40 gap includes hypersensitive sites, sensitive regions, and a protected region of DNA. The hypersensitive site of a chicken  $\beta$ -globin gene comprises a region that is susceptible to several nucleases.

Within the SV40 gap of ~300 bp, there are two hypersensitive DNAase I sites and a "protected" region. The protected region presumably reflects the association of

(nonhistone) protein(s) with the DNA. The gap is associated with the DNA sequence elements that are necessary for promoter function.

The hypersensitive site at the  $\beta$ -globin promoter is preferentially digested by several enzymes, including DNAase I, DNAase II, and micrococcal nuclease. The enzymes have preferred cleavage sites that lie at slightly different points in the same general region. So a region extending from about  $-70$  to  $-270$  is preferentially accessible to nucleases when the gene is transcribable.

What is the structure of the hypersensitive site? Its preferential accessibility to nucleases indicates that it is not protected by histone octamers, but this does not necessarily imply that it is free of protein. A region of free DNA might be vulnerable to damage; and in any case, how would it be able to exclude nucleosomes? We assume that the hypersensitive site results from the binding of specific regulatory proteins that exclude nucleosomes. Indeed, the binding of such proteins is probably the basis for the existence of the protected region within the hypersensitive site.

The proteins that generate hypersensitive sites are likely to be regulatory factors of various types, since hypersensitive sites are found associated with promoters, other elements that regulate transcription, origins of replication, centromeres, and sites with other structural significance. In some cases, they are associated with more extensive organization of chromatin structure. A hypersensitive site may provide a boundary for a series of positioned nucleosomes. Hypersensitive sites associated with transcription may be generated by transcription factors when they bind to the promoter as part of the process that makes it accessible to RNA polymerase (see *Molecular Biology 5.23.4 Nucleosome organization may be changed at the promoter*).

The stability of hypersensitive sites is revealed by the properties of chick fibroblasts transformed with temperature-sensitive tumor viruses. These experiments take advantage of an unusual property: although fibroblasts do not belong to the erythroid lineage, transformation of the cells at the normal temperature leads to activation of the globin genes. The activated genes have hypersensitive sites. If transformation is performed at the higher (nonpermissive) temperature, the globin genes are not activated; and hypersensitive sites do not appear. When the globin genes have been activated by transformation at low temperature, they can be inactivated by raising the temperature. But the hypersensitive sites are retained through at least the next 20 cell doublings (614).

This result demonstrates that acquisition of a hypersensitive site is only one of the features necessary to initiate transcription; and it implies that the events involved in establishing a hypersensitive site are distinct from those concerned with perpetuating it. Once the site has been established, it is perpetuated through replication in the absence of the circumstances needed for induction. Could some specific intervention be needed to abolish a hypersensitive site?

## NUCLEOSOMES

### 5.20.16 Domains define regions that contain active genes

---

#### Key Terms

A **domain** of a chromosome may refer *either* to a discrete structural entity defined as a region within which supercoiling is independent of other domains; *or* to an extensive region including an expressed gene that has heightened sensitivity to degradation by the enzyme DNAase I.

#### Key Concepts

- A domain containing a transcribed gene is defined by increased sensitivity to degradation by DNAase I.

---

A region of the genome that contains an active gene may have an altered structure. The change in structure precedes, and is different from, the disruption of nucleosome structure that may be caused by the actual passage of RNA polymerase.

One indication of the change in structure of transcribed chromatin is provided by its increased susceptibility to degradation by DNAase I. DNAase I sensitivity defines a chromosomal **domain**, a region of altered structure including at least one active transcription unit, and sometimes extending farther. (Note that use of the term "domain" does not imply any necessary connection with the structural domains identified by the loops of chromatin or chromosomes.)

When chromatin is digested with DNAase I, it is eventually degraded into acid-soluble material (very small fragments of DNA). The progress of the overall reaction can be followed in terms of the proportion of DNA that is rendered acid soluble. *When only 10% of the total DNA has become acid soluble, more than 50% of the DNA of an active gene has been lost.* This suggests that active genes are preferentially degraded (613).

The fate of individual genes can be followed by quantitating the amount of DNA that survives to react with a specific probe. The protocol is outlined in **Figure 20.46**. The principle is that the loss of a particular band indicates that the corresponding region of DNA has been degraded by the enzyme.

**Figure 20.46** Sensitivity to DNAase I can be measured by determining the rate of disappearance of the material hybridizing with a particular probe.

**Figure 20.47** shows what happens to  $\beta$ -globin genes and an ovalbumin gene in chromatin extracted from chicken red blood cells (in which globin genes are expressed and the ovalbumin gene is inactive). The restriction fragments representing the  $\beta$ -globin genes are rapidly lost, while those representing the ovalbumin gene show little degradation. (The ovalbumin gene in fact is digested at the same rate as the bulk of DNA.)

**Figure 20.47** In adult erythroid cells, the adult  $\beta$ -globin gene is highly sensitive to DNAase I digestion, the embryonic  $\beta$ -globin gene is partially sensitive (probably due to spreading effects), but ovalbumin is not sensitive. Data kindly provided by Harold Weintraub.

So the bulk of chromatin is relatively resistant to DNAase I and contains nonexpressed genes (as well as other sequences). A *gene becomes relatively susceptible to the enzyme specifically in the tissue(s) in which it is expressed.*

Is preferential susceptibility a characteristic only of rather actively expressed genes, such as globin, or of all active genes? Experiments using probes representing the entire cellular mRNA population suggest that all active genes, whether coding for abundant or for rare mRNAs, are preferentially susceptible to DNAase I. (However, there are variations in the degree of susceptibility.) Since the rarely expressed genes are likely to have very few RNA polymerase molecules actually engaged in transcription at any moment, this implies that the sensitivity to DNAase I does not result from the act of transcription, but is a feature of *genes that are able to be transcribed.*

What is the extent of the preferentially sensitive region? This can be determined by using a series of probes representing the flanking regions as well as the transcription unit itself. The sensitive region always extends over the entire transcribed region; an additional region of several kb on either side may show an intermediate level of sensitivity (probably as the result of spreading effects).

The critical concept implicit in the description of the domain is that a region of high sensitivity to DNAase I extends over a considerable distance. Often we think of regulation as residing in events that occur at a discrete site in DNA – for example, in the ability to initiate transcription at the promoter. Even if this is true, such regulation must determine, or must be accompanied by, a more wide-ranging change in

structure. This is a difference between eukaryotes and prokaryotes.

## NUCLEOSOMES

### 5.20.17 An LCR may control a domain

---

#### Key Terms

The **locus control region (LCR)** that is required for the expression of several genes in a domain.

A **domain** of a chromosome may refer *either* to a discrete structural entity defined as a region within which supercoiling is independent of other domains; *or* to an extensive region including an expressed gene that has heightened sensitivity to degradation by the enzyme DNAase I.

#### Key Concepts

- An LCR is located at the 5' end of the domain and consists of several hypersensitive sites.

---

Every gene is controlled by its promoter, and some genes also respond to enhancers (containing similar control elements but located farther away) as discussed in *Molecular Biology 5.21 Promoters and enhancers*. However, these local controls are not sufficient for all genes. In some cases, a gene lies within a domain of several genes all of which are influenced by regulatory elements that act on the whole domain. The existence of these elements was identified by the inability of a region of DNA including a gene and all its known regulatory elements to be properly expressed when introduced into an animal as a transgene.

The best characterized example of a regulated gene cluster is provided by the mouse  $\beta$ -globin genes. Recall from **Figure 4.3** that the  $\alpha$ -globin and  $\beta$ -globin genes in mammals each exist as clusters of related genes, expressed at different times during embryonic and adult development. These genes are provided with a large number of regulatory elements, which have been analyzed in detail. In the case of the adult human  $\beta$ -globin gene, regulatory sequences are located both 5' and 3' to the gene and include both positive and negative elements in the promoter region, and additional positive elements within and downstream of the gene.

But a human  $\beta$ -globin gene containing all of these control regions is never expressed in a transgenic mouse within an order of magnitude of wild-type levels. Some further regulatory sequence is required. Regions that provide the additional regulatory function are identified by DNAase I hypersensitive sites that are found at the ends of the cluster. The map of **Figure 20.48** shows that the 20 kb upstream of the  $\epsilon$ -gene contains a group of 5 sites; and there is a single site 30 kb downstream of the  $\beta$ -gene. Transfecting various constructs into mouse erythroleukemia cells shows that sequences between the individual hypersensitive sites in the 5' region can be removed without much effect, but that removal of any of the sites reduces the overall level of expression.

**Figure 20.48** A globin domain is marked by hypersensitive sites at either end. The group of sites at the 5' side constitutes the LCR and is essential for the function of all genes in the cluster.

The 5' regulatory sites are the primary regulators, and the cluster of hypersensitive sites is called the **LCR** (locus control region) (for review see 3182). We do not know whether the 3' site has any function. The LCR is absolutely required for expression of each of the globin genes in the cluster. Each gene is then further regulated by its own specific controls. Some of these controls are autonomous: expression of the  $\epsilon$ - and  $\gamma$ -genes appears intrinsic to those loci in conjunction with the LCR. Other controls appear to rely upon position in the cluster, which provides a suggestion that *gene order* in a cluster is important for regulation (615).

The entire region containing the globin genes, and extending well beyond them, constitutes a chromosomal **domain**. It shows increased sensitivity to digestion by DNAase I (see **Figure 20.46**). Deletion of the 5' LCR restores normal resistance to DNAase over the whole region. Two models for how an LCR works propose that its action is required in order to activate the promoter, or alternatively, to increase the rate of transcription from the promoter (3183; 3181). The exact nature of the interactions between the LCR and the individual promoters has not yet been fully defined.

Does this model apply to other gene clusters? The  $\alpha$ -globin locus has a similar organization of genes that are expressed at different times, with a group of hypersensitive sites at one end of the cluster, and increased sensitivity to DNAase I throughout the region. Only a small number of other cases are known in which an LCR controls a group of genes.

## NUCLEOSOMES

### 5.20.18 Summary

All eukaryotic chromatin consists of nucleosomes. A nucleosome contains a characteristic length of DNA, usually ~200 bp, wrapped around an octamer containing two copies each of histones H2A, H2B, H3, and H4. A single H1 protein is associated with each nucleosome. Virtually all genomic DNA is organized into nucleosomes. Treatment with micrococcal nuclease shows that the DNA packaged into each nucleosome can be divided operationally into two regions. The linker region is digested rapidly by the nuclease; the core region of 146 bp is resistant to digestion. Histones H3 and H4 are the most highly conserved and an H<sub>3</sub><sub>2</sub>·H<sub>4</sub><sub>2</sub> tetramer accounts for the diameter of the particle. The H2A and H2B histones are organized as two H2A·H2B dimers. Octamers are assembled by the successive addition of two H2A·H2B dimers to the H<sub>3</sub><sub>2</sub>·H<sub>4</sub><sub>2</sub> kernel.

The path of DNA around the histone octamer creates -1.65 supercoils. The DNA "enters" and "leaves" the nucleosome in the same vicinity, and could be "sealed" by histone H1. Removal of the core histones releases -1.0 supercoils. The difference can be largely explained by a change in the helical pitch of DNA, from an average of 10.2 bp/turn in nucleosomal form to 10.5 bp/turn when free in solution. There is variation in the structure of DNA from a periodicity of 10.0 bp/turn at the nucleosome ends to 10.7 bp/turn in the center. There are kinks in the path of DNA on the nucleosome.

Nucleosomes are organized into a fiber of 30 nm diameter which has 6 nucleosomes per turn and a packing ratio of 40. Removal of H1 allows this fiber to unfold into a 10 nm fiber that consists of a linear string of nucleosomes. The 30 nm fiber probably consists of the 10 nm fiber wound into a solenoid. The 30 nm fiber is the basic constituent of both euchromatin and heterochromatin; nonhistone proteins are responsible for further organization of the fiber into chromatin or chromosome ultrastructure.

There are two pathways for nucleosome assembly. In the replication-coupled pathway, the PCNA processivity subunit of the replisome recruits CAF-1, which is a nucleosome assembly factor. CAF-1 assists the deposition of H<sub>3</sub><sub>2</sub>·H<sub>4</sub><sub>2</sub> tetramers onto the daughter duplexes resulting from replication. The tetramers may be produced either by disruption of existing nucleosomes by the replication fork or as the result of assembly from newly synthesized histones. Similar sources provide the H2A·H2B dimers that then assemble with the H<sub>3</sub><sub>2</sub>·H<sub>4</sub><sub>2</sub> tetramer to complete the nucleosome. Because the H<sub>3</sub><sub>2</sub>·H<sub>4</sub><sub>2</sub> tetramer and the H2A·H2B dimers assemble at random, the new nucleosomes may include both pre-existing and newly synthesized histones.

RNA polymerase displaces histone octamers during transcription. Nucleosomes reform on DNA after the polymerase has passed, unless transcription is very intensive (such as in rDNA) when they may be displaced completely. The replication-independent pathway for nucleosome assembly is responsible for replacing histone octamers that have been displaced by transcription. It uses the histone variant H3.3 instead of H3. A similar pathway, with another alternative to H3, is used for assembling nucleosomes at centromeric DNA sequences following

replication.

Two types of changes in sensitivity to nucleases are associated with gene activity. Chromatin capable of being transcribed has a generally increased sensitivity to DNAase I, reflecting a change in structure over an extensive region that can be defined as a domain containing active or potentially active genes. Hypersensitive sites in DNA occur at discrete locations, and are identified by greatly increased sensitivity to DNAase I. A hypersensitive site consists of a sequence of ~200 bp from which nucleosomes are excluded by the presence of other proteins. A hypersensitive site forms a boundary that may cause adjacent nucleosomes to be restricted in position. Nucleosome positioning may be important in controlling access of regulatory proteins to DNA.

Hypersensitive sites occur at several types of regulators. Those that regulate transcription include promoters, enhancers, and LCRs. Other sites include origins for replication and centromeres. A promoter or enhancer acts on a single gene, but an LCR contains a group of hypersensitive sites and may regulate a domain containing several genes.

## PROMOTERS AND ENHANCERS

### 5.21.1 Introduction

---

#### Key Terms

A **basal factor** is a transcription factor required by RNA polymerase II to form the initiation complex at all promoters. Factors are identified as TF<sub>II</sub>X, where X is a number.

The **basal transcription apparatus** is the complex of transcription factors that assembles at the promoter before RNA polymerase is bound.

An **enhancer** is a *cis*-acting sequence that increases the utilization of (some) eukaryotic promoters, and can function in either orientation and in any location (upstream or downstream) relative to the promoter.

---

Initiation of transcription requires the enzyme RNA polymerase and transcription factors. Any protein that is needed for the initiation of transcription, but which is not itself part of RNA polymerase, is defined as a transcription factor. Many transcription factors act by recognizing *cis*-acting sites on DNA. However, binding to DNA is not the only means of action for a transcription factor. A factor may recognize another factor, or may recognize RNA polymerase, or may be incorporated into an initiation complex only in the presence of several other proteins. The ultimate test for membership of the transcription apparatus is functional: a protein must be needed for transcription to occur at a specific promoter or set of promoters.

A significant difference between the transcription of eukaryotic and prokaryotic mRNAs is that initiation at a eukaryotic promoter involves a large number of factors that bind to a variety of *cis*-acting elements. The promoter is defined as the region containing all these binding sites, that is, which can support transcription at the normal efficiency and with the proper control. So the major feature defining the promoter for a eukaryotic mRNA is the location of binding sites for transcription factors. RNA polymerase itself binds around the startpoint, but does not directly contact the extended upstream region of the promoter. By contrast, the bacterial promoters discussed in *Molecular Biology 3.9 Transcription* are largely defined in terms of the binding site for RNA polymerase in the immediate vicinity of the startpoint.

Transcription in eukaryotic cells is divided into three classes. Each class is transcribed by a different RNA polymerase:

- RNA polymerase I transcribes rRNA
- RNA polymerase II transcribes mRNA
- RNA polymerase III transcribes tRNA and other small RNAs.

Transcription factors are needed for initiation, but are not required subsequently. For

the three eukaryotic enzymes, the *factors*, rather than the RNA polymerases themselves, are principally responsible for recognizing the promoter. This is different from bacterial RNA polymerase, where it is the enzyme that recognizes the promoter sequences. For all eukaryotic RNA polymerases, the factors create a structure at the promoter to provide the target that is recognized by the enzyme. For RNA polymerases I and III, these factors are relatively simple, but for RNA polymerase II they form a sizeable group collectively known as the **basal factors**. The basal factors join with RNA polymerase II to form a complex surrounding the startpoint, and they determine the site of initiation. The basal factors together with RNA polymerase constitute the **basal transcription apparatus**.

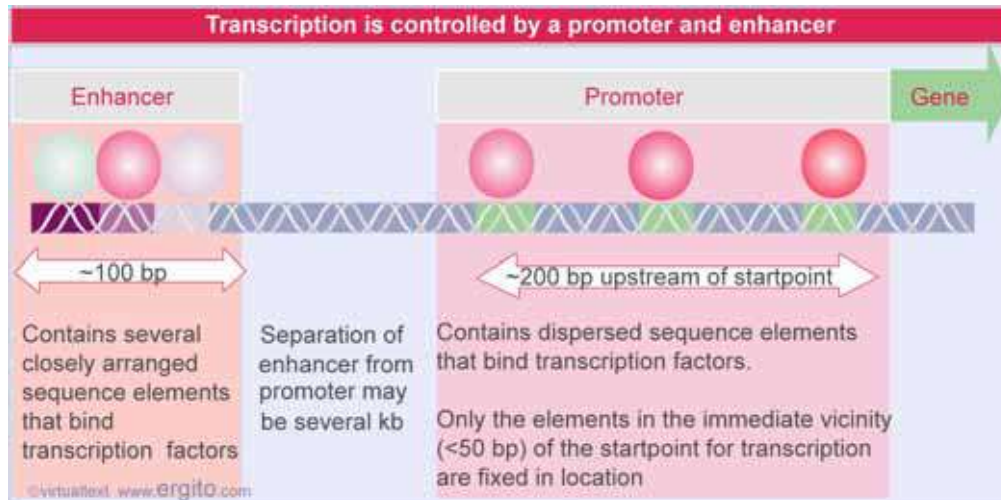

The promoters for RNA polymerases I and II are (mostly) upstream of the startpoint, but some promoters for RNA polymerase III lie downstream of the startpoint. Each promoter contains characteristic sets of short conserved sequences that are recognized by the appropriate class of factors. RNA polymerases I and III each recognize a relatively restricted set of promoters, and rely upon a small number of accessory factors.

Promoters utilized by RNA polymerase II show more variation in sequence, and have a modular organization. Short sequence elements that are recognized by transcription factors lie upstream of the startpoint. These *cis*-acting sites usually are spread out over a region of >200 bp. Some of these elements and the factors that recognize them are common: they are found in a variety of promoters and are used constitutively. Others are specific: they identify particular classes of genes and their use is regulated. The elements occur in different combinations in individual promoters.

All RNA polymerase II promoters have sequence elements close to the startpoint that are bound by the basal apparatus and that establish the site of initiation. The sequences farther upstream determine whether the promoter is expressed in all cell types or is specifically regulated. Promoters that are constitutively expressed (their genes are sometimes called housekeeping genes) have upstream sequence elements that are recognized by ubiquitous activators. No element/factor combination is an essential component of the promoter, which suggests that initiation by RNA polymerase II may be sponsored in many different ways. Promoters that are expressed only in certain times or places have sequence elements that require activators that are available only at those times or places.

Sequence components of the promoter are defined operationally by the demand that they must be located in the general vicinity of the startpoint and are required for initiation. The **enhancer** is another type of site involved in initiation. It is identified by sequences that stimulate initiation, but that are located a considerable distance from the startpoint. Enhancer elements are often targets for tissue-specific or temporal regulation. **Figure 21.1** illustrates the general properties of promoters and enhancers.

**Figure 21.1** A typical gene transcribed by RNA polymerase II has a promoter that extends upstream from the site where transcription is initiated. The promoter contains several short (<10 bp) sequence elements that bind transcription factors, dispersed over >200 bp. An enhancer containing a more closely packed array of elements that also bind transcription factors may be located several kb distant. (DNA may be coiled or otherwise rearranged so that transcription factors at the promoter and at the enhancer interact to form a large protein complex.)

The components of an enhancer resemble those of the promoter; they consist of a variety of modular elements. However, the elements are organized in a closely packed array. The elements in an enhancer function like those in the promoter, but the enhancer does not need to be near the startpoint. However, proteins bound at enhancer elements interact with proteins bound at promoter elements. The distinction between promoters and enhancers is operational, rather than implying a fundamental difference in mechanism. This view is strengthened by the fact that some types of element are found in both promoters and enhancers.

Eukaryotic transcription is most often under positive regulation: a transcription factor is provided under tissue-specific control to activate a promoter or set of promoters that contain a common target sequence. Regulation by specific repression of a target promoter is less common.

A eukaryotic transcription unit generally contains a single gene, and termination occurs beyond the end of the coding region. Termination lacks the regulatory importance that applies in prokaryotic systems. RNA polymerases I and III terminate at discrete sequences in defined reactions, but the mode of termination by RNA polymerase II is not clear. However, the significant event in generating the 3' end of an mRNA is not the termination event itself, but instead results from a cleavage reaction in the primary transcript (see *Molecular Biology 5.24 RNA splicing and processing*).

## PROMOTERS AND ENHANCERS

### 5.21.2 Eukaryotic RNA polymerases consist of many subunits

---

#### Key Terms

The **carboxy terminal domain (CTD)** of eukaryotic RNA polymerase is phosphorylated at initiation and is involved in coordinating several activities with transcription.

**Amanitin** (more fully  $\alpha$ -amanitin) is a bicyclic octapeptide derived from the poisonous mushroom *Amanita phalloides*; it inhibits transcription by certain eukaryotic RNA polymerases, especially RNA polymerase II.

#### Key Concepts

- RNA polymerase I synthesizes rRNA in the nucleolus.
- RNA polymerase II synthesizes mRNA in the nucleoplasm.
- RNA polymerase III synthesizes small RNAs in the nucleoplasm.
- All eukaryotic RNA polymerases have ~12 subunits and are aggregates of >500 kD.
- Some subunits are common to all three RNA polymerases.
- The largest subunit in RNA polymerase II has a CTD (carboxy-terminal domain) consisting of multiple repeats of a septamer.

---

The three eukaryotic RNA polymerases have different locations in the nucleus, corresponding with the genes that they transcribe (for review see 71).

The most prominent activity is the enzyme RNA polymerase I, which resides in the nucleolus and is responsible for transcribing the genes coding for rRNA. It accounts for most cellular RNA synthesis (in terms of quantity).

The other major enzyme is RNA polymerase II, located in the nucleoplasm (the part of the nucleus excluding the nucleolus). It represents most of the remaining cellular activity and is responsible for synthesizing heterogeneous nuclear RNA (hnRNA), the precursor for mRNA.

RNA polymerase III is a minor enzyme activity. This nucleoplasmic enzyme synthesizes tRNAs and other small RNAs.

All eukaryotic RNA polymerases are large proteins, appearing as aggregates of >500 kD. They typically have ~12 subunits. The purified enzyme can undertake template-dependent transcription of RNA, but is not able to initiate selectively at promoters. The general constitution of a eukaryotic RNA polymerase II enzyme as

typified in *S. cerevisiae* is illustrated in **Figure 21.2**. The two largest subunits are homologous to the  $\beta$  and  $\beta'$  subunits of bacterial RNA polymerase. Three of the remaining subunits are common to all the RNA polymerases, that is, they are also components of RNA polymerases I and III (for review see 222).

**Figure 21.2** Some subunits are common to all classes of eukaryotic RNA polymerases and some are related to bacterial RNA polymerase.

The largest subunit in RNA polymerase II has a carboxy-terminal domain (CTD), which consists of multiple repeats of a consensus sequence of 7 amino acids. The sequence is unique to RNA polymerase II. There are ~26 repeats in yeast and ~50 in mammals. The number of repeats is important, because deletions that remove (typically) more than half of the repeats are lethal (in yeast). The CTD can be highly phosphorylated on serine or threonine residues; this is involved in the initiation reaction (see *Molecular Biology 5.21.11 Initiation is followed by promoter clearance*).

The RNA polymerases of mitochondria and chloroplasts are smaller, and resemble bacterial RNA polymerase rather than any of the nuclear enzymes. Of course, the organelle genomes are much smaller, the resident polymerase needs to transcribe relatively few genes, and the control of transcription is likely to be very much simpler (if existing at all). So these enzymes are analogous to the phage enzymes that do not need the ability to respond to a more complex environment.

A major practical distinction between the eukaryotic enzymes is drawn from their response to the bicyclic octapeptide  $\alpha$ -amanitin. In basically all eukaryotic cells the activity of RNA polymerase II is rapidly inhibited by low concentrations of  $\alpha$ -amanitin. RNA polymerase I is not inhibited. The response of RNA polymerase III to  $\alpha$ -amanitin is less well conserved; in animal cells it is inhibited by high levels, but in yeast and insects it is not inhibited.

## PROMOTERS AND ENHANCERS

### 5.21.3 Promoter elements are defined by mutations and footprinting

---

#### Key Terms

A **transgene** is a gene that is introduced into a cell or animal from an external source.

#### Key Concepts

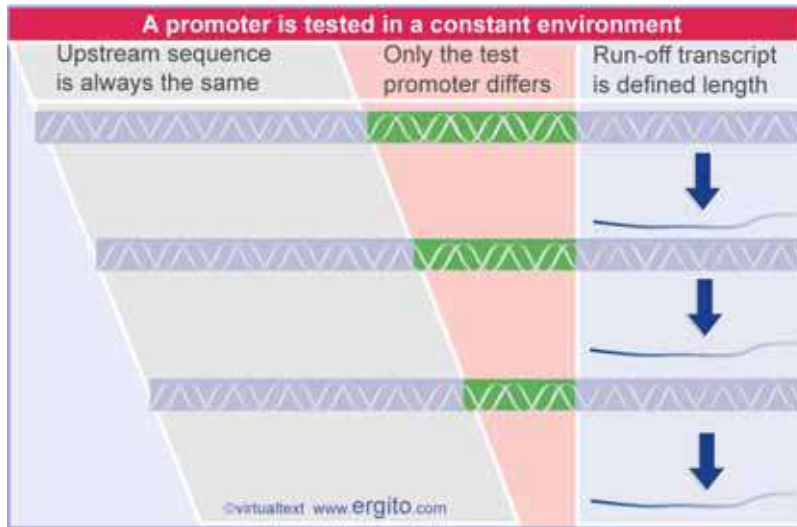

- Promoters are defined by their ability to cause transcription of an attached sequence in an appropriate test system *in vitro* or *in vivo*.

---

The first step in characterizing a promoter is to define the overall length of DNA that contains all the necessary sequence elements. To do this, we need a test system in which the promoter is responsible for the production of an easily assayed product. Historically, several types of systems have been used:

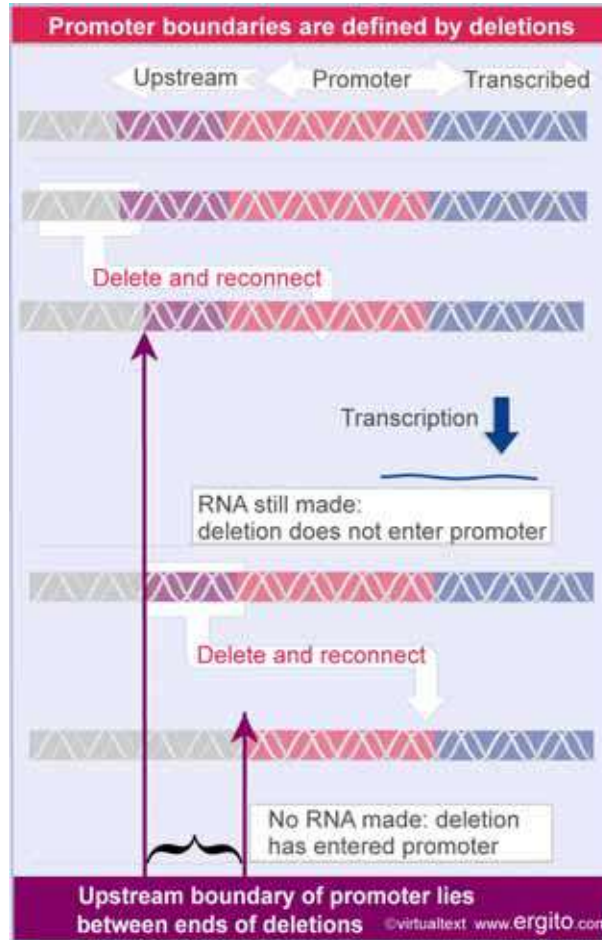

- In the *oocyte system*, a DNA template is injected into the nucleus of the *X. laevis* oocyte. The RNA transcript can be recovered and analyzed. The main limitation of this system is that it is restricted to the conditions that prevail in the oocyte. It allows characterization of DNA sequences, but not of the factors that normally bind them.
- *Transfection systems* allow exogenous DNA to be introduced into a cultured cell and expressed. (The procedure is discussed in *Molecular Biology 4.18.17 Transfection introduces exogenous DNA into cells*.) The system is genuinely *in vivo* in the sense that transcription is accomplished by the same apparatus responsible for expressing the cell's own genome. However, it differs from the natural situation because the template consists of a gene that would not usually be transcribed in the host cell. The usefulness of the system may be extended by using a variety of host cells.
- *Transgenic systems* involve the addition of a gene to the germline of an animal. Expression of the **transgene** can be followed in any or all of the tissues of the animal. Some common limitations apply to transgenic systems and to transfection: the additional gene often is present in multiple copies, and is integrated at a different location from the endogenous gene. Discrepancies between the expression of a gene *in vitro* and its expression as a transgene can yield important information about the role of the genomic context of the gene.
- The *in vitro* system takes the classic approach of purifying all the components and manipulating conditions until faithful initiation is seen. "Faithful" initiation is defined as production of an RNA starting at the site corresponding to the 5' end of mRNA (or rRNA or tRNA precursors). Ultimately this allows us to characterize the individual sequence elements in the promoter and the transcription factors that bind to them.

When a promoter is analyzed, it is important that *only* the promoter sequence changes. **Figure 21.3** shows that the same long upstream sequence is always placed next to the promoter to ensure that it is always in the same context. Because termination does not occur properly in the *in vitro* systems, the template is cut at some distance from the promoter (usually ~500 bp downstream), to ensure that all polymerases "run off" at the same point, generating an identifiable transcript.

**Figure 21.3** A promoter is tested by modifying the sequence that is connected to a constant upstream sequence and a constant downstream transcription unit.

We start with a particular fragment of DNA that can initiate transcription in one of these systems. Then the boundaries of the sequence constituting the promoter can be determined by reducing the length of the fragment from either end, until at some point it ceases to be active, as illustrated in **Figure 21.4**. The boundary upstream can be identified by progressively removing material from this end until promoter function is lost. To test the boundary downstream, it is necessary to reconnect the shortened promoter to the sequence to be transcribed (since otherwise there is no product to assay).

**Figure 21.4** Promoter boundaries can be determined by making deletions that progressively remove more material from one side. When one deletion fails to prevent RNA synthesis but the next stops transcription, the boundary of the promoter must lie between them.

Once the boundaries of the promoter have been defined, the importance of particular bases within it can be determined by introducing point mutations or other rearrangements in the sequence. As with bacterial RNA polymerase, these can be characterized as *up* or *down* mutations. Some of these rearrangements affect only the *rate* of initiation; others influence the *site* at which initiation occurs, as seen in a change of the startpoint. To be sure that we are dealing with comparable products, in each case it is necessary to characterize the 5' end of the RNA.

We can apply several criteria in identifying the sequence components of a promoter (or any other site in DNA):

- Mutations in the site prevent function *in vitro* or *in vivo*. (Many techniques now exist for introducing point mutations at particular base pairs, and in principle every position in a promoter can be mutated, and the mutant sequence tested *in vitro* or *in vivo*.)

- Proteins that act by binding to a site may be footprinted on it. There should be a correlation between the ability of mutations to prevent promoter function and to prevent binding of the factor.
- When a site recognized by a particular factor is present at multiple promoters, it should be possible to derive a consensus sequence that is bound by the factor. A new promoter should become responsive to this factor when an appropriate copy of the element is introduced.

*This content is available online at <http://www.ergito.com/main.jsp?bcs=MBIO.5.21.3>*

---

## PROMOTERS AND ENHANCERS

### 5.21.4 RNA polymerase I has a bipartite promoter

---

#### Key Terms

A **spacer** is a sequence in a gene cluster that separates the repeated copies of the transcription unit.

#### Key Concepts

- The RNA polymerase I promoter consists of a core promoter and an upstream control element (UCE).
- The factor UBF1 wraps DNA around a protein structure to bring the core and UPE into proximity.
- SL1 includes the factor TBP that is involved in initiation by all three RNA polymerases.
- RNA polymerase binds to the UBF1-SL1 complex at the core promoter.

---

RNA polymerase I transcribes only the genes for ribosomal RNA, from a single type of promoter. The transcript includes the sequences of both large and small rRNAs, which are later released by cleavages and processing. There are many copies of the transcription unit, alternating with nontranscribed **spacers**, and organized in a cluster as discussed in *Molecular Biology 1.4.8 Genes for rRNA form tandem repeats*. The organization of the promoter, and the events involved in initiation, are illustrated in **Figure 21.5**.

**Figure 21.5** Transcription units for RNA polymerase I have a core promoter separated by ~70 bp from the upstream promoter element. UBF binding to the UPE increases the ability of core-binding factor to bind to the core promoter. Core-binding factor positions RNA polymerase I at the startpoint.

The promoter consists of two separate regions. The **core promoter** surrounds the startpoint, extending from  $-45$  to  $+20$ , and is sufficient for transcription to initiate. It is generally G-C-rich (unusual for a promoter) except for the only conserved sequence element, a short A-T-rich sequence around the startpoint called the Inr. However, its efficiency is very much increased by the upstream promoter element (UPE), another G-C-rich sequence, related to the core promoter sequence, which extends from  $-180$  to  $-107$ . This type of organization is common to pol I promoters in many species, although the actual sequences vary widely (for review see 1672).

RNA polymerase I requires two ancillary factors. The factor that binds to the core promoter consists of 4 proteins. (It is called SL1, TIF-IB, Rib1 in different species). One of its components, called TBP, is a factor that is required also for initiation by RNA polymerases II and III (see *Molecular Biology 5.21.8 TBP is a universal factor*). TBP does not bind directly to G-C-rich DNA, and DNA-binding is the responsibility of the other components of the core-binding factor. It is likely that TBP interacts with RNA polymerase, probably with a common subunit or a feature that has been conserved among polymerases. Core-binding factor enables RNA polymerase I to initiate from the promoter at a low basal frequency.

The core-binding factor has primary responsibility for ensuring that the RNA polymerase is properly localized at the startpoint. We see shortly that a comparable function is provided for RNA polymerases II and III by a factor that consists of TBP associated with other proteins. So a common feature in initiation by all three polymerases is a reliance on a "positioning" factor that consists of TBP associated

with proteins that are specific for each type of promoter.

For high frequency initiation, the factor UBF is required. This is a single polypeptide that binds to a G·C-rich element in the upstream promoter element. One indication of how UBF interacts with the core-binding factor is given by the importance of the spacing between the upstream promoter element and the core promoter. This can be changed by distances involving integral numbers of turns of DNA, but not by distances that introduce half turns (1676). UBF binds to the minor groove of DNA and wraps the DNA in a loop of almost 360°, thus bringing the core and the UPE into close proximity.

**Figure 21.5** shows initiation as a series of sequential interactions. However, RNA polymerase I exists as a holoenzyme that contains most or all of the factors required for initiation, and which is probably recruited directly to the promoter (for review see 4177).

## PROMOTERS AND ENHANCERS

### 5.21.5 RNA polymerase III uses both downstream and upstream promoters

---

#### Key Concepts

- RNA polymerase III has two types of promoters.
  - Internal promoters have short consensus sequences located within the transcription unit and cause initiation to occur a fixed distance upstream.
  - Upstream promoters contain three short consensus sequences upstream of the startpoint that are bound by transcription factors.
- 

Recognition of promoters by RNA polymerase III strikingly illustrates the relative roles of transcription factors and the polymerase enzyme. The promoters fall into two general classes that are recognized in different ways by different groups of factors. The promoters for 5S and tRNA genes are *internal*; they lie downstream of the startpoint. The promoters for snRNA (small nuclear RNA) genes lie upstream of the startpoint in the more conventional manner of other promoters. In both cases, the individual elements that are necessary for promoter function consist exclusively of sequences recognized by transcription factors, which in turn direct the binding of RNA polymerase.

Before the promoter of 5S RNA genes was identified in *X. laevis*, all attempts to identify promoter sequences assumed that they would lie upstream of the startpoint. But deletion analysis showed that the 5S RNA product continues to be synthesized when the entire sequence upstream of the gene is removed!

When the deletions continue into the gene, a product very similar in size to the usual 5S RNA continues to be synthesized so long as the deletion ends before base +55. **Figure 21.6** shows that the first part of the RNA product corresponds to plasmid DNA; the second part represents the segment remaining of the usual 5S RNA sequence. But when the deletion extends past +55, transcription does not occur. So the promoter lies *downstream of position +55*, but causes RNA polymerase III to initiate transcription a more or less fixed distance upstream (641; 642).

**Figure 21.6** Deletion analysis shows that the promoter for 5S RNA genes is internal; initiation occurs a fixed distance (~55 bp) upstream of the promoter.

When deletions extend into the gene from its distal end, transcription is unaffected so long as the first 80 bp remain intact. Once the deletion cuts into this region, transcription ceases. This places the downstream boundary position of the promoter at about position +80.

*So the promoter for 5S RNA transcription lies between positions +55 and +80 within the gene. A fragment containing this region can sponsor initiation of any DNA in which it is placed, from a startpoint ~55 bp farther upstream. (The wild-type startpoint is unique; in deletions that lack it, transcription initiates at the purine base nearest to the position 55 bp upstream of the promoter.)*

The structures of three types of promoters for RNA polymerase III are summarized in **Figure 21.7**. There are two types of internal promoter. Each contains a bipartite structure, in which two short sequence elements are separated by a variable sequence. Type 1 consists of a boxA sequence separated from a boxC sequence (1673), and type 2 consists of a boxA sequence separated from a boxB sequence (1674). The distance between boxA and boxB in a type 2 promoter can vary quite extensively, but the boxes usually cannot be brought too close together without abolishing function. Type 3 promoters have three sequence elements all located upstream of the startpoint (1675).

**Figure 21.7** Promoters for RNA polymerase III may consist of bipartite sequences downstream of the startpoint, with boxA separated from either boxC or boxB. Or they may consist of separated sequences upstream of the startpoint (Oct, PSE, TATA).

## PROMOTERS AND ENHANCERS

### 5.21.6 TF<sub>III</sub>B is the commitment factor for pol III promoters

---

#### Key Terms

An **assembly factor** is a protein that is required for formation of a macromolecular structure but is not itself part of that structure.

**Preinitiation complex** in eukaryotic transcription describes the assembly of transcription factors at the promoter before RNA polymerase binds.

#### Key Concepts

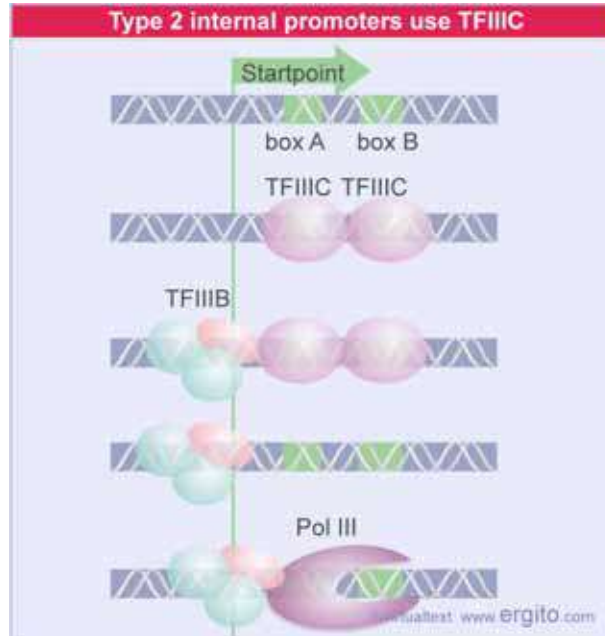

- TF<sub>III</sub>A and TF<sub>III</sub>C bind to the consensus sequences and enable TF<sub>III</sub>B to bind at the startpoint.
- TF<sub>III</sub>B has TBP as one subunit and enables RNA polymerase to bind.

---

The detailed interactions are different at the two types of internal promoter, but the principle is the same. TF<sub>III</sub>C binds downstream of the startpoint, either independently (type 2 promoters) or in conjunction with TF<sub>III</sub>A (type 1 promoters). The presence of TF<sub>III</sub>C enables the positioning factor TF<sub>III</sub>B to bind at the startpoint. Then RNA polymerase is recruited.

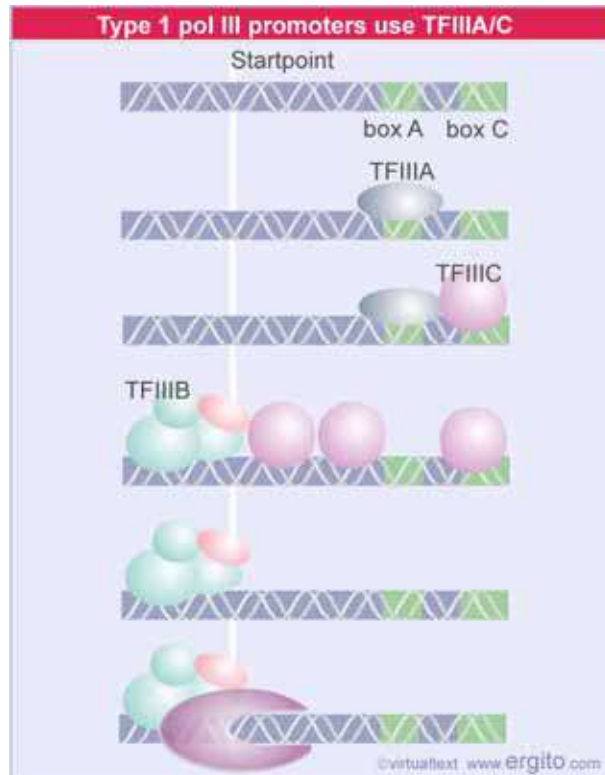

**Figure 21.8** summarizes the stages of reaction at type 2 internal promoters. TF<sub>III</sub>C binds to both boxA and boxB. This enables TF<sub>III</sub>B to bind at the startpoint. Then RNA polymerase III can bind.

**Figure 21.8** Internal type 2 pol III promoters use binding of TFIIIC to boxA and boxB sequences to recruit the positioning factor TFIIIB, which recruits RNA polymerase III.

The difference at type 1 internal promoters is that TF<sub>III</sub>A must bind at boxA to enable TF<sub>III</sub>C to bind at boxC. **Figure 21.9** shows that, once TF<sub>III</sub>C has bound, events follow the same course as at type 2 promoters, with TF<sub>III</sub>B binding at the startpoint, and RNA polymerase III joining the complex. Type 1 promoters are found only in the genes for 5S rRNA.

**Figure 21.9** Internal type 1 pol III promoters use the assembly factors TFIIIA and TFIIIC, at boxA and boxC, to recruit the positioning factor TFIIIB, which recruits RNA polymerase III.

TF<sub>III</sub>A and TF<sub>III</sub>C are **assembly factors**, whose sole role is to assist the binding of TF<sub>III</sub>B at the right location. Once TF<sub>III</sub>B has bound, TF<sub>III</sub>A and TF<sub>III</sub>C can be removed from the promoter (by high salt concentration *in vitro*) without affecting the initiation reaction. *TF<sub>III</sub>B remains bound in the vicinity of the startpoint and its presence is sufficient to allow RNA polymerase III to bind at the startpoint.* So TF<sub>III</sub>B is the only true initiation factor required by RNA polymerase III (643). This sequence of events explains how the promoter boxes downstream can cause RNA polymerase to bind at the startpoint, farther upstream. Although the ability to transcribe these genes is conferred by the internal promoter, changes in the region immediately upstream of the startpoint can alter the efficiency of transcription.

TF<sub>III</sub>C is a large protein complex (>500 kD), comparable in size to RNA polymerase itself, and containing 6 subunits. TF<sub>III</sub>A is a member of an interesting class of proteins containing a nucleic acid-binding motif called a zinc finger (see *Molecular Biology 5.22.9 A zinc finger motif is a DNA-binding domain*). The positioning factor, TF<sub>III</sub>B, consists of three subunits. It includes the same protein, TBP, that is present in the core-binding factor for pol I promoters, and also in the corresponding transcription factor (TF<sub>II</sub>D) for RNA polymerase II (1677). It also contains Brf, which is related to the factor TF<sub>II</sub>B that is used by RNA polymerase II. The third subunit is called B''; it is dispensable if the DNA duplex is partially melted, which suggests that its function is to initiate the transcription bubble (945). The role of B'' may be comparable to the role played by sigma factor in bacterial RNA polymerase (see *Molecular Biology 3.9.16 Substitution of sigma factors may control initiation*).

The upstream region has a conventional role in the third class of polymerase III promoters. In the example shown in **Figure 21.7**, there are three upstream elements. These elements are also found in promoters for snRNA genes that are transcribed by RNA polymerase II. (Genes for some snRNAs are transcribed by RNA polymerase II, while others are transcribed by RNA polymerase III.) The upstream elements function in a similar manner in promoters for both polymerases II and III.

Initiation at an upstream promoter for RNA polymerase III can occur on a short region that immediately precedes the startpoint and contains only the TATA element. However, efficiency of transcription is much increased by the presence of the PSE and OCT elements. The factors that bind at these elements interact cooperatively. (The PSE element may be essential at promoters used by RNA polymerase II, whereas it is stimulatory in promoters used by RNA polymerase III; its name stands for proximal sequence element.)

The TATA element confers specificity for the type of polymerase (II or III) that is recognized by an snRNA promoter. It is bound by a factor that includes the TBP, which actually recognizes the sequence in DNA. The TBP is associated with other proteins, which are specific for the type of promoter. The function of TBP and its associated proteins is to position the RNA polymerase correctly at the startpoint. We discuss this in more detail for RNA polymerase II (see *Molecular Biology 5.21.8 TBP is a universal factor*).

The factors work in the same way for both types of promoters for RNA polymerase III. *The factors bind at the promoter before RNA polymerase itself can bind.* They form a **preinitiation complex** that directs binding of the RNA polymerase. RNA polymerase III does not itself recognize the promoter sequence, but binds adjacent to factors that are themselves bound just upstream of the startpoint. For the type 1 and type 2 internal promoters, the assembly factors ensure that TF<sub>III</sub>B (which includes TBP) is bound just upstream of the startpoint, to provide the positioning information. For the upstream promoters, TF<sub>III</sub>B binds directly to the region including the TATA box. So irrespective of the location of the promoter sequences, factor(s) are bound close to the startpoint in order to direct binding of RNA polymerase III (for review see 220; 3231).

## PROMOTERS AND ENHANCERS

### 5.21.7 The startpoint for RNA polymerase II

#### Key Terms

**TAFs (TF<sub>II</sub>X)** are the subunits of TF<sub>II</sub>D that assist TBP in binding to DNA. They also provide points of contact for other components of the transcription apparatus.

The **core promoter** of RNA polymerase I is the region immediately surrounding the startpoint. It is necessary and sufficient to initiate transcription, but only at a low level.

A **core promoter** is the shortest sequence at which an RNA polymerase can initiate transcription (typically at much lower level than that displayed by a promoter containing additional elements). For RNA polymerase II it is the minimal sequence at which the basal transcription apparatus can assemble, and includes two sequence elements, the InR and TATA box. It is typically ~40 bp long.

The **Inr** is the sequence of a pol II promoter between -3 and +5 and has the general sequence Py<sub>2</sub>CAPy<sub>5</sub>. It is the simplest possible pol II promoter.

**TATA box** is a conserved A·T-rich septamer found about 25 bp before the startpoint of each eukaryotic RNA polymerase II transcription unit; may be involved in positioning the enzyme for correct initiation.

A **TATA-less promoter** does not have a TATA box in the sequence upstream of its startpoint.

#### Key Concepts

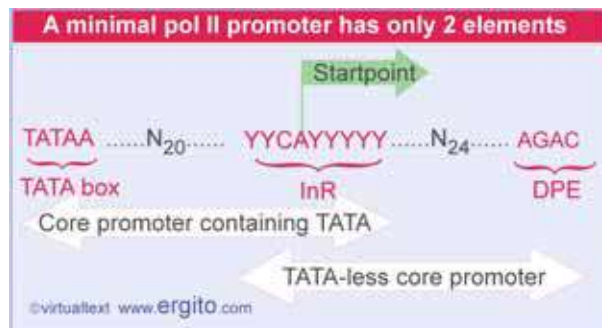

- RNA polymerase II requires general transcription factors (called **TF<sub>II</sub>X**) to initiate transcription.
- RNA polymerase II promoters have a short conserved sequence Py<sub>2</sub>CAPy<sub>5</sub> (the initiator InR) at the startpoint.
- The TATA box is a common component of RNA polymerase II promoters and consists of an A·T-rich octamer located ~25 bp upstream of the startpoint
- The DPE is a common component of RNA polymerase II promoters that do not contain a TATA box.
- A core promoter for RNA polymerase II includes the InR and either a TATA box or a DPE.

The basic organization of the apparatus for transcribing protein-coding genes was revealed by the discovery that purified RNA polymerase II can catalyze synthesis of mRNA, but cannot initiate transcription unless an additional extract is added (2406). The purification of this extract led to the definition of the general transcription factors – a group of proteins that are needed for initiation by RNA polymerase II at all promoters (for review see 2407). RNA polymerase II in conjunction with these factors constitutes the basal transcription apparatus that is needed to transcribe any promoter. The general factors are described as **TF<sub>II</sub>X**, where "X" is a letter that

identifies the individual factor. The subunits of RNA polymerase II and the general transcription factors are conserved among eukaryotes.

Our starting point for considering promoter organization is to define the **core promoter** as the shortest sequence at which RNA polymerase II can initiate transcription. A core promoter can in principle be expressed in any cell. It comprises the minimum sequence that enables the general transcription factors to assemble at the startpoint. They are involved in the mechanics of binding to DNA and enable RNA polymerase II to initiate transcription. A core promoter functions at only a low efficiency. Other proteins, called activators, are required for a proper level of function (see *Molecular Biology 5.21.13 Short sequence elements bind activators*). The activators are not described systematically, but have casual names reflecting their histories of identification.

We may expect any sequence components involved in the binding of RNA polymerase and general transcription factors to be conserved at most or all promoters. As with bacterial promoters, when promoters for RNA polymerase II are compared, homologies in the regions near the startpoint are restricted to rather short sequences. These elements correspond with the sequences implicated in promoter function by mutation. **Figure 21.10** shows the construction of a typical pol II core promoter (for review see 3225, 4527).

**Figure 21.10** The minimal pol II promoter has a TATA box ~25 bp upstream of the Inr. The TATA box has the consensus sequence of TATAA. The Inr has pyrimidines (Y) surrounding the CA at the startpoint. The sequence shows the coding strand.

At the startpoint, there is no extensive homology of sequence, but there is a tendency for the first base of mRNA to be A, flanked on either side by pyrimidines. (This description is also valid for the CAT start sequence of bacterial promoters.) This region is called the *initiator* (**Inr**), and may be described in the general form Py<sub>2</sub>CAPy<sub>5</sub> (3228; 3229). The Inr is contained between positions -3 and +5.

Many promoters have a sequence called the **TATA box**, usually located ~25 bp upstream of the startpoint. It constitutes the only upstream promoter element that has a relatively fixed location with respect to the startpoint. The core sequence is TATAA, usually followed by three more A·T base pairs (see 3227). The TATA box tends to be surrounded by G·C-rich sequences, which could be a factor in its function. It is almost identical with the -10 sequence found in bacterial promoters; in fact, it could pass for one except for the difference in its location at -25 instead of -10.

Single base substitutions in the TATA box act as strong down mutations. Some mutations reverse the orientation of an A·T pair, so base composition alone is not sufficient for its function. So the TATA box comprises an element whose behavior is analogous to our concept of the bacterial promoter: a short, well-defined sequence just upstream of the startpoint, which is necessary for transcription.

Promoters that do not contain a TATA element are called **TATA-less promoters**. Surveys of promoter sequences suggest that 50% or more of promoters may be TATA-less. When a promoter does not contain a TATA box, it usually contains another element, the DPE (downstream promoter element) which is located at +28 - +32 (3230).

A core promoter can consist either of a TATA box plus InR or of an InR plus DPE.

## PROMOTERS AND ENHANCERS

### 5.21.8 TBP is a universal factor

#### Key Terms

**TF<sub>II</sub>D** is the transcription factor that binds to the TATA sequence upstream of the startpoint of promoters for RNA polymerase II. It consists of TBP (TATA binding protein) and the TAF subunits that bind to TBP.

The **TATA-binding protein (TBP)** is the subunit of transcription factor TF<sub>II</sub>D that binds to DNA.

**TAFs (TF<sub>II</sub>X)** are the subunits of TF<sub>II</sub>D that assist TBP in binding to DNA. They also provide points of contact for other components of the transcription apparatus.

#### Key Concepts

- TBP is a component of the positioning factor that is required for each type of RNA polymerase to bind its promoter.
- The factor for RNA polymerase II is TF<sub>II</sub>D, which consists of TBP and 11 TAFs, with a total mass ~800 kD.

The first step in complex formation at a promoter containing a TATA box is binding of the factor **TF<sub>II</sub>D** to a region that extends upstream from the TATA sequence. TF<sub>II</sub>D contains two types of component. Recognition of the TATA box is conferred by the **TATA-binding protein (TBP)**, a small protein of ~30 kD. The other subunits are called **TAFs** (for TBP-associated factors). Some TAFs are stoichiometric with TBP; others are present in lesser amounts. TF<sub>II</sub>Ds containing different TAFs could recognize different promoters. Some (substoichiometric) TAFs are tissue-specific. The total mass of TF<sub>II</sub>D typically is ~800 kD, containing TBP and 11 TAFs, varying in mass from 30-250 kD. The TAFs in TF<sub>II</sub>D are named in the form TAF<sub>II</sub>00, where "00" gives the molecular mass of the subunit.

Positioning factors that consist of TBP associated with a set of TAFs are responsible for identifying all classes of promoters. TF<sub>III</sub>B (for pol III promoters) and SL1 (for pol I promoters) may both be viewed as consisting of TBP associated with a particular group of proteins that substitute for the TAFs that are found in TF<sub>II</sub>D (for review see 1709). TBP is the key component, and is incorporated at each type of promoter by a different mechanism (for review see 2394). In the case of promoters for RNA polymerase II, the key feature in positioning is the fixed distance of the TATA box from the startpoint.

**Figure 21.11** shows that the positioning factor recognizes the promoter in a different way in each case. At promoters for RNA polymerase III, TF<sub>III</sub>B binds adjacent to TF<sub>III</sub>C. At promoters for RNA polymerase I, SL1 binds in conjunction with UBF. TF<sub>II</sub>D is solely responsible for recognizing promoters for RNA polymerase II. At a promoter that has a TATA element, TBP binds specifically to DNA, but at other promoters it may be incorporated by association with other proteins that bind to DNA. Whatever its means of entry into the initiation complex, it has the common

purpose of interaction with the RNA polymerase.

**Figure 21.11** RNA polymerases are positioned at all promoters by a factor that contains TBP.

TF<sub>II</sub>D is ubiquitous, but not unique. All multicellular eukaryotes also express an alternative complex, which has TLF (TBP like factor) instead of TBP (1708). A TLF is typically ~60% similar to TBP. It probably initiates complex formation by the usual set of TF<sub>II</sub> factors. However, TLF does not bind to the TATA box, and we do not yet know how it works. *Drosophila* also has a third factor, TRF1, which behaves in the same way as TBP and binds its own set of TAFs, to form a complex that functions as an alternative to TF<sub>II</sub>D at a specific set of promoters (1707).

## PROMOTERS AND ENHANCERS

### 5.21.9 TBP binds DNA in an unusual way

#### Key Concepts

- TBP binds to the TATA box in the minor groove of DNA.
- It forms a saddle around the DNA and bends it by  $\sim 80^\circ$ .
- Some of the TAFs resemble histones and may form a structure resembling a histone octamer.

TBP has the unusual property of binding to DNA in the minor groove. (Virtually all known DNA-binding proteins bind in the major groove.) The crystal structure of TBP suggests a detailed model for its binding to DNA. **Figure 21.12** shows that it surrounds one face of DNA, forming a "saddle" around the double helix. In effect, the inner surface of TBP binds to DNA, and the larger outer surface is available to extend contacts to other proteins. The DNA-binding site consists of a C-terminal domain that is conserved between species, while the variable N-terminal tail is exposed to interact with other proteins (647; 648; 649). It is a measure of the conservation of mechanism in transcriptional initiation that the DNA-binding sequence of TBP is 80% conserved between yeast and Man.

**Figure 21.12** A view in cross-section shows that TBP surrounds DNA from the side of the narrow groove. TBP consists of two related (40% identical) conserved domains, which are shown in light and dark blue. The N-terminal region varies extensively and is shown in green. The two strands of the DNA double helix are in light and dark grey. Photograph kindly provided by Stephen Burley.

Binding of TBP may be inconsistent with the presence of nucleosomes. Because nucleosomes form preferentially by placing A·T-rich sequences with the minor grooves facing inward, they could prevent binding of TBP. This may explain why the presence of nucleosomes prevents initiation of transcription.

TBP binds to the minor groove and bends the DNA by  $\sim 80^\circ$ , as illustrated in **Figure**

**21.13.** The TATA box bends towards the major groove, widening the minor groove. The distortion is restricted to the 8 bp of the TATA box; at each end of the sequence, the minor groove has its usual width of  $\sim 5 \text{ \AA}$ , but at the center of the sequence the minor groove is  $>9 \text{ \AA}$ . This is a deformation of the structure, but does not actually separate the strands of DNA, because base pairing is maintained. The extent of the bend can vary with the exact sequence of the TATA box, and is correlated with the efficiency of the promoter (4532).

**Figure 21.13** The cocrystal structure of TBP with DNA from -40 to the startpoint shows a bend at the TATA box that widens the narrow groove where TBP binds. Photograph provided by Stephen Burley.

This structure has several functional implications. By changing the spatial organization of DNA on either side of the TATA box, it allows the transcription factors and RNA polymerase to form a closer association than would be possible on linear DNA. The bending at the TATA box corresponds to unwinding of about 1/3 of a turn of DNA, and is compensated by a positive writhe.

The presence of TBP in the minor groove, combined with other proteins binding in the major groove, creates a high density of protein-DNA contacts in this region. Binding of purified TBP to DNA *in vitro* protects  $\sim 1$  turn of the double helix at the TATA box, typically extending from -37 to -25; but binding of the TF<sub>II</sub>D complex in the initiation reaction regularly protects the region from -45 to -10, and also extends farther upstream beyond the startpoint. TBP is the only general transcription factor that makes sequence-specific contacts with DNA.

Within TF<sub>II</sub>D as a free protein complex, the factor TAF<sub>II</sub>230 binds to TBP, where it occupies the concave DNA-binding surface. In fact, the structure of the binding site, which lies in the N-terminal domain of TAF<sub>II</sub>230, mimics the surface of the minor groove in DNA. This molecular mimicry allows TAF<sub>II</sub>230 to control the ability of TBP to bind to DNA; the N-terminal domain of TAF<sub>II</sub>230 must be displaced from the DNA-binding surface of TBP in order for TF<sub>II</sub>D to bind to DNA (654).

Some TAFs resemble histones; in particular TAF<sub>II</sub>42 and TAF<sub>II</sub>62 appear to be (distant) homologues of histones H3 and H4, and they form a heterodimer using the same motif (the histone fold) that histones use for the interaction. (Histones H3 and H4 form the kernel of the histone octamer – the basic complex that binds DNA in

eukaryotic chromatin; see *Molecular Biology 5.20.8 Organization of the histone octamer*.) Together with other TAFs, TAF<sub>II</sub>42 and TAF<sub>II</sub>62 may form the basis for a structure resembling a histone octamer; such a structure may be responsible for the nonsequence-specific interactions of TF<sub>II</sub>D with DNA. Histone folds are also used in pairwise interactions between other TAF<sub>II</sub>s.

Some of the TAF<sub>II</sub>s may be found in other complexes as well as in TF<sub>II</sub>D. In particular, the histone-like TAF<sub>II</sub>s are found also in protein complexes that modify the structure of chromatin prior to transcription (see *Molecular Biology 5.23.7 Acetylases are associated with activators*) (651; 653; 657; 695; for review see 225; 1709; 2395).

**PROMOTERS AND ENHANCERS****5.21.10 The basal apparatus assembles at the promoter**

---

**Key Concepts**

- Binding of TF<sub>II</sub>D to the TATA box is the first step in initiation.
  - Other transcription factors bind to the complex in a defined order, extending the length of the protected region on DNA.
  - When RNA polymerase II binds to the complex, it initiates transcription.
- 

Initiation requires the transcription factors to act in a defined order to build a complex that is joined by RNA polymerase. The series of events was initially defined by following the increasing size of the protein complex associated with DNA. Now we can define the events in more detail in terms of the interactions revealed by the crystal structures of the various factors, and of RNA polymerase bound to DNA.

Footprinting of the DNA regions protected by each complex suggests the model summarized in **Figure 21.15**. As each TF<sub>II</sub> factor joins the complex, an increasing length of DNA is covered. RNA polymerase is incorporated at a late stage (644; for review see 223; 226).

**Figure 21.15** An initiation complex assembles at promoters for RNA polymerase II by an ordered sequence of association with transcription factors.

Commitment to a promoter is initiated when TF<sub>II</sub>D binds the TATA box. (TF<sub>II</sub>D also recognizes the InR sequence at the startpoint.) When TF<sub>II</sub>A joins the complex, TF<sub>II</sub>D becomes able to protect a region extending farther upstream. TF<sub>II</sub>A may activate TBP by relieving the repression that is caused by the TAF<sub>II</sub>230.

Addition of TF<sub>II</sub>B gives partial protection of the region of the template strand in the vicinity of the startpoint, from -10 to +10. This suggests that TF<sub>II</sub>B is bound downstream of the TATA box, perhaps loosely associated with DNA and asymmetrically oriented with regard to the two DNA strands. The crystal structure shown in **Figure 21.16** extends this model. TF<sub>II</sub>B binds adjacent to TBP, extending contacts along one face of DNA. It makes contacts in the minor groove downstream of the TATA box, and contacts the major groove upstream of the TATA box, in a region called the BRE (2408). In archaea, the homologue of TF<sub>II</sub>B actually makes sequence-specific contacts with the promoter in the BRE region (652). TF<sub>II</sub>B may provide the surface that is in turn recognized by RNA polymerase, so that it is responsible for the directionality of the binding of the enzyme.

**Figure 21.16** Two views of the ternary complex of TFIIB-TBP-DNA show that TFIIB binds along the bent face of DNA. The two strands of DNA are green and yellow, TBP is blue, and TFIIB is red and purple. Photograph kindly provided by Stephen Burley.

The crystal structure of TFIIB with RNA polymerase shows that three domains of the factor interact with the enzyme (4832). As illustrated schematically in **Figure 21.14**, an N-terminal zinc ribbon from TFIIB contacts the enzyme near the site where RNA exits; it is possible that this interferes with the exit of RNA and influences the switch from abortive initiation to promoter escape. An elongated "finger" of TFIIB is inserted into the polymerase active center. The C-terminal domain interacts with the RNA polymerase and with TFIID to orient the DNA. It also determines the path of the DNA where it contacts the factors TFIIE, TFIIF, and TFIIH, which may align them in the basal factor complex.

**Figure 21.14** TF<sub>II</sub>B binds to DNA and contacts RNA polymerase near the RNA exit site and at the active center, and orients it on DNA. Compare with 1170, which shows the polymerase structure engaged in transcription.

The factor TF<sub>II</sub>F is a heterotetramer consisting of two types of subunit. The larger subunit (RAP<sup>II</sup>74) has an ATP-dependent DNA helicase activity that could be involved in melting the DNA at initiation. The smaller subunit (RAP38) has some homology to the regions of bacterial sigma factor that contact the core polymerase; it binds tightly to RNA polymerase II. TF<sub>II</sub>F may bring RNA polymerase II to the assembling transcription complex and provide the means by which it binds. The complex of TBP and TAFs may interact with the CTD tail of RNA polymerase, and interaction with TF<sub>II</sub>B may also be important when TF<sub>II</sub>F/polymerase joins the complex.

Polymerase binding extends the sites that are protected downstream to +15 on the template strand and +20 on the nontemplate strand. The enzyme extends the full length of the complex, since additional protection is seen at the upstream boundary.

What happens at TATA-less promoters? The same general transcription factors, including TF<sub>II</sub>D, are needed. The Inr provides the positioning element; TF<sub>II</sub>D binds to it via an ability of one or more of the TAFs to recognize the Inr directly. Other TAFs in TF<sub>II</sub>D also recognize the DPE element downstream from the startpoint (3230). The function of TBP at these promoters is more like that at promoters for RNA polymerase I and at internal promoters for RNA polymerase III.

Assembly of the RNA polymerase II initiation complex provides an interesting contrast with prokaryotic transcription. Bacterial RNA polymerase is essentially a coherent aggregate with intrinsic ability to bind DNA; the sigma factor, needed for initiation but not for elongation, becomes part of the enzyme before DNA is bound, although it is later released. But RNA polymerase II can bind to the promoter only after separate transcription factors have bound. The factors play a role analogous to that of bacterial sigma factor – to allow the basic polymerase to recognize DNA

specifically at promoter sequences – but have evolved more independence. Indeed, the factors are primarily responsible for the specificity of promoter recognition. Only some of the factors participate in protein-DNA contacts (and only TBP makes sequence-specific contacts); thus protein-protein interactions are important in the assembly of the complex.

When a TATA box is present, it determines the location of the startpoint. Its deletion causes the site of initiation to become erratic, although any overall reduction in transcription is relatively small. Indeed, some TATA-less promoters lack unique startpoints; initiation occurs instead at any one of a cluster of startpoints. The TATA box aligns the RNA polymerase (via the interaction with TF<sub>D</sub> and other factors) so that it initiates at the proper site. This explains why its location is fixed with respect to the startpoint. Binding of TBP to TATA is the predominant feature in recognition of the promoter, but two large TAFs (TAF<sub>250</sub> and TAF<sub>150</sub>) also contact DNA in the vicinity of the startpoint and influence the efficiency of the reaction.

Although assembly can take place just at the core promoter *in vitro*, this reaction is not sufficient for transcription *in vivo*, where interactions with activators that recognize the more upstream elements are required. The activators interact with the basal apparatus at various stages during its assembly (see *Molecular Biology 5.22.5 Activators interact with the basal apparatus*).

**PROMOTERS AND ENHANCERS****5.21.11 Initiation is followed by promoter clearance**

---

**Key Concepts**

- $TF_{II}E$  and  $TF_{II}H$  are required to melt DNA to allow polymerase movement.
  - Phosphorylation of the CTD may be required for elongation to begin.
  - Further phosphorylation of the CTD is required at some promoters to end abortive initiation.
  - The CTD may coordinate processing of RNA with transcription.
- 

Most of the transcription factors are required solely to bind RNA polymerase to the promoter, but some act at a later stage (for review see 2407). Binding of  $TF_{II}E$  causes the boundary of the region protected downstream to be extended by another turn of the double helix, to +30. Two further factors,  $TF_{II}H$  and  $TF_{II}J$ , join the complex after  $TF_{II}E$ . They do not change the pattern of binding to DNA.

$TF_{II}H$  is the only general transcription factor that has independent enzymatic activities. Its several activities include an ATPase, helicases of both polarities, and a kinase activity that can phosphorylate the CTD tail of RNA polymerase II.  $TF_{II}H$  is an exceptional factor that may play a role also in elongation. Its interaction with DNA downstream of the startpoint is required for RNA polymerase to escape from the promoter (2207).  $TF_{II}H$  is also involved in repair of damage to DNA (see *Molecular Biology 5.21.12 A connection between transcription and repair*) (650).

The initiation reaction, as defined by formation of the first phosphodiester bond, occurs once RNA polymerase has bound. **Figure 21.17** proposes a model in which phosphorylation of the tail is needed to release RNA polymerase II from the transcription factors so that it can make the transition to the elongating form. Most of the transcription factors are released from the promoter at this stage.

**Figure 21.17** Phosphorylation of the CTD by the kinase activity of TF<sub>II</sub>H may be needed to release RNA polymerase to start transcription.

On a linear template, ATP hydrolysis, TF<sub>II</sub>E, and the helicase activity of TF<sub>II</sub>H (provided by the XPB subunit) are required for polymerase movement. This requirement is bypassed with a supercoiled template. This suggests that TF<sub>II</sub>E and TF<sub>II</sub>H are required to melt DNA to allow polymerase movement to begin (946). The helicase activity of the XPB subunit of TF<sub>II</sub>H is responsible for the actual melting of DNA (2409; 2410).

RNA polymerase II stutters at some genes when it starts transcription. (The result is not dissimilar to the abortive initiation of bacterial RNA polymerase discussed in *Molecular Biology 3.9.11 Sigma factor controls binding to DNA*, although the mechanism is different.) At many genes, RNA polymerase II terminates after a short distance. The short RNA product is degraded rapidly. To extend elongation into the gene, a kinase called P-TEFb is required (for review see 948). This kinase is a member of the cdk family that controls the cell cycle (see *Molecular Biology 6.29 Cell cycle and growth regulation*). P-TEFb acts on the CTD, to

phosphorylate it further. We do not yet understand why this effect is required at some promoters but not others or how it is regulated.

The CTD may also be involved, directly or indirectly, in processing RNA after it has been synthesized by RNA polymerase II (for review see 2421, 4528). **Figure 21.18** summarizes processing reactions in which the CTD may be involved. The capping enzyme (guanylyl transferase), which adds the G residue to the 5' end of newly synthesized mRNA, binds to the phosphorylated CTD: this may be important in enabling it to modify the 5' end as soon as it is synthesized. A set of proteins called SCAFs bind to the CTD, and they may in turn bind to splicing factors. This may be a means of coordinating transcription and splicing. Some components of the cleavage/polyadenylation apparatus also bind to the CTD. Oddly enough, they do so at the time of initiation, so that RNA polymerase is all ready for the 3' end processing reactions as soon as it sets out! All of this suggests that the CTD may be a general focus for connecting other processes with transcription (2239; for review see 2007, 4181). In the cases of capping and splicing, the CTD functions indirectly to promote formation of the protein complexes that undertake the reactions. In the case of 3' end generation, it may participate directly in the reaction.

**Figure 21.18** The CTD is important in recruiting enzymes that modify RNA.

The general process of initiation is similar to that catalyzed by bacterial RNA polymerase. Binding of RNA polymerase generates a closed complex, which is converted at a later stage to an open complex in which the DNA strands have been separated. In the bacterial reaction, formation of the open complex completes the necessary structural change to DNA; a difference in the eukaryotic reaction is that further unwinding of the template is needed after this stage.

**PROMOTERS AND ENHANCERS****5.21.12 A connection between transcription and repair**

---

**Key Concepts**

- Transcribed genes are preferentially repaired when DNA damage occurs.
  - TF<sub>II</sub>H provides the link to a complex of repair enzymes.
  - Mutations in the XPD component of TF<sub>II</sub>H cause three types of human diseases
- 

In both bacteria and eukaryotes, there is a direct link from RNA polymerase to the activation of repair. The basic phenomenon was first observed because transcribed genes are preferentially repaired. Then it was discovered that it is only the template strand of DNA that is the target – the nontemplate strand is repaired at the same rate as bulk DNA.

In bacteria, the repair activity is provided by the *uvr* excision-repair system (see *Molecular Biology 4.15.21 Excision repair systems in E. coli*). Preferential repair is abolished by mutations in the gene *mfd*, whose product provides the link from RNA polymerase to the Uvr enzymes (for review see 224).

**Figure 21.19** shows a model for the link between transcription and repair. When RNA polymerase encounters DNA damage in the template strand, it stalls because it cannot use the damaged sequences as a template to direct complementary base pairing. This explains the specificity of the effect for the template strand (damage in the nontemplate strand does not impede progress of the RNA polymerase).

**Figure 21.19** Mfd recognizes a stalled RNA polymerase and directs DNA repair to the damaged template strand.

The Mfd protein has two roles. First, it displaces the ternary complex of RNA polymerase from DNA. Second, it causes the UvrABC enzyme to bind to the damaged DNA. This leads to repair of DNA by the excision-repair mechanism (see **Figure 15.40**). After the DNA has been repaired, the next RNA polymerase to traverse the gene is able to produce a normal transcript (661).

A similar mechanism, although relying on different components, is used in eukaryotes. The template strand of a transcribed gene is preferentially repaired following UV-induced damage. The general transcription factor TF<sub>H</sub> is involved. TF<sub>H</sub> is found in alternative forms, which consist of a core associated with other subunits.

TF<sub>II</sub>H has a common function in both initiating transcription and repairing damage. The same helicase subunit (XPD) creates the initial transcription bubble and melts DNA at a damaged site. Its other functions differ between transcription and repair, as provided by the appropriate form of the complex.

**Figure 21.20** shows that the basic factor involved in transcription consists of a core (of 5 subunits) associated with other subunits that have a kinase activity; this complex also includes a repair subunit. The kinase catalytic subunit that phosphorylates the CTD of RNA polymerase belongs to a group of kinases that are involved in cell cycle control (see *Molecular Biology 6.29 Cell cycle and growth regulation*). It is possible that this connection influences transcription in response to the stage of the cell cycle.

**Figure 21.20** The TF<sub>II</sub>H core may associate with a kinase at initiation and associate with a repair complex when damaged DNA is encountered.

The alternative complex consists of the core associated with a large group of proteins that are coded by repair genes. (The basic model for repair is shown in **Figure 15.53**.) The repair proteins include a subunit (XPC) that recognizes damaged DNA, which provides the coupling function that enables a template strand to be preferentially repaired when RNA polymerase becomes stalled at damaged DNA. Other proteins associated with the complex include endonucleases (XPG, XPF, ERCC1). Homologous proteins are found in the complexes in yeast (where they are often identified by *rad* mutations that are defective in repair) and in Man (where they are identified by mutations that cause diseases resulting from deficiencies in

---

repairing damaged DNA) (662; 663). (Subunits with the name XP are coded by genes in which mutations cause the disease xeroderma pigmentosum (see *Molecular Biology 4.15.28 Eukaryotic cells have conserved repair systems*).

The kinase complex and the repair complex can associate and dissociate reversibly from the core TF<sub>II</sub>H. This suggests a model in which the first form of TF<sub>II</sub>H is required for initiation, but may be replaced by the other form (perhaps in response to encountering DNA damage). TF<sub>II</sub>H dissociates from RNA polymerase at an early stage of elongation (after transcription of ~50 bp); its reassociation at a site of damaged DNA may require additional coupling components.

The repair function may require modification or degradation of RNA polymerase. The large subunit of RNA polymerase is degraded when the enzyme stalls at sites of UV damage. We do not yet understand the connection between the transcription/repair apparatus as such and the degradation of RNA polymerase. It is possible that removal of the polymerase is necessary once it has become stalled (664).

This degradation of RNA polymerase is deficient in cells from patients with Cockayne's syndrome (a repair disorder). Cockayne's syndrome is caused by mutations in either of two genes (*CSA* and *CSB*), both of whose products appear to be part of or bound to TF<sub>II</sub>H. Cockayne's syndrome is also occasionally caused by mutations in XPD.

Another disease that can be caused by mutations in XPD is trichothiodystrophy, which has little in common with XP or Cockayne's (it involves mental retardation and is marked by changes in the structure of hair). All of this marks XPD as a pleiotropic protein, in which different mutations can affect different functions. In fact, XPD is required for the stability of the TF<sub>II</sub>H complex during transcription, but the helicase activity as such is not needed. Mutations that prevent XPD from stabilizing the complex cause trichothiodystrophy. The helicase activity is required for the repair function. Mutations that affect the helicase activity cause the repair deficiency that results in XP or Cockayne's syndrome (for review see 1641).

## PROMOTERS AND ENHANCERS

### 5.21.13 Short sequence elements bind activators

---

#### Key Terms

An **activator** is a protein that stimulates the expression of a gene, typically by acting at a promoter to stimulate RNA polymerase. In eukaryotes, the sequence to which it binds in the promoter is called a response element.

A **CAAT box** is part of a conserved sequence located upstream of the startpoints of eukaryotic transcription units; it is recognized by a large group of transcription factors.

The **GC box** is a common pol II promoter element consisting of the sequence GGGCGG.

#### Key Concepts

- Short conserved sequence elements are dispersed in the region preceding the startpoint.
- The upstream elements increase the frequency of initiation.
- The factors that bind to them to stimulate transcription are called activators.

---

A promoter for RNA polymerase II consists of two types of region. The startpoint itself is identified by the Inr and/or by the TATA box close by. In conjunction with the general transcription factors, RNA polymerase II forms an initiation complex surrounding the startpoint, as we have just described. The efficiency and specificity with which a promoter is recognized, however, depend upon short sequences, farther upstream, which are recognized by a different group of factors, usually called **activators**. Usually the target sequences are ~100 bp upstream of the startpoint, but sometimes they are more distant. Binding of activators at these sites may influence the formation of the initiation complex at (probably) any one of several stages.

An analysis of a typical promoter is summarized in **Figure 21.21**. Individual base substitutions were introduced at almost every position in the 100 bp upstream of the  $\beta$ -globin startpoint. The striking result is that *most mutations do not affect the ability of the promoter to initiate transcription*. Down mutations occur in three locations, corresponding to three short discrete elements. The two upstream elements have a greater effect on the level of transcription than the element closest to the startpoint. Up mutations occur in only one of the elements. We conclude that the three short sequences centered at -30, -75, and -90 constitute the promoter. Each of them corresponds to the consensus sequence for a common type of promoter element.

**Figure 21.21** Saturation mutagenesis of the upstream region of the  $\beta$ -globin promoter identifies three short regions (centered at -30, -75, and -90) that are needed to initiate transcription. These correspond to the TATA, CAAT, and GC boxes.

The TATA box (centered at -30) is the least effective component of the promoter as measured by the reduction in transcription that is caused by mutations. But although initiation is not prevented when a TATA box is mutated, the startpoint varies from its usual precise location. This confirms the role of the TATA box as a crucial positioning component of the core promoter.

The basal elements and the elements upstream of them have different types of functions. The basal elements (the TATA box and Inr) primarily determine the location of the startpoint, but can sponsor initiation only at a rather low level. They identify the *location* at which the general transcription factors assemble to form the basal complex. The sequence elements farther upstream influence the *frequency* of initiation, most likely by acting directly on the general transcription factors to enhance the efficiency of assembly into an initiation complex (see *Molecular Biology 5.22.5 Activators interact with the basal apparatus*).

The sequence at -75 is the **CAAT box**. Named for its consensus sequence, it was one of the first common elements to be described. It is often located close to -80, but it can function at distances that vary considerably from the startpoint. It functions in either orientation. Susceptibility to mutations suggests that the CAAT box plays a strong role in determining the efficiency of the promoter, but does not influence its specificity.

The **GC box** at -90 contains the sequence GGGCGG. Often multiple copies are present in the promoter, and they occur in either orientation. It too is a relatively common promoter component.

This content is available online at <http://www.ergito.com/main.jsp?bcs=MBIO.5.21.13>

## PROMOTERS AND ENHANCERS

### 5.21.14 Promoter construction is flexible but context can be important

#### Key Concepts

- No individual upstream element is essential for promoter function, although one or more elements must be present for efficient initiation.
- Some elements are recognized by multiple factors, and the factor that is used at any particular promoter may be determined by the context of the other factors that are bound.

Promoters are organized on a principle of "mix and match." A variety of elements can contribute to promoter function, but none is essential for all promoters. Some examples are summarized in **Figure 21.22**. Four types of elements are found altogether in these promoters: TATA, GC boxes, CAAT boxes, and the octamer (an 8 bp element). The elements found in any individual promoter differ in number, location, and orientation. No element is common to all of the promoters. Although the promoter conveys directional information (transcription proceeds only in the downstream direction), the GC and CAAT boxes seem to be able to function in either orientation. This implies that the elements function solely as DNA-binding sites to bring transcription factors into the vicinity of the startpoint; the structure of a factor must be flexible enough to allow it to make protein-protein contacts with the basal apparatus irrespective of the way in which its DNA-binding domain is oriented and its exact distance from the startpoint.

**Figure 21.22** Promoters contain different combinations of TATA boxes, CAAT boxes, GC boxes, and other elements.

Activators that are more or less ubiquitous are assumed to be available to any promoter that has a copy of the element that they recognize. Common elements

recognized by ubiquitous activators include the CAAT box, GC box, and the octamer. All promoters probably require one or more of these elements in order to function efficiently. An activator typically has a consensus sequence of <10 bp, but actually covers a length of ~20 bp of DNA. Given the sizes of the activators, and the length of DNA each covers, we expect that the various proteins will together cover the entire region upstream of the startpoint in which the elements reside.

Usually a particular consensus sequence is recognized by a corresponding activator (or by a member of a family of factors). However, sometimes a particular promoter sequence can be recognized by one of several activators. A ubiquitous activator, Oct-1, binds to the octamer to activate the histone H2B (and presumably also other) genes. Oct-1 is the only octamer-binding factor in nonlymphoid cells. But in lymphoid cells, a different activator, Oct-2, binds to the octamer to activate the immunoglobulin  $\kappa$  light gene. So Oct-2 is a tissue-specific activator, while Oct-1 is ubiquitous. The exact details of recognition are not so important to know as the fact that a variety of activators recognize CAAT boxes.

The use of the same octamer in the ubiquitously expressed H2B gene and the lymphoid-specific immunoglobulin genes poses a paradox. Why does the ubiquitous Oct-1 fail to activate the immunoglobulin genes in nonlymphoid tissues? The *context* must be important: Oct-2 rather than Oct-1 may be needed to interact with other proteins that bind at the promoter. These results mean that we cannot predict whether a gene will be activated by a particular activator simply on the basis of the presence of particular elements in its promoter.

*This content is available online at <http://www.ergito.com/main.jsp?bcs=MBIO.5.21.14>*

---

## PROMOTERS AND ENHANCERS

### 5.21.15 Enhancers contain bidirectional elements that assist initiation

---

#### Key Terms

An **enhancer** is a *cis*-acting sequence that increases the utilization of (some) eukaryotic promoters, and can function in either orientation and in any location (upstream or downstream) relative to the promoter.

An **upstream activator sequence (UAS)** is the equivalent in yeast of the enhancer in higher eukaryotes.

#### Key Concepts

- An enhancer activates the nearest promoter to it, and can be any distance either upstream or downstream of the promoter.
- A UAS (upstream activator sequence) in yeast behaves like an enhancer but works only upstream of the promoter.
- Similar sequence elements are found in enhancers and promoters.
- Enhancers form complexes of activators that interact directly or indirectly with the promoter.

---

We have considered the promoter so far as an isolated region responsible for binding RNA polymerase. But eukaryotic promoters do not necessarily function alone. In at least some cases, the activity of a promoter is enormously increased by the presence of an **enhancer**, which consists of another group of elements, but located at a variable distance from those regarded as comprising part of the promoter itself (665; for review see 219).

The concept that the enhancer is distinct from the promoter reflects two characteristics. The position of the enhancer relative to the promoter need not be fixed, but can vary substantially. **Figure 21.23** shows that it can be either upstream or downstream. And it can function in either orientation (that is, it can be inverted) relative to the promoter. Manipulations of DNA show that an enhancer can stimulate any promoter placed in its vicinity. In natural genomes, enhancers can be located within genes (that is, just downstream of the promoter) or tens of kilobases away in either direction.

**Figure 21.23** An enhancer can activate a promoter from upstream or downstream locations, and its sequence can be inverted relative to the promoter,

For operational purposes, it is sometimes useful to define the promoter *as a sequence or sequences of DNA that must be in a (relatively) fixed location with regard to the startpoint*. By this definition, the TATA box and other upstream elements are included, but the enhancer is excluded. This is, however, a working definition rather than a rigid classification.

Elements analogous to enhancers, called upstream activator sequences (**UAS**), are found in yeast. They can function in either orientation, at variable distances upstream of the promoter, but cannot function when located downstream. They have a regulatory role: in several cases the UAS is bound by the regulatory protein(s) that activates the genes downstream.

Reconstruction experiments in which the enhancer sequence is removed from the DNA and then is inserted elsewhere show that normal transcription can be sustained so long as it is present *anywhere* on the DNA molecule. If a  $\beta$ -globin gene is placed on a DNA molecule that contains an enhancer, its transcription is increased *in vivo* more than 200-fold, even when the enhancer is several kb upstream or downstream of the startpoint, in either orientation. We have yet to discover at what distance the enhancer fails to work.

## PROMOTERS AND ENHANCERS

### 5.21.16 Enhancers contain the same elements that are found at promoters

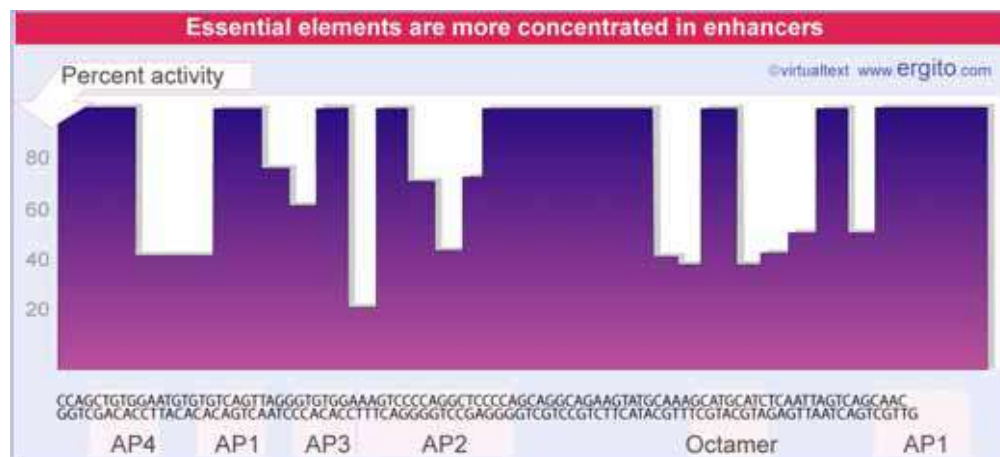

#### Key Terms

An **enhanceosome** is a complex of transcription factors that assembles cooperatively at an enhancer.

#### Key Concepts

- Enhancers are made of the same short sequence elements that are found in promoters.
- The density of sequence components is greater in the enhancer than in the promoter.

A difference between the enhancer and a typical promoter is presented by the density of regulatory elements. **Figure 21.24** summarizes the susceptibility of the SV40 enhancer to damage by mutation; and we see that a much greater proportion of its sites directly influences its function than is the case with the promoter analyzed in the same way in **Figure 21.21**. There is a corresponding increase in the density of protein-binding sites. Many of these sites are common elements in promoters; for example, AP1 and the octamer.

**Figure 21.24** An enhancer contains several structural motifs. The histogram plots the effect of all mutations that reduce enhancer function to <75% of wild type. Binding sites for proteins are indicated below the histogram.

The specificity of transcription may be controlled by either a promoter or an enhancer. A promoter may be specifically regulated, and a nearby enhancer used to increase the efficiency of initiation; or a promoter may lack specific regulation, but become active only when a nearby enhancer is specifically activated. An example is provided by immunoglobulin genes, which carry enhancers *within* the transcription

unit. The immunoglobulin enhancers appear to be active only in the B lymphocytes in which the immunoglobulin genes are expressed. Such enhancers provide part of the regulatory network by which gene expression is controlled.

A difference between enhancers and promoters may be that an enhancer shows greater cooperativity between the binding of factors. A complex that assembles at the enhancer that responds to IFN (interferon)  $\gamma$  assembles cooperatively to form a functional structure called the **enhanceosome**. Binding of the nonhistone protein HMGI(Y) bends the DNA into a structure that then binds several activators (NF- $\kappa$ B, IRF, ATF-Jun). In contrast with the "mix and match" construction of promoters, all of these components are required to create an active structure at the enhancer. These components do not themselves directly bind to RNA polymerase, but they create a surface that binds a *coactivating complex*. The complex helps the pre-initiation complex of basal transcription factors that is assembling at the promoter to recruit RNA polymerase (for review see 1866; 1867). We discuss the function of coactivators in more detail in *Molecular Biology 5.22.5 Activators interact with the basal apparatus*.

## PROMOTERS AND ENHANCERS

### 5.21.17 Enhancers work by increasing the concentration of activators near the promoter

---

#### Key Concepts

- Enhancers usually work only in *cis* configuration with a target promoter.
- Enhancers can be made to work in *trans* configuration by linking the DNA that contains the target promoter to the DNA that contains the enhancer via a protein bridge or by catenating the two molecules.
- The principle is that an enhancer works in any situation in which it is constrained to be in the same proximity as the promoter.

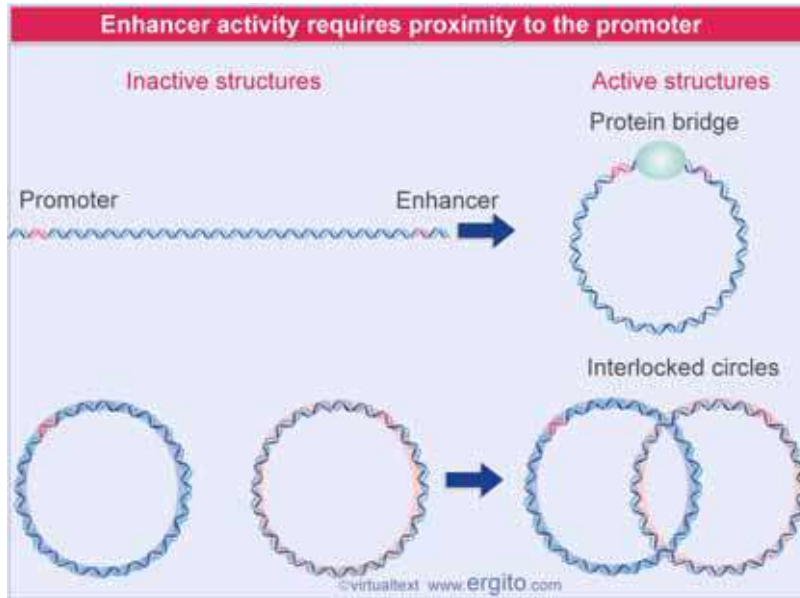

---

How can an enhancer stimulate initiation at a promoter that can be located any distance away on either side of it? When enhancers were first discovered, several possibilities were considered for their action as elements distinctly different from promoters (for review see 1715):

- An enhancer could change the overall structure of the template – for example, by influencing the density of supercoiling.
- It could be responsible for locating the template at a particular place within the cell – for example, attaching it to the nuclear matrix.
- An enhancer could provide an "entry site," a point at which RNA polymerase (or some other essential protein) initially associates with chromatin.

Now we take the view that enhancer function involves the same sort of interaction with the basal apparatus as the interactions sponsored by upstream promoter elements. Enhancers are modular, like promoters. Some elements are found in both enhancers and promoters. Some individual elements found in promoters share with enhancers the ability to function at variable distance and in either orientation. So the distinction between enhancers and promoters is blurred: enhancers might be viewed as containing promoter elements that are grouped closely together, with the ability to function at increased distances from the startpoint (666).

The essential role of the enhancer may be to increase the concentration of activator in the vicinity of the promoter (vicinity in this sense being a relative term). Two types of experiment illustrated in **Figure 21.25** suggest that this is the case.

**Figure 21.25** An enhancer may function by bringing proteins into the vicinity of the promoter. An enhancer does not act on a promoter at the opposite end of a long linear DNA, but becomes effective when the DNA is joined into a circle by a protein bridge. An enhancer and promoter on separate circular DNAs do not interact, but can interact when the two molecules are catenated.

A fragment of DNA that contains an enhancer at one end and a promoter at the other is not effectively transcribed, but the enhancer can stimulate transcription from the promoter when they are connected by a protein bridge. Since structural effects, such as changes in supercoiling, could not be transmitted across such a bridge, this suggests that the critical feature is bringing the enhancer and promoter into close proximity (667).

A bacterial enhancer provides a binding site for the regulator NtrC, which acts upon RNA polymerase using promoters recognized by  $\sigma^{54}$ . When the enhancer is placed upon a circle of DNA that is catenated (interlocked) with a circle that contains the promoter, initiation is almost as effective as when the enhancer and promoter are on the same circular molecule. But there is no initiation when the enhancer and promoter are on separated circles. Again this suggests that the critical feature is localization of the protein bound at the enhancer, to increase its chance of contacting a protein bound at the promoter.

If proteins bound at an enhancer several kb distant from a promoter interact directly with proteins bound in the vicinity of the startpoint, the organization of DNA must be flexible enough to allow the enhancer and promoter to be closely located. This requires the intervening DNA to be extruded as a large "loop." Such loops have been directly observed in the case of the bacterial enhancer.

There is an interesting exception to the rule that enhancers are *cis*-acting in natural situations. This is seen in the phenomenon of transvection. Pairing of somatic chromosomes allows an enhancer on one chromosome to activate a promoter on the partner chromosome. This reinforces the view that enhancers work by proximity.

What limits the activity of an enhancer? Typically it works upon the nearest promoter. There are situations in which an enhancer is located between two promoters, but activates only one of them on the basis of specific protein-protein contacts between the complexes bound at the two elements. The action of an enhancer may be limited by an insulator – an element in DNA that prevents it from acting on promoters beyond (see *Molecular Biology 5.21.20 Insulators block the actions of enhancers and heterochromatin*).

The generality of enhancement is not yet clear. We do not know what proportion of cellular promoters require an enhancer to achieve their usual level of expression. Nor do we know how often an enhancer provides a target for regulation. Some enhancers are activated only in the tissues in which their genes function, but others could be active in all cells.

## PROMOTERS AND ENHANCERS

### 5.21.18 Gene expression is associated with demethylation

---

#### Key Terms

**Isoschizomers** are restriction enzymes that cleave the same DNA sequence but are affected differently by its state of methylation.

#### Key Concepts

- Demethylation at the 5' end of the gene is necessary for transcription.
- 

Methylation of DNA is one of the parameters that controls transcription. Methylation in the vicinity of the promoter is associated with the absence of transcription. This is one of several regulatory events that influence the activity of a promoter; like the other regulatory events, typically this will apply to both (allelic) copies of the gene. However, methylation also occurs as an epigenetic event that can distinguish alleles whose sequences are identical. This can result in differences in the expression of the paternal and maternal alleles (see *Molecular Biology 5.23.20 DNA methylation is responsible for imprinting*). In this chapter we are concerned with the means by which methylation influences transcription.

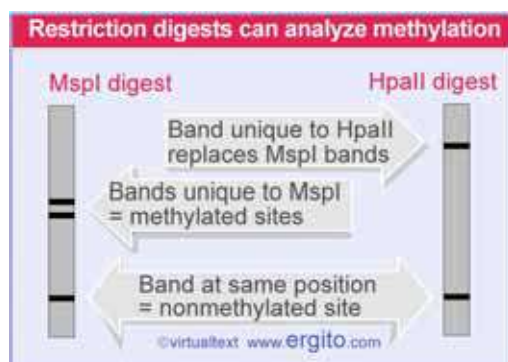

The distribution of methyl groups can be examined by taking advantage of restriction enzymes that cleave target sites containing the CG doublet. Two types of restriction activity are compared in **Figure 21.26**. These **isoschizomers** are enzymes that cleave the same target sequence in DNA, but have a different response to its state of methylation.

**Figure 21.26** The restriction enzyme MspI cleaves all CCGG sequences whether or not they are methylated at the second C, but HpaII cleaves only nonmethylated CCGG tetramers.

The enzyme HpaII cleaves the sequence CCGG (writing the sequence of only one strand of DNA). But if the second C is methylated, the enzyme can no longer recognize the site. However, the enzyme MspI cleaves the same target site *irrespective* of the state of methylation at this C. So MspI can be used to identify all the CCGG sequences; and HpaII can be used to determine whether or not they are methylated.

With a substrate of nonmethylated DNA, the two enzymes would generate the same restriction bands. But in methylated DNA, the modified positions are not cleaved by HpaII. For every such position, one larger HpaII fragment replaces two MspI fragments. **Figure 21.27** gives an example.

**Figure 21.27** The results of MspI and HpaII cleavage are compared by gel electrophoresis of the fragments.

Many genes show a pattern in which the state of methylation is constant at most sites, but varies at others. Some of the sites are methylated in all tissues examined;

some sites are unmethylated in all tissues. *A minority of sites are methylated in tissues in which the gene is not expressed, but are not methylated in tissues in which the gene is active.* So an active gene may be described as *undermethylated*.

Experiments with the drug 5-azacytidine produce indirect evidence that demethylation can result in gene expression. The drug is incorporated into DNA in place of cytidine, and cannot be methylated, because the 5' position is blocked. This leads to the appearance of demethylated sites in DNA as the consequence of replication (following the scheme on the right of **Figure 14.35**).

The phenotypic effects of 5-azacytidine include the induction of changes in the state of cellular differentiation; for example, muscle cells are induced to develop from nonmuscle cell precursors. The drug also activates genes on a silent X chromosome, which raises the possibility that the state of methylation could be connected with chromosomal inactivity.

As well as examining the state of methylation of resident genes, we can compare the results of introducing methylated or nonmethylated DNA into new host cells. Such experiments show a clear correlation: *the methylated gene is inactive, but the nonmethylated gene is active.*

What is the extent of the undermethylated region? In the chicken  $\alpha$ -globin gene cluster in adult erythroid cells, the undermethylation is confined to sites that extend from ~500 bp upstream of the first of the two adult  $\alpha$  genes to ~500 bp downstream of the second. Sites of undermethylation are present in the entire region, including the spacer between the genes. The region of undermethylation coincides with the region of maximum sensitivity to DNAase I. This argues that undermethylation is a feature of a domain that contains a transcribed gene or genes. As with other changes in chromatin, it seems likely that the absence of methyl groups is associated with the *ability to be transcribed* rather than with the act of transcription itself.

Our problem in interpreting the general association between undermethylation and gene activation is that only a minority (sometimes a small minority) of the methylated sites are involved. It is likely that the state of methylation is critical at specific sites or in a restricted region. It is also possible that a reduction in the level of methylation (or even the complete removal of methyl groups from some stretch of DNA) is part of some structural change needed to permit transcription to proceed.

In particular, demethylation at the promoter may be necessary to make it available for the initiation of transcription. In the  $\gamma$ -globin gene, for example, the presence of methyl groups in the region around the startpoint, between -200 and +90, suppresses transcription. Removal of the 3 methyl groups located upstream of the startpoint or of the 3 methyl groups located downstream does not relieve the suppression. But removal of all methyl groups allows the promoter to function. Transcription may therefore require a methyl-free region at the promoter (see *Molecular Biology 5.21.19 CpG islands are regulatory targets*). There are exceptions to this general relationship.

Some genes can be expressed even when they are extensively methylated. Any connection between methylation and expression thus is not universal in an organism, but the general rule is that methylation prevents gene expression and demethylation

is required for expression.

---

## PROMOTERS AND ENHANCERS

### 5.21.19 CpG islands are regulatory targets

---

#### Key Terms

**CpG island** is a stretch of 1-2 kb in a mammalian genome that is rich in unmethylated CpG doublets.

#### Key Concepts

- CpG islands surround the promoters of constitutively expressed genes where they are unmethylated.
- They are also found at the promoters of some tissue-regulated genes.
- There are ~29,000 CpG islands in the human genome.
- Methylation of a CpG island prevents activation of a promoter within it.
- Repression is caused by proteins that bind to methylated CpG doublets.

---

The presence of **CpG islands** in the 5' regions of some genes is connected with the effect of methylation on gene expression. These islands are detected by the presence of an increased density of the dinucleotide sequence, CpG.

The CpG doublet occurs in vertebrate DNA at only ~20% of the frequency that would be expected from the proportion of G-C base pairs. (This may be because CpG doublets are methylated on C, and spontaneous deamination of methyl-C converts it to T, introducing a mutation that removes the doublet.) In certain regions, however, the density of CpG doublets reaches the predicted value; in fact, it is increased by 10× relative to the rest of the genome. The CpG doublets in these regions are unmethylated.

These CpG-rich islands have an average G-C content of ~60%, compared with the 40% average in bulk DNA. They take the form of stretches of DNA typically 1-2 kb long. There are ~45,000 such islands altogether in the human genome (1443). Some of the islands are present in repeated Alu elements, and may just be the consequence of their high G-C-content. The human genome sequence confirms that, excluding these, there are ~29,000 islands. There are fewer in the mouse genome, ~15,500. About 10,000 of the predicted islands in both species appear to reside in a context of sequences that are conserved between the species, suggesting that these may be the islands with regulatory significance. The structure of chromatin in these regions has changes associated with gene expression (see *Molecular Biology 5.23.11 Promoter activation involves an ordered series of events*); there is a reduced content of histone H1 (which probably means that the structure is less compact), the other histones are extensively acetylated (a feature that tends to be associated with gene expression), and there are hypersensitive sites (as would be expected of active promoters) (710).

In several cases, CpG-rich islands begin just upstream of a promoter and extend

downstream into the transcribed region before petering out. **Figure 21.28** compares the density of CpG doublets in a "general" region of the genome with a CpG island identified from the DNA sequence. The CpG island surrounds the 5' region of the APRT gene, which is constitutively expressed.

**Figure 21.28** The typical density of CpG doublets in mammalian DNA is  $\sim 1/100$  bp, as seen for a  $\gamma$ -globin gene. In a CpG-rich island, the density is increased to  $>10$  doublets/100 bp. The island in the APRT gene starts  $\sim 100$  bp upstream of the promoter and extends  $\sim 400$  bp into the gene. Each vertical line represents a CpG doublet.

All of the "housekeeping" genes that are constitutively expressed have CpG islands; this accounts for about half of the islands altogether. The other half of the islands occur at the promoters of tissue-regulated genes; only a minority ( $<40\%$ ) of these genes have islands. In these cases, the islands are unmethylated irrespective of the state of expression of the gene. The presence of unmethylated CpG-rich islands may be necessary, but therefore is not sufficient, for transcription. So the presence of unmethylated CpG islands may be taken as an indication that a gene is potentially active, rather than inevitably transcribed. Many islands that are nonmethylated in the animal become methylated in cell lines in tissue culture, and this could be connected with the inability of these lines to express all of the functions typical of the tissue from which they were derived.

Methylation of a CpG island can affect transcription. Two mechanisms can be involved:

- Methylation of a binding site for some factor may prevent it from binding. This happens in a case of binding to a regulatory site other than the promoter (see *Molecular Biology 5.23.21 Oppositely imprinted genes can be controlled by a single center*).
- Or methylation may cause specific repressors to bind to the DNA.

Repression is caused by either of two types of protein that bind to methylated CpG sequences (for review see 2424). The protein MeCP1 requires the presence of several methyl groups to bind to DNA, while MeCP2 and a family of related proteins can bind to a single methylated CpG base pair. This explains why a methylation-free zone is required for initiation of transcription. Binding of proteins of either type prevents transcription *in vitro* by a nuclear extract (711).

MeCP2, which directly represses transcription by interacting with complexes at the promoter, is bound also to the Sin3 repressor complex, which contains histone deacetylase activities (see **Figure 23.15**). This observation provides a direct connection between two types of repressive modifications: methylation of DNA and acetylation of histones.

The absence of methyl groups is associated with gene expression. However, there are some difficulties in supposing that the state of methylation provides a general means for controlling gene expression. In the case of *D. melanogaster* (and other Dipteran insects), there is very little methylation of DNA (although there is gene potentially coding a methyltransferase), and in the nematode *C. elegans* there is no methylation of DNA. The other differences between inactive and active chromatin appear to be the same as in species that display methylation. So in these organisms, any role that methylation has in vertebrates is replaced by some other mechanism.

We have described three changes that occur in active genes:

- A hypersensitive site (s) is established near the promoter.
- The nucleosomes of a domain including the transcribed region become more sensitive to DNAase I.
- The DNA of the same region is undermethylated.

All of these changes are necessary for transcription.

## PROMOTERS AND ENHANCERS

### 5.21.20 Insulators block the actions of enhancers and heterochromatin

#### Key Terms

An **insulator** is a sequence that prevents an activating or inactivating effect passing from one side to the other.

#### Key Concepts

- Insulators are able to block passage of any activating or inactivating effects from enhancers, silencers, or LCRs.
- Insulators may provide barriers against the spread of heterochromatin.

Elements that prevent the passage of activating or inactivating effects are called **insulators** (for review see 2290). They have either or both of two key properties:

- When an insulator is placed between an enhancer and a promoter, *it prevents the enhancer from activating the promoter*. The blocking effect is shown in **Figure 21.29**. This may explain how the action of an enhancer is limited to a particular promoter.
- When an insulator is placed between an active gene and heterochromatin, *it provides a barrier that protects the gene against the inactivating effect that spreads from the heterochromatin*. (Heterochromatin is a region of chromatin that is inactive as the result of its higher order structure; see *Molecular Biology 5.23.13 Heterochromatin propagates from a nucleation event*.) The barrier effect is shown in **Figure 21.30**.

**Figure 21.29** An enhancer activates a promoter in its vicinity, but may be blocked from doing so by an insulator located between them.

**Figure 21.30** Heterochromatin may spread from a center and then blocks any promoters that it covers. An insulator may be a barrier to propagation of heterochromatin that allows the promoter to remain active.

Some insulators possess both these properties, but others have only one, or the blocking and barrier functions can be separated. Although both actions are likely to be mediated by changing chromatin structure, they may involve different effects (for review see 2376). In either case, however, the insulator defines a limit for long-range effects.

What is the purpose of an insulator? A major function may be to counteract the indiscriminate actions of enhancers on promoters. Most enhancers will work with any promoter in the vicinity. An insulator can restrict an enhancer by blocking the effects from passing beyond a certain point, so that it can act only on a specific promoter. Similarly, when a gene is located near heterochromatin, an insulator can prevent it from being inadvertently inactivated by the spread of the heterochromatin. Insulators therefore function as elements for increasing the precision of gene regulation.

**PROMOTERS AND ENHANCERS****5.21.21 Insulators can define a domain****Key Concepts**

- Insulators are specialized chromatin structures that have hypersensitive sites. Two insulators can protect the region between them from all external effects.

Insulators were discovered during the analysis of the region of the *D. melanogaster* genome summarized in **Figure 21.31**. Two genes for the protein Hsp70 lie within an 18 kb region that constitutes band 87A7. Special structures, called *scs* and *scs'* (specialized chromatin structures, are found at the ends of the band. Each consists of a region that is highly resistant to degradation by DNAase I, flanked on either side by hypersensitive sites, spaced at about 100 bp. The cleavage pattern at these sites is altered when the genes are turned on by heat shock.

**Figure 21.31** Specialized chromatin structures that include hypersensitive sites mark the ends of a domain in the *D. melanogaster* genome and insulate genes between them from the effects of surrounding sequences.

The *scs* elements insulate the *hsp70* genes from the effects of surrounding regions. If we take *scs* units and place them on either side of a *white* gene, the gene can function anywhere it is placed in the genome, even in sites where it would normally be repressed by context, for example, in heterochromatic regions (703).

The *scs* and *scs'* units do not seem to play either positive or negative roles in controlling gene expression, but just restrict effects from passing from one region to the next. If adjacent regions have repressive effects, however, the *scs* elements might be needed to block the spread of such effects, and therefore could be essential for gene expression. In this case, deletion of such elements could eliminate the expression of the adjacent gene(s).

*scs* and *scs'* have different structures and each appears to have a different basis for its insulator activity. The key sequence in the *scs* element is a stretch of 24 bp that binds the product of the *zw5* gene (2352). The insulator property of *scs'* resides in a series of CGATA repeats (2350). The repeats bind a group of related proteins called BEAF-32. The protein shows discrete localization within the nucleus, but the most remarkable data derive from its localization on polytene chromosomes. **Figure 21.32** shows that an anti-BEAF-32 antibody stains ~50% of the interbands of the polytene chromosomes (2351). This suggests that there are many insulators in the genome, and that BEAF-32 is a common part of the insulating apparatus. It would imply that the band is a functional unit, and that interbands often have insulators that block the propagation of activating or inactivating effects.

**Figure 21.32** A protein that binds to the insulator *scs'* is localized at interbands in *Drosophila* polytene chromosomes. Red staining identifies the DNA (the bands) on both the upper and lower samples; green staining identifies BEAF32 (often at interbands) on the upper sample. Yellow shows coincidence of the two labels (meaning that BEAF32 is in a band). Photograph kindly provided by Uli Laemmli.

Another example of an insulator that defines a domain is found in the chick  $\beta$ -globin LCR (the group of hypersensitive sites that controls expression of all  $\beta$ -globin genes; see *Molecular Biology 5.20.17 An LCR may control a domain*). The leftmost hypersensitive site of the chick  $\beta$ -globin LCR (HS4) is an insulator that marks the 5' end of the functional domain (705). This restricts the LCR to acting only on the globin genes in the domain.

A gene that is surrounded by insulators is usually protected against the propagation of inactivating effects from the surrounding regions. The test is to insert DNA into a genome at random locations by transfection. The expression of a gene in the inserted sequence is often erratic; in some instances it is properly expressed, but in others it is extinguished (see *Molecular Biology 4.18.18 Genes can be injected into animal eggs*). However, when insulators that have a barrier function are placed on either side of the gene in the inserted DNA, its expression typically is uniform in every case (3216).

## PROMOTERS AND ENHANCERS

### 5.21.22 Insulators may act in one direction

#### Key Concepts

- Some insulators have directionality, and may stop passage of effects in one direction but not the other.

Insulators may have directional properties. Insertions of the transposon *gypsy* into the *yellow* (*y*) locus of *D. melanogaster* cause loss of gene function in some tissues, but not in others. The reason is that the *y* locus is regulated by four enhancers, as shown in **Figure 21.33**. Wherever *gypsy* is inserted, it blocks expression of all enhancers that it separates from the promoter, but not those that lie on the other side. The sequence responsible for this effect is an insulator that lies at one end of the transposon. The insulator works irrespective of its orientation of insertion.

**Figure 21.33** The insulator of the *gypsy* transposon blocks the action of an enhancer when it is placed between the enhancer and the promoter.

Some of the enhancers are upstream of the promoter and others are downstream, so the effect cannot depend on position with regard to the promoter, nor can it require transcription to occur through the insulator. This is difficult to explain in terms of looping models for enhancer-promoter interaction, which essentially predict the irrelevance of the intervening DNA. The obvious model to invoke is a tracking mechanism, in which some component must move unidirectionally from the enhancer to the promoter, but this is difficult to reconcile with previous characterizations of the independence of enhancers from such effects.

Proteins that act upon the insulator have been identified through the existence of two other loci that affect insulator function in a *trans*-acting manner. Mutations in *su(Hw)*

abolish insulation: *y* is expressed in all tissues in spite of the presence of the insulator. This suggests that *su(Hw)* codes for a protein that recognizes the insulator and is necessary for its action. Su(Hw) has a zinc finger DNA-motif; mapping to polytene chromosomes shows that it is bound at a large number of sites. The insulator contains 12 copies of a 26 bp sequence that is bound by Su(Hw) (706; 709). Manipulations show that the strength of the insulator is determined by the number of copies of the binding sequence.

The second locus is *mod(mdg4)*, in which mutations have the opposite effect. This is observed by the loss of directionality. These mutations increase the effectiveness of the insulator by extending its effects so that it blocks utilization of enhancers on both sides. *su(Hw)* is epistatic to *mod(mdg4)*; this means that in a double mutant we see only the effect of *su(Hw)*. This implies that *mod(mdg4)* acts through *su(Hw)*. The basic role of the wild-type protein from the *mod(mdg4)* locus is therefore to impose directionality on the ability of *su(Hw)* to insulate promoters from the boundary.

Binding of *su(Hw)* to DNA, followed by binding of *mod(mdg4)* to *su(Hw)*, therefore creates a unidirectional block to activation of a promoter. This suggests that the insulator bound by *su(Hw)* can spread inactivity in both directions, but *mod(mdg4)* stops the effect from spreading in one direction. Perhaps there is some intrinsic directionality to chromatin, which results ultimately in the incorporation of *su(Hw)*, *mod(mdg4)*, or some other component in one orientation, presumably by virtue of an interaction with some component of chromatin that is itself preferentially oriented. Any such directionality would need to reverse at the promoter.

It is likely that insulators act by making changes in chromatin structure. One model is prompted by the observation that Su(Hw) and *mod(mdg4)* binding sites are present at >500 locations in the *Drosophila* genome. But visualization of the sites where the proteins are bound in the nucleus shows that they are colocalized at ~25 discrete sites around the nuclear periphery (2377). This suggests the model of **Figure 21.34** in which Su(Hw) proteins bound at different sites on DNA are brought together by binding to *mod(mdg4)*. The Su(Hw)/*mod(mdg4)* complex is localized at the nuclear periphery. The DNA bound to it is organized into loops. An average complex might have ~20 such loops. Enhancer-promoter actions can occur only within a loop, and cannot propagate between them.

**Figure 21.34** Su(Hw)/mod(mdg4) complexes are found at the nuclear periphery. They may organize DNA into loops that limit enhancer-promoter interactions.

**PROMOTERS AND ENHANCERS****5.21.23 Insulators can vary in strength**

---

**Key Terms**

An **anti-insulator** is a sequence that allows an enhancer to overcome the effect of an insulator.

**Key Concepts**

- Insulators can differ in how effectively they block passage of an activating signal.
- 

Sometimes elements with different *cis*-acting properties are combined to generate regions with complex regulatory effects. The *Fab-7* region is defined by deletions in the *bithorax* locus of *Drosophila*. This locus contains a series of *cis*-acting regulatory elements that control the activities of three transcription units (see **Figure 31.36**). The relevant part of the locus is drawn in **Figure 21.35**. The regulatory elements *iab-6* and *iab-7* control expression of the adjacent gene *Abd-B* in successive regions of the embryo (segments A6 and A7). A deletion of *Fab-7* causes A6 to develop like A7, instead of in the usual way. This is a dominant effect, which suggests that *iab-7* has taken over control from *iab-6*. We can interpret this in molecular terms by supposing that *Fab-7* provides a boundary that prevents *iab-7* from acting when *iab-6* is usually active (707; 708).

**Figure 21.35** *Fab-7* is a boundary element that is necessary for the independence of regulatory elements *iab-6* and *iab-7*.

Like other boundary elements, *Fab-7* contains a distinctive chromatin structure that is marked by a series of hypersensitive sites. The region can be divided into two types of elements by smaller deletions and by testing fragments for their ability to provide a boundary. A sequence of ~3.3 kb behaves as an insulator when it is placed in other constructs. A sequence of ~0.8 kb behaves as a repressor that acts on *iab-7*. The presence of these two elements explains the complicated genetic behavior of *Fab-7* (which we have not described in detail).

An insight into the action of the boundary element is provided by the effects of substituting other insulators for *Fab-7*. The effect of *Fab-7* is simply to prevent interaction between *iab-6* and *iab-7*. But when *Fab-7* is replaced by a different insulator [in fact a binding site for the protein Su(Hw)], a stronger effect is seen: *iab-5* takes over from *iab-7*. And when an *scs* element is used, the effect extends to *iab-4*. This suggests a scheme in which stronger elements can block the actions of regulatory sequences that lie farther away.

This conclusion introduces a difficulty for explaining the action of boundary elements. They cannot be functioning in this instance simply by preventing the transmission of effects past the boundary. This argues against models based on simple tracking or inhibiting the linear propagation of structural effects. It suggests that there may be some sort of competitive effect, in which the strength of the element determines how far its effect can stretch.

The situation is further complicated by the existence of **anti-insulator** elements, which allow an enhancer to overcome the blocking effects of an insulator (940). This again suggests that these effects are mediated by some sort of control over local chromatin structure.

## PROMOTERS AND ENHANCERS

### 5.21.24 What constitutes a regulatory domain?

#### Key Terms

An **insulator** is a sequence that prevents an activating or inactivating effect passing from one side to the other.

A **matrix attachment site (MAR)** is a region of DNA that attaches to the nuclear matrix. It is also known as a scaffold attachment site (SAR).

The **locus control region (LCR)** that is required for the expression of several genes in a domain.

#### Key Concepts

- A domain has an insulator, an LCR, a matrix attachment site, and transcription unit(s).

If we now put together the various types of structures that have been found in different systems, we can think about the possible nature of a chromosomal domain. The basic feature of a regulatory domain is that regulatory elements can act only on transcription units within the same domain. A domain might contain more than one transcription unit and/or enhancer.

**Figure 21.36** summarizes the structures that might be involved in defining a domain.

**Figure 21.36** Domains may possess three types of sites: insulators to prevent effects from spreading between domains; MARs to attach the domain to the nuclear matrix; and LCRs that are required for initiation of transcription. An enhancer may act on more than one promoter within the domain.

An **insulator** stops activating or repressing effects from passing. In its simplest form, an insulator blocks either type of effect from passing across it, but there can be more complex relationships in which the insulator blocks only one type of effect and/or acts directionally. We assume that insulators act by affecting higher order chromatin structure, but we do not know the details and varieties of such effects.

A **matrix attachment site (MAR)** may be responsible for attaching chromatin to a site on the nuclear periphery (see *Molecular Biology 5.19.6 Specific sequences attach DNA to an interphase matrix*). These are likely to be responsible for creating physical domains of DNA that take the form of loops extending out from the attachment sites. This looks very like one model for insulator action. In fact, some

MAR elements behave as insulators in assays *in vitro*, but it seems that their ability to attach DNA to the matrix can be separated from the insulator function, so there is not a simple cause and effect. It would not be surprising if insulator and MAR elements were associated to maintain a relationship between regulatory effects and physical structure (for review see 2376).

An **LCR** functions at a distance and may be required for any and all genes in a domain to be expressed (see *Molecular Biology 5.20.17 An LCR may control a domain*). When a domain has an LCR, its function is essential for all genes in the domain, but LCRs do not seem to be common. Several types of *cis*-acting structures could be required for function. As defined originally, the property of the LCR rests with an enhancer-like hypersensitive site that is needed for the full activity of promoter(s) within the domain.

The organization of domains may help to explain the large size of the genome. A certain amount of space could be required for such a structure to operate, for example, to allow chromatin to become decondensed and to become accessible. Although the exact sequences of much of the unit might be irrelevant, there might be selection for the overall amount of DNA within it, or at least selection might prevent the various transcription units from becoming too closely spaced.

## PROMOTERS AND ENHANCERS

### 5.21.25 Summary

---

Of the three eukaryotic RNA polymerases, RNA polymerase I transcribes rDNA and accounts for the majority of activity, RNA polymerase II transcribes structural genes for mRNA and has the greatest diversity of products, and RNA polymerase III transcribes small RNAs. The enzymes have similar structures, with two large subunits and many smaller subunits; there are some common subunits among the enzymes.

None of the three RNA polymerases recognize their promoters directly. A unifying principle is that transcription factors have primary responsibility for recognizing the characteristic sequence elements of any particular promoter, and they serve in turn to bind the RNA polymerase and to position it correctly at the startpoint. At each type of promoter, the initiation complex is assembled by a series of reactions in which individual factors join (or leave) the complex. The factor TBP is required for initiation by all three RNA polymerases. In each case it provides one subunit of a transcription factor that binds in the vicinity of the startpoint.

A promoter consists of a number of short sequence elements in the region upstream of the startpoint. Each element is bound by a transcription factor. The basal apparatus, which consists of the TF<sub>II</sub> factors, assembles at the startpoint and enables RNA polymerase to bind. The TATA<sub>II</sub> box (if there is one) near the startpoint, and the initiator region immediately at the startpoint, are responsible for selection of the exact startpoint at promoters for RNA polymerase II. TBP binds directly to the TATA box when there is one; in TATA-less promoters it is located near the startpoint by binding to the DPE downstream. After binding of TF<sub>II</sub>D, the other general transcription factors for RNA polymerase II assemble the basal<sub>II</sub> transcription apparatus at the promoter. Other elements in the promoter, located upstream of the TATA box, bind activators that interact with the basal apparatus. The activators and basal factors are released when RNA polymerase begins elongation.

The CTD of RNA polymerase II is phosphorylated during the initiation reaction. TF<sub>II</sub>D and SRB proteins both may interact with the CTD. It may also provide a point of contact for proteins that modify the RNA transcript, including the 5' capping enzyme, splicing factors, and the 3' processing complex.

Promoters may be stimulated by enhancers, sequences that can act at great distances and in either orientation on either side of a gene. Enhancers also consist of sets of elements, although they are more compactly organized. Some elements are found in both promoters and enhancers. Enhancers probably function by assembling a protein complex that interacts with the proteins bound at the promoter, requiring that DNA between is "looped out."

An insulator blocks the transmission of activating or inactivating effects in chromatin. An insulator that is located between an enhancer and a promoter prevents the enhancer from activating the promoter. Two insulators define the region between them as a regulatory domain; regulatory interactions within the domain are limited to it, and the domain is insulated from outside effects. Most insulators block regulatory

effects from passing in either direction, but some are directional. Insulators usually can block both activating effects (enhancer-promoter interactions) and inactivating effects (mediated by spread of heterochromatin), but some are limited to one or the other. Insulators are thought to act via changing higher order chromatin structure, but the details are not certain.

CpG islands contain concentrations of CpG doublets and often surround the promoters of constitutively expressed genes, although they are also found at the promoters of regulated genes. The island including a promoter must be unmethylated for that promoter to be able to initiate transcription. A specific protein binds to the methylated CpG doublets and prevents initiation of transcription.

## ACTIVATING TRANSCRIPTION

### 5.22.1 Introduction

---

#### Key Concepts

- Eukaryotic gene expression is usually controlled at the level of initiation of transcription.
- 

The phenotypic differences that distinguish the various kinds of cells in a higher eukaryote are largely due to differences in the expression of genes that code for proteins, that is, those transcribed by RNA polymerase II. In principle, the expression of these genes might be regulated at any one of several stages. We can distinguish (at least) five potential control points, forming the series:

Activation of gene structure

↓

Initiation of transcription

↓

Processing the transcript

↓

Transport to cytoplasm

↓

Translation of mRNA

As we see in **Figure 22.1**, gene expression in eukaryotes is largely controlled at the initiation of transcription. For most genes, this is the major control point in their expression. It involves changes in the structure of chromatin at the promoter (see *Molecular Biology 5.23.11 Promoter activation involves an ordered series of events*), accompanied by the binding of the basal transcription apparatus (including RNA polymerase II) to the promoter. (Regulation at subsequent stages of transcription is rare in eukaryotic cells. Premature termination occurs at some genes, and is counteracted by a kinase, P-TEFb, but otherwise anti-termination does not seem to be employed.)

**Figure 22.1** Gene expression is controlled principally at the initiation of transcription, and it is rare for the subsequent stages of gene expression to be used to determine whether a gene is expressed, although control of processing may be used to determine which form of a gene is represented in mRNA.

The primary transcript is modified by capping at the 5' end, and usually also by polyadenylation at the 3' end. Introns must be excised from the transcripts of interrupted genes. The mature RNA must be exported from the nucleus to the cytoplasm. Regulation of gene expression by selection of sequences at the level of nuclear RNA might involve any or all of these stages, but the one for which we have most evidence concerns changes in splicing; some genes are expressed by means of alternative splicing patterns whose regulation controls the type of protein product (see *Molecular Biology 5.24.12 Alternative splicing involves differential use of splice junctions*).

Finally, the translation of an mRNA in the cytoplasm can be specifically controlled. There is little evidence for the employment of this mechanism in adult somatic cells, but it occurs in some embryonic situations. This can involve localization of the

mRNA to specific sites where it is expressed and/or the blocking of initiation of translation by specific protein factors (see *Molecular Biology 6.31.7 How are mRNAs and proteins transported and localized?*).

Regulation of tissue-specific gene transcription lies at the heart of eukaryotic differentiation; indeed, we see examples in *Molecular Biology 6.31 Gradients, cascades, and signaling pathways* in which proteins that regulate embryonic development prove to be transcription factors. A regulatory transcription factor serves to provide common control of a large number of target genes, and we seek to answer two questions about this mode of regulation: how does the transcription factor identify its group of target genes; and how is the activity of the transcription factor itself regulated in response to intrinsic or extrinsic signals?

---

## ACTIVATING TRANSCRIPTION

### 5.22.2 There are several types of transcription factors

---

#### Key Terms

A **basal factor** is a transcription factor required by RNA polymerase II to form the initiation complex at all promoters. Factors are identified as  $TF_{II}^X$ , where X is a number.

An **activator** is a protein that stimulates the expression of a gene, typically by acting at a promoter to stimulate RNA polymerase. In eukaryotes, the sequence to which it binds in the promoter is called a response element.

A **response element** is a sequence in a eukaryotic promoter or enhancer that is recognized by a specific transcription factor.

**Coactivators** are factors required for transcription that do not bind DNA but are required for (DNA-binding) activators to interact with the basal transcription factors.

#### Key Concepts

- The basal apparatus determines the startpoint for transcription.
- Activators determine the frequency of transcription.
- Activators work by making protein-protein contacts with the basal factors.
- Activators may work via coactivators.
- Some components of the transcriptional apparatus work by changing chromatin structure.

---

Initiation of transcription involves many protein-protein interactions among transcription factors bound at the promoter or at an enhancer as well as with RNA polymerase. We can divide the factors required for transcription into several classes (for review see 1710; 1712). **Figure 22.2** summarizes their properties:

**Figure 22.2** Factors involved in gene expression include RNA polymerase and the basal apparatus, activators that bind directly to DNA at the promoter or at enhancers, co-activators that bind to both activators and the basal apparatus, and regulators that act on chromatin structure.

- **Basal factors**, together with RNA polymerase, bind at the startpoint and TATA box (see *Molecular Biology 5.21.10 The basal apparatus assembles at the promoter*).
- **Activators** are transcription factors that recognize specific short consensus elements. They bind to sites in the promoter or in enhancers (see *Molecular Biology 5.21.13 Short sequence elements bind activators*). They act by increasing the efficiency with which the basal apparatus binds to the promoter. They therefore increase the frequency of transcription, and are required for a promoter to function at an adequate level. Some activators act constitutively

(they are ubiquitous), but others have a regulatory role, and are synthesized or activated at specific times or in specific tissues. These factors are therefore responsible for the control of transcription patterns in time and space. The sequences that they bind are called **response elements**.

- Another group of factors necessary for efficient transcription do not themselves bind DNA. **Coactivators** provide a connection between activators and the basal apparatus (see *Molecular Biology 5.22.5 Activators interact with the basal apparatus*). They work by protein-protein interactions, forming bridges between activators and the basal transcription apparatus.
- Some regulators act to make changes in chromatin (see *Molecular Biology 5.23.7 Acetylases are associated with activators*).

The diversity of elements from which a functional promoter may be constructed, and the variations in their locations relative to the startpoint, argues that the activators have an ability to interact with one another by protein-protein interactions in multiple ways. There appear to be no constraints on the potential relationships between the elements. The modular nature of the promoter is illustrated by experiments in which equivalent regions of different promoters have been exchanged. Hybrid promoters, for example, between the thymidine kinase and  $\beta$ -globin genes, work well. This suggests that the main purpose of the elements is to bring the activators they bind into the vicinity of the initiation complex, where protein-protein interactions determine the efficiency of the initiation reaction.

The organization of RNA polymerase II promoters contrasts with that of bacterial promoters, where all the transcription factors must interact directly with RNA polymerase. In the eukaryotic system, only the basal factors interact directly with the enzyme. Activators may interact with the basal factors, or may interact with coactivators that in turn interact with the basal factors. The construction of the apparatus through layers of interactions explains the flexibility with which elements may be arranged, and the distance over which they can be dispersed.

## ACTIVATING TRANSCRIPTION

### 5.22.3 Independent domains bind DNA and activate transcription

---

#### Key Concepts

- DNA-binding activity and transcription-activation are carried by independent domains of an activator.
  - The role of the DNA-binding domain is to bring the transcription-activation domain into the vicinity of the promoter.
- 

Activators and other regulatory proteins require two types of ability:

- They recognize specific target sequences located in enhancers, promoters, or other regulatory elements that affect a particular target gene.
- Having bound to DNA, an activator exercises its function by binding to other components of the transcription apparatus.

Can we characterize domains in the activator that are responsible for these activities? Often an activator has separate domains that bind DNA and activate transcription. Each domain behaves as a separate module that functions independently when it is linked to a domain of the other type. The geometry of the overall transcription complex must allow the activating domain to contact the basal apparatus irrespective of the exact location and orientation of the DNA-binding domain.

Upstream promoter elements may be an appreciable distance from the startpoint, and in many cases may be oriented in either direction. Enhancers may be even farther away and always show orientation independence. This organization has implications for both the DNA and proteins. The DNA may be looped or condensed in some way to allow the formation of the transcription complex. And the domains of the activator may be connected in a flexible way, as illustrated diagrammatically in **Figure 22.3**. The main point here is that the DNA-binding and activating domains are independent, and connected in a way that allows the activating domain to interact with the basal apparatus irrespective of the orientation and exact location of the DNA-binding domain.

**Figure 22.3** DNA-binding and activating functions in a transcription factor may comprise independent domains of the protein.

Binding to DNA is necessary for activating transcription. But does activation depend on the *particular* DNA-binding domain?

**Figure 22.4** illustrates an experiment to answer this question. The activator GAL4 has a DNA-binding domain that recognizes a *UAS*, and an activating domain that stimulates initiation at the target promoter. The bacterial repressor LexA has an N-terminal DNA-binding domain that recognizes a specific operator. When LexA binds to this operator, it represses the adjacent promoter. In a "swap" experiment, the DNA-binding domain of LexA can be substituted for the DNA-binding domain of GAL4. The hybrid gene can then be introduced into yeast together with a target gene that contains either the *UAS* or a LexA operator.

**Figure 22.4** The ability of GAL4 to activate transcription is independent of its specificity for binding DNA. When the GAL4 DNA-binding domain is replaced by the LexA DNA-binding domain, the hybrid protein can activate transcription when a LexA operator is placed near a promoter.

An authentic GAL4 protein can activate a target gene only if it has a *UAS*. The LexA repressor by itself of course lacks the ability to activate either sort of target. The LexA-GAL4 hybrid can no longer activate a gene with a *UAS*, but it can now activate a gene that has a LexA operator!

This result fits the modular view of transcription activators. The DNA-binding domain serves to bring the protein into the right location. Precisely how or where it is bound to DNA is irrelevant, but, once it is there, the transcription-activating domain can play its role. According to this view, it does not matter whether the transcription-activating domain is brought to the vicinity of the promoter by recognition of a *UAS* via the DNA-binding domain of GAL4 or by recognition of a LexA operator via the LexA specificity module. The ability of the two types of module to function in hybrid proteins suggests that each domain of the protein folds independently into an active structure that is not influenced by the rest of the protein (for review see 230; 232).

The idea that activators have independent domains that bind DNA and that activate transcription is reinforced by the ability of the *tat* protein of HIV to stimulate initiation without binding DNA at all. The *tat* protein binds to a region of secondary structure in the RNA product; the part of the RNA required for *tat* action is called the *tar* sequence. A model for the role of the *tat-tar* interaction in stimulating transcription is shown in **Figure 22.5**.

**Figure 22.5** The activating domain of the *tat* protein of HIV can stimulate transcription if it is tethered in the vicinity by binding to the RNA product of a previous round of transcription. Activation is independent of the means of tethering, as shown by the substitution of a DNA-binding domain for the RNA-binding domain.

The *tar* sequence is located just downstream of the startpoint, so that when *tat* binds to *tar*, it is brought into the vicinity of the initiation complex. This is sufficient to ensure that its activation domain is in close enough proximity to the initiation complex. The activation domain interacts with one or more of the transcription

factors bound at the complex in the same way as an activator. (Of course, the first transcript must be made in the absence of *tat* in order to provide the binding site.)

An extreme demonstration of the independence of the localizing and activating domains is indicated by some constructs in which *tat* was engineered so that the activating domain was connected to a DNA-binding domain instead of to the usual *tar*-binding sequence. When an appropriate target site was placed into the promoter, the *tat* activating-domain could activate transcription. This suggests that we should think of the DNA-binding (or in this case the RNA-binding) domain as providing a "tethering" function, *whose main purpose is to ensure that the activating domain is in the vicinity of the initiation complex.*

The notion of tethering is a more specific example of the general idea that initiation requires a high concentration of transcription factors in the vicinity of the promoter. This may be achieved when activators bind to enhancers in the general vicinity, when activators bind to upstream promoter components, or in an extreme case by tethering to the RNA product. The common requirement of all these situations is flexibility in the exact three dimensional arrangement of DNA and proteins. The principle of independent domains is common in transcriptional activators.

We might view the function of the DNA-binding domain as *bringing the activating domain into the vicinity of the startpoint.* This explains why the exact locations of DNA-binding sites can vary within the promoter.

## ACTIVATING TRANSCRIPTION

### 5.22.4 The two hybrid assay detects protein-protein interactions

---

#### Key Terms

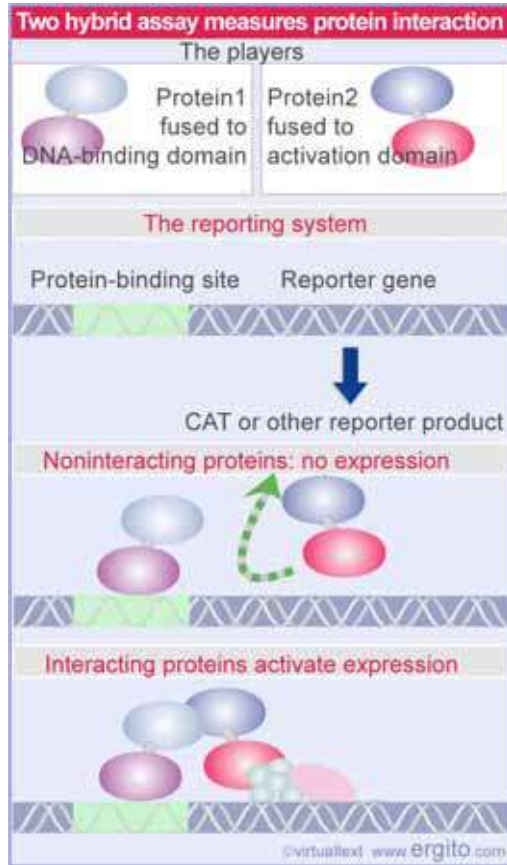

**Two hybrid** assay detects interaction between two proteins by means of their ability to bring together a DNA-binding domain and a transcription-activating domain. The assay is performed in yeast using a reporter gene that responds to the interaction.

#### Key Concepts

- The two hybrid assay works by requiring an interaction between two proteins where one has a DNA-binding domain and the other has a transcription-activation domain.

---

The model of domain independence is the basis for an extremely useful assay for detecting protein interactions. In effect, we replace the connecting domain in **Figure 22.3** with a protein-protein interaction. The principle is illustrated in **Figure 22.6**. We fuse one of the proteins to be tested to a DNA-binding domain. We fuse the other protein to a transcription-activating domain. (This is done by linking the appropriate coding sequences in each case and making synthetic proteins by expressing each hybrid gene.)

**Figure 22.6** The two hybrid technique tests the ability of two proteins to interact by incorporating them into hybrid proteins where one has a DNA-binding domain and the other has a transcription-activating domain.

If the two proteins that are being tested can interact with one another, the two hybrid proteins will interact. This is reflected in the name of the technique: the **two hybrid** assay (952). The protein with the DNA-binding domain binds to a reporter gene that has a simple promoter containing its target site. But it cannot activate the gene by itself. Activation occurs only if the second hybrid binds to the first hybrid to bring the activation domain to the promoter. Any reporter gene can be used where the product is readily assayed, and this technique has given rise to several automated procedures for rapidly testing protein-protein interactions.

The effectiveness of the technique dramatically illustrates the modular nature of proteins. Even when fused to another protein, the DNA-binding domain can bind to DNA and the transcription-activating domain can activate transcription. Correspondingly, the interaction ability of the two proteins being tested is not inhibited by the attachment of the DNA-binding or transcription-activating domains. (Of course, there are some exceptions where these simple rules do not apply and interference between the domains of the hybrid protein prevents the technique from working.)

The power of this assay is that it requires only that the two proteins being tested can

interact with each other. They need not have anything to do with transcription. Because of the independence of the DNA-binding and transcription-activating domains, all we require is that they are brought together. This will happen so long as the two proteins being tested can interact in the environment of the nucleus.

## ACTIVATING TRANSCRIPTION

### 5.22.5 Activators interact with the basal apparatus

#### Key Terms

**Mediator** is a large protein complex associated with yeast bacterial RNA polymerase II. It contains factors that are necessary for transcription from many or most promoters.

#### Key Concepts

- The principle that governs the function of all activators is that a DNA-binding domain determines specificity for the target promoter or enhancer.
- The DNA-binding domain is responsible for localizing a transcription-activating domain in the proximity of the basal apparatus.
- An activator that works directly has a DNA-binding domain and an activating domain.
- An activator that does not have an activating domain may work by binding a coactivator that has an activating domain.
- Several factors in the basal apparatus are targets with which activators or coactivators interact.
- RNA polymerase may be associated with various alternative sets of transcription factors in the form of a holoenzyme complex.

An activator may work directly when it consists of a DNA-binding domain linked to a transcription-activating domain, as illustrated in **Figure 22.3**. In other cases, the activator does not itself have a transcription-activating domain, but binds another protein – a coactivator – that has the transcription-activating domain. **Figure 22.8** shows the action of such an activator. We may regard coactivators as transcription factors whose specificity is conferred by the ability to bind to DNA-binding transcription factors instead of directly to DNA. A particular activator may require a specific coactivator.

**Figure 22.8** An activator may bind a coactivator that contacts the basal apparatus.

But although the protein components are organized differently, the mechanism is the same. An activator that contacts the basal apparatus directly has an activation domain covalently connected to the DNA-binding domain. When an activator works through a coactivator, the connections involve noncovalent binding between protein subunits (compare **Figure 22.3** and **Figure 22.8**). The same interactions are responsible for activation, irrespective of whether the various domains are present in the same protein subunit or divided into multiple protein subunits (645).

A transcription-activating domain works by making protein-protein contacts with general transcription factors that promote assembly of the basal apparatus (for review see 218; 221). Contact with the basal apparatus may be made with any one of several basal factors, typically TF<sub>II</sub>D, TF<sub>II</sub>B, or TF<sub>II</sub>A. All of these factors participate in early stages of assembly of the basal apparatus (see **Figure 21.15**). **Figure 22.9** illustrates the situation when such a contact is made. The major effect of the activators is to influence the assembly of the basal apparatus (646; 659).

**Figure 22.9** Activators may work at different stages of initiation, by contacting the TAFs of TFIIID or contacting TFIIIB.

TF<sub>II</sub>D may be the most common target for activators, which may contact any one of several TAFs. In fact, a major role of the TAFs is to provide the connection from the basal apparatus to activators. This explains why TBP alone can support basal-level transcription, but the TAFs of TF<sub>II</sub>D are required for the higher levels of transcription that are stimulated by activators. Different TAFs in TF<sub>II</sub>D may provide surfaces that interact with different activators. Some activators interact only with individual TAFs; others interact with multiple TAFs. We assume that the interaction either assists binding of TF<sub>II</sub>D to the TATA box or assists the binding of other activators around the TF<sub>II</sub>D-TATA box complex. In either case, the interaction stabilizes the basal transcription complex; this speeds the process of initiation, and thereby increases use of the promoter.

The activating domains of the yeast activators GAL4 and GCN4 have multiple negative charges, giving rise to their description as "acidic activators." Another particularly effective activator of this type is carried by the VP16 protein of the Herpes Simplex Virus. (VP16 does not itself have a DNA-binding domain, but interacts with the transcription apparatus via an intermediary protein.) Experiments

to characterize acidic activator functions have often made use of the VP16 activating region linked to a DNA-binding motif (658).

Acidic activators function by enhancing the ability of TF<sub>B</sub> to join the basal initiation complex. Experiments *in vitro* show that binding of TF<sub>B</sub> to an initiation complex at an adenovirus promoter is stimulated by the presence of GAL4 or VP16 acid activators; and the VP16 activator can bind directly to TF<sub>B</sub>. Assembly of TF<sub>B</sub> into the complex at this promoter is therefore a rate-limiting step that is stimulated by the presence of an acidic activator.

The resilience of an RNA polymerase II promoter to the rearrangement of elements, and its indifference even to the particular elements present, suggests that the events by which it is activated are relatively general in nature. Any activators whose activating region is brought within range of the basal initiation complex may be able to stimulate its formation. Some striking illustrations of such versatility have been accomplished by constructing promoters consisting of new combinations of elements. For example, when a yeast *UAS<sub>G</sub>* element is inserted near the promoter of a higher eukaryotic gene, this gene can be activated by GAL4 in a mammalian cultured cell. Whatever means GAL4 uses to activate the promoter seems therefore to have been conserved between yeast and higher eukaryotes. The GAL4 protein must recognize some feature of the mammalian transcription apparatus that resembles its normal contacts in yeast.

How does an activator stimulate transcription? We can imagine two general types of model:

- The recruitment model argues that its sole effect is to increase the binding of RNA polymerase to the promoter.
- An alternative model is to suppose that it induces some change in the transcriptional complex, for example, in the conformation of the enzyme, which increases its efficiency.

A test of these models in one case in yeast showed that recruitment can account for activation. When the concentration of RNA polymerase was increased sufficiently, the activator failed to produce any increase in transcription, suggesting that its sole effect is to increase the effective concentration of RNA polymerase at the promoter.

Adding up all the components required for efficient transcription – basal factors, RNA polymerase, activators, coactivators – we get a very large apparatus, consisting of >40 proteins. Is it feasible for this apparatus to assemble step by step at the promoter? Some activators, coactivators, and basal factors may assemble stepwise at the promoter, but then may be joined by a very large complex consisting of RNA polymerase preassembled with further activators and coactivators, as illustrated in **Figure 22.7** (for review see 1710).

**Figure 22.7** RNA polymerase exists as a holoenzyme containing many activators.

Several forms of RNA polymerase have been found in which the enzyme is associated with various transcription factors. The most prominent "holoenzyme complex" in yeast (defined as being capable of initiating transcription without additional components) consists of RNA polymerase associated with a 20-subunit complex called **mediator** (1713; for review see 1711). The mediator includes products of several genes in which mutations block transcription, including some *SRB* loci (so named because many of their genes were originally identified as suppressors of mutations in RNA polymerase *B*.) The name was suggested by its ability to mediate the effects of activators. Mediator is necessary for transcription of most yeast genes. Homologous complexes are required for the transcription of most higher eukaryotic genes (2411). Mediator undergoes a conformational change when it interacts with the CTD domain of RNA polymerase (2412). It can transmit either activating or repressing effects from upstream components to the RNA polymerase. It is probably released when a polymerase starts elongation. Some transcription factors influence transcription directly by interacting with RNA polymerase or the basal apparatus, but others work by manipulating structure of chromatin (see *Molecular Biology 5.23.3 Chromatin remodeling is an active process*).

## ACTIVATING TRANSCRIPTION

### 5.22.6 Some promoter-binding proteins are repressors

---

#### Key Concepts

- Repression is usually achieved by affecting chromatin structure, but there are repressors that act by binding to specific promoters.

---

Repression of transcription in eukaryotes is generally accomplished at the level of influencing chromatin structure; regulator proteins that function like *trans*-acting bacterial repressors to block transcription are relatively rare, but some examples are known. One case is the global repressor NC2/Dr1/DRAP1, a heterodimer that binds to TBP to prevent it from interacting with other components of the basal apparatus (1741; 1742; 1743). The importance of this interaction is suggested by the lethality of null mutations in the genes that code for the repressor in yeast. Repressors that work in this way have an active role in inhibiting basal apparatus function.

In a more specific case, the CAAT sequence is a target for regulation. Two copies of this element are found in the promoter of a gene for histone H2B (see **Figure 21.22**) that is expressed only during spermatogenesis in a sea urchin. CAAT-binding factors can be extracted from testis tissue and also from embryonic tissues, but only the former can bind to the CAAT box. In the embryonic tissues, another protein, called the CAAT-displacement protein (CDP), binds to the CAAT boxes, *preventing the activator from recognizing them*.

**Figure 22.10** illustrates the consequences for gene expression. In testis, the promoter is bound by transcription factors at the TATA box, CAAT boxes, and octamer sequences. In embryonic tissue, the exclusion of the CAAT-binding factor from the promoter prevents a transcription complex from being assembled. The analogy with the effect of a bacterial repressor in preventing RNA polymerase from initiating at the promoter is obvious. These results also make the point that the function of a protein in binding to a known promoter element cannot be assumed: it may be an activator, a repressor, or even irrelevant to gene transcription.

**Figure 22.10** A transcription complex involves recognition of several elements in the sea urchin H2B promoter in testis. Binding of the CAAT displacement factor in embryo prevents the CAAT-binding factor from binding, so an active complex cannot form.

## ACTIVATING TRANSCRIPTION

### 5.22.7 Response elements are recognized by activators

---

#### Key Terms

A **response element** is a sequence in a eukaryotic promoter or enhancer that is recognized by a specific transcription factor.

The **heat shock response element (HSE)** is a sequence in a promoter or enhancer that is used to activate a gene by an activator induced by heat shock.

The **glucocorticoid response element (GRE)** is a sequence in a promoter or enhancer that is recognized by the glucocorticoid receptor, which is activated by glucocorticoid steroids.

The **serum response element (SRE)** is a sequence in a promoter or enhancer that is activated by transcription factor(s) induced by treatment with serum. This activates genes that stimulate cell growth.

**Heat shock genes** are a set of loci that are activated in response to an increase in temperature (and other abuses to the cell). They occur in all organisms. They usually include chaperones that act on denatured proteins.

#### Key Concepts

- Response elements may be located in promoters or enhancers.
- Each response element is recognized by a specific activator.
- A promoter may have many response elements, which may activate transcription independently or in certain combinations.

---

The principle that emerges from characterizing groups of genes under common control is that *they share a promoter (or enhancer) element that is recognized by an activator*. An element that causes a gene to respond to such a factor is called a **response element**; examples are the **HSE** (heat shock response element), **GRE** (glucocorticoid response element), **SRE** (serum response element). Response elements contain short consensus sequences; copies of the response elements found in different genes are closely related, but not necessarily identical. The region bound by the factor extends for a short distance on either side of the consensus sequence. In promoters, the elements are not present at fixed distances from the startpoint, but are usually <200 bp upstream of it. The presence of a single element usually is sufficient to confer the regulatory response, but sometimes there are multiple copies.

Response elements may be located in promoters or in enhancers. Some types of elements are typically found in one rather than the other: usually an HSE is found in a promoter, while a GRE is found in an enhancer. We assume that all response elements function by the same general principle. Binding of an activator to the response element is required to allow RNA polymerase to initiate transcription. The difference from constitutively active activators is that the protein is either available

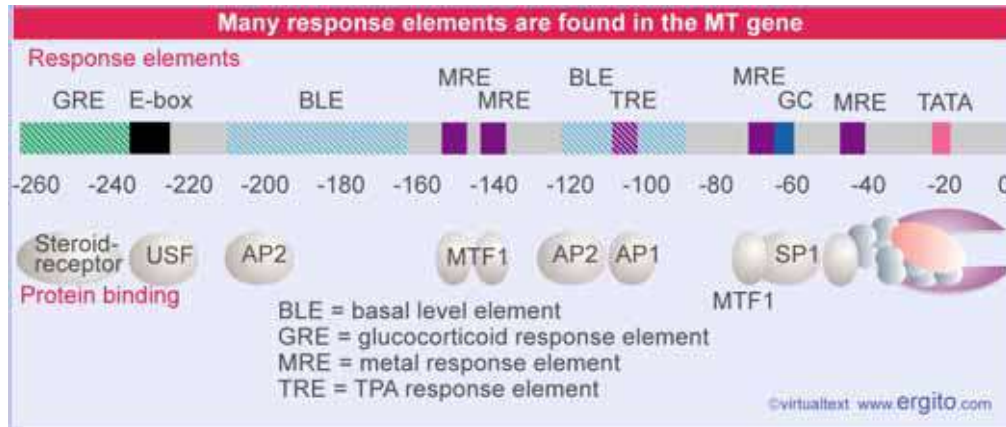

or is active only under certain conditions, which determine when the gene is to be expressed.

An example of a situation in which many genes are controlled by a single factor is provided by the heat shock response. This is common to a wide range of prokaryotes and eukaryotes and involves multiple controls of gene expression: an increase in temperature turns off transcription of some genes, turns on transcription of the **heat shock genes**, and causes changes in the translation of mRNAs. The control of the heat shock genes illustrates the differences between prokaryotic and eukaryotic modes of control. In bacteria, a new sigma factor is synthesized that directs RNA polymerase holoenzyme to recognize an alternative  $-10$  sequence common to the promoters of heat shock genes (see *Molecular Biology 3.9.16 Substitution of sigma factors may control initiation*). In eukaryotes, the heat shock genes also possess a common consensus sequence (HSE), but it is located at various positions relative to the startpoint, and is recognized by an independent activator, HSTF. The activation of this factor therefore provides a means to initiate transcription at the specific group of  $\sim 20$  genes that contains the appropriate target sequence at its promoter.

All the heat shock genes of *D. melanogaster* contain multiple copies of the HSE. The HSTF binds cooperatively to adjacent response elements. Both the HSE and HSTF have been conserved in evolution, and it is striking that a heat shock gene from *D. melanogaster* can be activated in species as distant as mammals or sea urchins. The HSTF proteins of fruit fly and yeast appear similar, and show the same footprint pattern on DNA containing HSE sequences. Yeast HSTF becomes phosphorylated when cells are heat-shocked; this modification is responsible for activating the protein.

The metallothionein (MT) gene provides an example of how a single gene may be regulated by many different circuits. The metallothionein protein protects the cell against excess concentrations of heavy metals, by binding the metal and removing it from the cell. The gene is expressed at a basal level, but is induced to greater levels of expression by heavy metal ions (such as cadmium) or by glucocorticoids. The control region combines several different kinds of regulatory elements.

The organization of the promoter for a MT gene is summarized in **Figure 22.11**. A major feature of this map is the high density of elements that can activate transcription. The TATA and GC boxes are located at their usual positions fairly close to the startpoint. Also needed for the basal level of expression are the two basal level elements (BLE), which fit the formal description of enhancers. Although located near the startpoint, they can be moved elsewhere without loss of effect. They contain sequences related to those found in other enhancers, and are bound by proteins that bind the SV40 enhancer.

**Figure 22.11** The regulatory region of a human metallothionein gene contains regulator elements in both its promoter and enhancer. The promoter has elements for metal induction; an enhancer has an element for response to glucocorticoid. Promoter elements are shown above the map, and proteins that bind them are indicated below.

The TRE is a consensus sequence that is present in several enhancers, including one BLE of metallothionein and the 72 bp repeats of the virus SV40. The TRE has a binding site for factor AP1; this interaction is part of the mechanism for constitutive expression, for which AP1 is an activator. However, AP1 binding also has a second function. The TRE confers a response to phorbol esters such as TPA (an agent that promotes tumors), and this response is mediated by the interaction of AP1 with the TRE. This binding reaction is one (not necessarily the sole) means by which phorbol esters trigger a series of transcriptional changes.

The inductive response to metals is conferred by the multiple MRE sequences, which function as promoter elements. The presence of one MRE confers the ability to respond to heavy metal; a greater level of induction is achieved by the inclusion of multiple elements. The factor MTF1 binds to the MRE in response to the presence of metal ions.

The response to steroid hormones is governed by a GRE, located 250 bp upstream of the startpoint, which behaves as an enhancer. Deletion of this region does not affect the basal level of expression or the level induced by metal ions. But it is absolutely needed for the response to steroids.

The regulation of metallothionein illustrates the general principle that *any one of several different elements, located in either an enhancer or promoter, can independently activate the gene*. The absence of an element needed for one mode of activation does not affect activation in other modes. The variety of elements, their independence of action, and the apparently unlimited flexibility of their relative arrangements, suggest that a factor binding to any one element is able independently to increase the efficiency of initiation by the basal transcription apparatus, probably by virtue of protein-protein interactions that stabilize or otherwise assist formation of the initiation complex.

## ACTIVATING TRANSCRIPTION

### 5.22.8 There are many types of DNA-binding domains

---

#### Key Terms

The **zinc finger** is a DNA-binding motif that typifies a class of transcription factor.

**Steroid receptors** are transcription factors that are activated by binding of a steroid ligand.

The **helix-turn-helix** motif describes an arrangement of two  $\alpha$  helices that form a site that binds to DNA, one fitting into the major groove of DNA and other lying across it.

The **homeodomain** is a DNA-binding motif that typifies a class of transcription factors. The DNA sequence that codes for it is called the homeobox.

The **helix-loop-helix (HLH)** motif is responsible for dimerization of a class of transcription factors called HLH proteins. A bHLH protein has a basic DNA-binding sequence close to the dimerization motif.

The **leucine zipper** is a dimerization motif adjacent to a basic DNA-binding region that is found in a class of transcription factors.

#### Key Concepts

- Activators are classified according to the type of DNA-binding domain.
- Members of the same group have sequence variations of a specific motif that confer specificity for individual target sites.

---

It is common for an activator to have a modular structure in which different domains are responsible for binding to DNA and for activating transcription. Factors are often classified according to the type of DNA-binding domain (for review see 235; 238). Typically a relatively short motif in this domain is responsible for binding to DNA:

- The **zinc finger** motif comprises a DNA-binding domain. It was originally recognized in factor TF<sub>III</sub>A, which is required for RNA polymerase III to transcribe 5S rRNA genes. It has since been identified in several other transcription factors (and presumed transcription factors). A distinct form of the motif is found also in the steroid receptors (672).
- The **steroid receptors** are defined as a group by a functional relationship: each receptor is activated by binding a particular steroid. The glucocorticoid receptor is the most fully analyzed. Together with other receptors, such as the thyroid hormone receptor or the retinoic acid receptor, the steroid receptors are members of the superfamily of ligand-activated activators with the same general *modus operandi*: *the protein factor is inactive until it binds a small ligand*.
- The **helix-turn-helix** motif was originally identified as the DNA-binding domain

of phage repressors. One  $\alpha$ -helix lies in the major groove of DNA; the other lies at an angle across DNA. A related form of the motif is present in the **homeodomain**, a sequence first characterized in several proteins coded by genes concerned with developmental regulation in *Drosophila*. It is also present in genes for mammalian transcription factors.

- The amphipathic **helix-loop-helix (HLH)** motif has been identified in some developmental regulators and in genes coding for eukaryotic DNA-binding proteins. Each amphipathic helix presents a face of hydrophobic residues on one side and charged residues on the other side. The length of the connecting loop varies from 12-28 amino acids. The motif enables proteins to dimerize, and a basic region near this motif contacts DNA.
- **Leucine zippers** consist of a stretch of amino acids with a leucine residue in every seventh position. A leucine zipper in one polypeptide interacts with a zipper in another polypeptide to form a dimer. Adjacent to each zipper is a stretch of positively charged residues that is involved in binding to DNA.

The activity of an inducible activator may be regulated in any one of several ways, as illustrated schematically in **Figure 22.12**:

**Figure 22.12** The activity of a regulatory transcription factor may be controlled by synthesis of protein, covalent modification of protein, ligand binding, or binding of inhibitors that sequester the protein or affect its ability to bind to DNA.

- A factor is tissue-specific because it is synthesized only in a particular type of cell. This is typical of factors that regulate development, such as homeodomain proteins.
- The activity of a factor may be directly controlled by modification. HSTF is converted to the active form by phosphorylation. AP1 (a heterodimer between the subunits Jun and Fos) is converted to the active form by phosphorylating the Jun subunit.
- A factor is activated or inactivated by binding a ligand. The steroid receptors are prime examples. Ligand binding may influence the localization of the protein (causing transport from cytoplasm to nucleus), as well as determining its ability to bind to DNA.
- Availability of a factor may vary; for example, the factor NF-κB (which activates immunoglobulin κ genes in B lymphocytes) is present in many cell

types. But it is sequestered in the cytoplasm by the inhibitory protein I- $\kappa$ B. In B lymphocytes, NF- $\kappa$ B is released from I- $\kappa$ B and moves to the nucleus, where it activates transcription.

- An extreme example of control of availability is found when a factor is actually part of a cytoplasmic structure, and is released from that structure to translocate to the nucleus.
- A dimeric factor may have alternative partners. One partner may cause it to be inactive; synthesis of the active partner may displace the inactive partner. Such situations may be amplified into networks in which various alternative partners pair with one another, especially among the HLH proteins (675).
- The factor may be cleaved from an inactive precursor. One activator is produced as a protein bound to the nuclear envelope and endoplasmic reticulum. The absence of sterols (such as cholesterol) causes the cytosolic domain to be cleaved; it then translocates to the nucleus and provides the active form of the activator.

(We note *en passant* that mutations of the transcription factors in some of these classes give rise to factors that inappropriately activate, or prevent activation, of transcription; their roles in generating tumors are discussed in *Molecular Biology 6.30.18 Oncoproteins may regulate gene expression*, and **Figure 30.26** should be compared with **Figure 22.12**.)

We now discuss in more detail the DNA-binding and activation reactions that are sponsored by some of these classes of proteins.

## ACTIVATING TRANSCRIPTION

### 5.22.9 A zinc finger motif is a DNA-binding domain

#### Key Concepts

- A zinc finger is a loop of ~23 amino acids that protrudes from a zinc-binding site formed by His and Cys amino acids.
- A zinc finger protein usually has multiple zinc fingers.
- The C-terminal part of each finger forms an  $\alpha$ -helix that binds one turn of the major groove of DNA.
- Some zinc finger proteins bind RNA instead of or as well as DNA.

Zinc fingers take their name from the structure illustrated in **Figure 22.13**, in which a small group of conserved amino acids binds a zinc ion to form an independent domain in the protein. Two types of DNA-binding proteins have structures of this type: the classic "zinc finger" proteins; and the steroid receptors.

**Figure 22.13** Transcription factor SP1 has a series of three zinc fingers, each with a characteristic pattern of cysteine and histidine residues that constitute the zinc-binding site.

A "finger protein" typically has a series of zinc fingers, as depicted in the figure. The consensus sequence of a single finger is:

The motif takes its name from the loop of amino acids that protrudes from the zinc-binding site and is described as the Cys<sub>2</sub>/His<sub>2</sub> finger. The zinc is held in a tetrahedral structure formed by the conserved Cys and His residues. The finger itself comprises ~23 amino acids, and the linker between fingers is usually 7-8 amino acids.

Zinc fingers are a common motif in DNA-binding proteins. The fingers usually are

organized as a single series of tandem repeats; occasionally there is more than one group of fingers. The stretch of fingers ranges from 9 repeats that occupy almost the entire protein (as in TF<sub>A</sub>) to providing just one small domain consisting of 2 fingers (as in the *Drosophila* regulator ADR1). The activator Sp1 has a DNA-binding domain that consists of 3 zinc fingers (656; 672).

The crystal structure of DNA bound by a protein with three fingers suggests the structure illustrated schematically in **Figure 22.14**. The C-terminal part of each finger forms  $\alpha$ -helices that bind DNA; the N-terminal part forms a  $\beta$ -sheet. (For simplicity, the  $\beta$ -sheet and the location of the zinc ion are not shown in the lower part of the figure.) The three  $\alpha$ -helical stretches fit into one turn of the major groove; each  $\alpha$ -helix (and thus each finger) makes two sequence-specific contacts with DNA (indicated by the arrows). We expect that the nonconserved amino acids in the C-terminal side of each finger are responsible for recognizing specific target sites (677).

**Figure 22.14** Zinc fingers may form  $\alpha$ -helices that insert into the major groove, associated with  $\beta$ -sheets on the other side.

Knowing that zinc fingers are found in authentic activators that assist both RNA polymerases II and III, we may view finger proteins from the reverse perspective. When a protein is found to have multiple zinc fingers, there is at least a *prima facie* case for investigating a possible role as a transcription factor. Such an identification has suggested that several loci involved in embryonic development of *D. melanogaster* are regulators of transcription.

However, it is necessary to be cautious about interpreting the presence of (putative) zinc fingers, especially when the protein contains only a single finger motif. Fingers may be involved in binding RNA rather than DNA or even unconnected with any nucleic acid binding activity. For example, the prototype zinc finger protein, TF<sub>A</sub>, binds both to the 5S gene and to the product, 5S rRNA. A translation initiation

factor, eIF2  $\beta$  has a zinc finger; and mutations in the finger influence the recognition of initiation codons. Retroviral capsid proteins have a motif related to the finger that may be involved in binding the viral RNA.

**ACTIVATING TRANSCRIPTION****5.22.10 Steroid receptors are activators**

---

**Key Concepts**

- Steroid receptors are examples of ligand-responsive activators that are activated by binding a steroid (or other related molecules).
  - There are separate DNA-binding and ligand-binding domains.
- 

Steroid hormones are synthesized in response to a variety of neuroendocrine activities, and exert major effects on growth, tissue development, and body homeostasis in the animal world. The major groups of steroids and some other compounds with related (molecular) activities are classified in **Figure 22.15**.

**Figure 22.15** Several types of hydrophobic small molecules activate transcription factors.

The adrenal gland secretes >30 steroids, the two major groups being the glucocorticoids and mineralocorticoids. Steroids provide the reproductive hormones (androgen male sex hormones and estrogen female sex hormones). Vitamin D is required for bone development.

Other hormones, with unrelated structures and physiological purposes, function at the molecular level in a similar way to the steroid hormones. Thyroid hormones, based on iodinated forms of tyrosine, control basal metabolic rate in animals. Steroid and thyroid hormones also may be important in metamorphosis (ecdysteroids in insects, and thyroid hormones in frogs).

Retinoic acid (vitamin A) is a morphogen responsible for development of the anterior-posterior axis in the developing chick limb bud. Its metabolite, 9-*cis* retinoic acid, is found in tissues that are major sites for storage and metabolism of vitamin A.

*We may account for these various actions in terms of pathways for regulating gene expression. These diverse compounds share a common mode of action: each is a small molecule that binds to a specific receptor that activates gene transcription. ("Receptor" may be a misnomer: the protein is a receptor for steroid or thyroid hormone in the same sense that lac repressor is a receptor for a  $\beta$ -galactoside; it is not a receptor in the sense of comprising a membrane-bound protein that is exposed to the cell surface.)*

Receptors for the diverse groups of steroid hormones, thyroid hormones, and retinoic acid represent a new "superfamily" of gene regulators, the ligand-responsive activators. All the receptors have independent domains for DNA-binding and hormone binding, in the same relative locations. Their general organization is summarized in **Figure 22.16** (for review see 231).

**Figure 22.16** Receptors for many steroid and thyroid hormones have a similar organization, with an individual N-terminal region, conserved DNA-binding region, and a C-terminal hormone-binding region.

The central part of the protein is the DNA-binding domain. These regions are closely related for the various steroid receptors (from the most closely related pair with 94% sequence identity to the least well related pair at 42% identity). The act of binding DNA cannot be disconnected from the ability to activate transcription, because mutations in this domain affect both activities.

The N-terminal regions of the receptors show the least conservation of sequence. They include other regions that are needed to activate transcription.

The C-terminal domains bind the hormones. Those in the steroid receptor family show identities ranging from 30-57%, reflecting specificity for individual hormones. Their relationships with the other receptors are minimal, reflecting specificity for a variety of compounds – thyroid hormones, vitamin D, retinoic acid, etc. This domain also has the motifs responsible for dimerization and a region involved in transcriptional activation (for review see 1436).

Some ligands have multiple receptors that are closely related, such as the 3 retinoic acid receptors (RAR  $\alpha$ ,  $\beta$ ,  $\gamma$ ) and the three receptors for 9-*cis*-retinoic acid (RXR  $\alpha$ ,  $\beta$ ,  $\gamma$ ).

**ACTIVATING TRANSCRIPTION****5.22.11 Steroid receptors have zinc fingers**

---

**Key Concepts**

- The DNA binding domain of a steroid receptor is a type of zinc finger that has Cys but not His residues.
- Glucocorticoid and estrogen receptors each have two zinc fingers, the first of which determines the DNA target sequence.
- Steroid receptors bind to DNA as dimers.

---

Steroid receptors (and some other proteins) have another type of zinc finger that is different from Cys<sub>2</sub>/His<sub>2</sub> fingers. The structure is based on a sequence with the zinc-binding consensus:

Cys-X<sub>2</sub>-Cys-X<sub>13</sub>-Cys-X<sub>2</sub>-Cys

These are called Cys<sub>2</sub>/Cys<sub>2</sub> fingers. Proteins with Cys<sub>2</sub>/Cys<sub>2</sub> fingers often have nonrepetitive fingers, in contrast with the tandem repetition of the Cys<sub>2</sub>/His<sub>2</sub> type. Binding sites in DNA (where known) are short and palindromic.

The glucocorticoid and estrogen receptors each have two fingers, each with a zinc atom at the center of a tetrahedron of cysteines. The two fingers form α-helices that fold together to form a large globular domain. The aromatic sides of the α-helices form a hydrophobic center together with a β-sheet that connects the two helices. One side of the N-terminal helix makes contacts in the major groove of DNA. Two glucocorticoid receptors dimerize upon binding to DNA, and each engages a successive turn of the major groove. This fits with the palindromic nature of the response element (see *Molecular Biology 5.22.13 Steroid receptors recognize response elements by a combinatorial code*).

Each finger controls one important property of the receptor. **Figure 22.18** identifies the relevant amino acids. Those on the right side of the first finger determine the sequence of the target in DNA; those on the left side of the second finger control the spacing between the target sites recognized by each subunit in the dimer (see *Molecular Biology 5.22.13 Steroid receptors recognize response elements by a combinatorial code*).

**Figure 22.18** The first finger of a steroid receptor controls which DNA sequence is bound (positions shown in red); the second finger controls spacing between the sequences (positions shown in blue).

Direct evidence that the first finger binds DNA was obtained by a "specificity swap" experiment. The finger of the estrogen receptor was deleted and replaced by the sequence of the glucocorticoid receptor. The new protein recognized the GRE sequence (the usual target of the glucocorticoid receptor) instead of the ERE (the usual target of the estrogen receptor). This region therefore establishes the specificity with which DNA is recognized.

The differences between the sequences of the glucocorticoid receptor and estrogen receptor fingers lie mostly at the base of the finger. The substitution at two positions shown in **Figure 22.17** allows the glucocorticoid receptor to bind at an ERE instead of a GRE (1768; for review see 240).

**Figure 22.17** Discrimination between GRE and ERE target sequences is determined by two amino acids at the base of the first zinc finger in the receptor.

**ACTIVATING TRANSCRIPTION****5.22.12 Binding to the response element is activated by ligand-binding****Key Concepts**

- Binding of ligand to the C-terminal domain increases the affinity of the DNA-binding domain for its specific target site in DNA.

We know most about the interaction of glucocorticoids with their receptor, whose action is illustrated in **Figure 22.19**. A steroid hormone can pass through the cell membrane to enter the cell by simple diffusion. Within the cell, a glucocorticoid binds the glucocorticoid receptor. (Work on the glucocorticoid receptor has relied on the synthetic steroid hormone, dexamethasone.) The localization of free receptors is not entirely clear; they may be in equilibrium between the nucleus and cytoplasm. But when hormone binds to the receptor, the protein is converted into an activated form that has an increased affinity for DNA, so the hormone-receptor complex is always localized in the nucleus.

**Figure 22.19** Glucocorticoids regulate gene transcription by causing their receptor to bind to an enhancer whose action is needed for promoter function.

The activated receptor recognizes a specific consensus sequence that identifies the GRE, the glucocorticoid response element. The GRE is typically located in an enhancer that may be several kb upstream or downstream of the promoter. When the steroid-receptor complex binds to the enhancer, the nearby promoter is activated, and transcription initiates there. Enhancer activation provides the general mechanism by which steroids regulate a wide set of target genes.

The C-terminal region regulates the activity of the receptor in a way that varies for the individual receptor. If the C-terminal domain of the glucocorticoid receptor is deleted, the remaining N-terminal protein is constitutively active: it no longer requires steroids for activity. This suggests that, in the absence of steroid, the steroid-binding domain prevents the receptor from recognizing the GRE; it functions as an internal negative regulator. The addition of steroid inactivates the inhibition, releasing the receptor's ability to bind the GRE and activate transcription. The basis for the repression could be internal, relying on interactions with another part of the receptor. Or it could result from an interaction with some other protein, which is displaced when steroid binds.

The interaction between the domains is different in the estrogen receptor. If the hormone-binding domain is deleted, the protein is unable to activate transcription, although it continues to bind to the ERE. This region is therefore required to activate rather than to repress activity.

## ACTIVATING TRANSCRIPTION

### 5.22.13 Steroid receptors recognize response elements by a combinatorial code

---

#### Key Concepts

- A steroid response element consists of two short half sites that may be palindromic or directly repeated.
- There are only two types of half sites.
- A receptor recognizes its response element by the orientation and spacing of the half sites.
- The sequence of the half site is recognized by the first zinc finger.
- The second zinc finger is responsible for dimerization, which determines the distance between the subunits.
- Subunit separation in the receptor determines the recognition of spacing in the response element.
- Some steroid receptors function as homodimers but others form heterodimers.
- Homodimers recognize palindromic response elements; heterodimers recognize response elements with directly repeated half sites.

---

Each receptor recognizes a response element that consists of two short repeats (or half sites). This immediately suggests that the receptor binds as a dimer, so that each half of the consensus is contacted by one subunit (reminiscent of the  $\lambda$  operator-repressor interaction described in *Molecular Biology 3.12.12 Repressor uses a helix-turn-helix motif to bind DNA*).

The half sites may be arranged either as palindromes or as repeats in the same orientation. They are separated by 0-4 base pairs whose sequence is irrelevant. Only two types of half site are used by the various receptors. Their orientation and spacing determine which receptor recognizes the response element. This behavior allows response elements that have restricted consensus sequences to be recognized specifically by a variety of receptors. The rules that govern recognition are not absolute, but may be modified by context, and there are also cases in which palindromic response elements are recognized permissively by more than one receptor (for review see 229).

The receptors fall into two groups:

- Glucocorticoid (GR), mineralocorticoid (MR), androgen (AR), and progesterone (PR) receptors all form homodimers. They recognize response elements whose half sites have the consensus sequence TGTCT. **Figure 22.20** shows that the

half sites are arranged as palindromes, and the spacing between the sites determines the type of element. The estrogen (ER) receptor functions in the same way, but has the half site sequence TGACCT.

- The *9-cis*-retinoic acid (RXR) receptor forms homodimers and also forms heterodimers with ~15 other receptors, including thyroid (T3R), vitamin D (VDR), and retinoic acid (RAR) (1436). **Figure 22.21** shows that the dimers recognize half elements with the sequence TGACCT. The half sites are arranged as direct repeats, and recognition is controlled by spacing between them (1769). Some of the heterodimeric receptors are activated when the ligand binds to the partner for RXR; others can be activated by ligand binding either to this subunit or to the RXR subunit. These receptors can also form homodimers, which recognize palindromic sequences.

**Figure 22.20** Response elements formed from the palindromic half site TGTTCT are recognized by several different receptors depending on the spacing between the half sites.

**Figure 22.21** Response elements with the direct repeat TGACCT are recognized by heterodimers of which one member is RXR.

Now we are in a position to understand the basis for specificity of recognition. Recall that **Figure 22.18** shows how recognition of the sequence of the half site is conferred by the amino acid sequence in the first finger. Specificity for the spacing between half sites is carried by amino acids in the second finger. The structure of the dimer determines the distance between the subunits that sit in successive turns of the major groove, and thus controls the response to the spacing of half sites (679). The exact positions of the residues responsible for dimerization differ in individual pairwise combinations.

How do the steroid receptors activate transcription? They do not act directly on the basal apparatus, but function via a coactivating complex. The coactivator includes various activities, including the common component CBP/p300, one of whose functions is to modify the structure of chromatin by acetylating histones (see **Figure 23.13**).

All receptors in the superfamily are ligand-dependent activators of transcription. However, some are also able to repress transcription. The TR and RAR receptors, in the form of heterodimers with RXR, bind to certain loci in the *absence* of ligand and repress transcription by means of their ability to interact with a corepressor protein. The corepressor functions by the reverse of the mechanism used by coactivators: it inhibits the function of the basal transcription apparatus, one of its actions being the deacetylation of histones (see **Figure 23.15**). We do not know the relative importance of the repressor activity *vis-à-vis* the ligand-dependent activation in the physiological response to hormone (660).

The effect of ligand binding on the receptor is to convert it from a repressing complex to an activating complex, as shown in **Figure 22.22**. In the absence of ligand, the receptor is bound to a corepressor complex. The component of the corepressor that binds to the receptor is SMRT. Binding of ligand causes a conformational change that displaces SMRT. This allows the coactivator to bind.

**Figure 22.22** TR and RAR bind the SMRT corepressor in the absence of ligand. The promoter is not expressed. When SMRT is displaced by binding of ligand, the receptor binds a coactivator complex. This leads to activation of transcription by the basal apparatus.

**ACTIVATING TRANSCRIPTION****5.22.14 Homeodomains bind related targets in DNA**

---

**Key Concepts**

- The homeodomain is a DNA-binding domain of 60 amino acids that has three  $\alpha$ -helices.
  - The C-terminal  $\alpha$ -helix-3 is 17 amino acids and binds in the major groove of DNA.
  - The N-terminal arm of the homeodomain projects into the minor groove of DNA.
  - Proteins containing homeodomains may be either activators or repressors of transcription.
- 

The homeobox is a sequence that codes for a domain of 60 amino acids present in proteins of many or even all eukaryotes. Its name derives from its original identification in *Drosophila* homeotic loci (whose genes determine the identity of body structures). It is present in many of the genes that regulate early development in *Drosophila*, and a related motif is found in genes in a wide range of higher eukaryotes. The homeodomain is found in many genes concerned with developmental regulation (see *Molecular Biology* 6.31.22 *The homeobox is a common coding motif in homeotic genes*). Sequences related to the homeodomain are found in several types of animal transcription factors.

In *Drosophila* homeotic genes, the homeodomain often (but not always) occurs close to the C-terminal end. Some examples of genes containing homeoboxes are summarized in **Figure 22.23**. Often the genes have little conservation of sequence except in the homeobox. The conservation of the homeobox sequence varies. A major group of homeobox-containing genes in *Drosophila* has a well conserved sequence, with 80-90% similarity in pairwise comparisons. Other genes have less closely related homeoboxes. The homeodomain is sometimes combined with other motifs in animal transcription factors. One example is presented by the Oct (octamer-binding) proteins, in which a conserved stretch of 75 amino acids called the Pou region is located close to a region resembling the homeodomain. The homeoboxes of the Pou group of proteins are the least closely related to the original group, and thus comprise the farthest extension of the family.

**Figure 22.23** The homeodomain may be the sole DNA-binding motif in a transcriptional regulator or may be combined with other motifs. It represents a discrete (60 residue) part of the protein.

The homeodomain is responsible for binding to DNA, and experiments to swap homeodomains between proteins suggest that the specificity of DNA recognition lies within the homeodomain, but (like the situation with phage repressors) no simple code relating protein and DNA sequences can be deduced. The C-terminal region of the homeodomain shows homology with the helix-turn-helix motif of prokaryotic repressors. We recall from *Molecular Biology 3.12.12 Repressor uses a helix-turn-helix motif to bind DNA* that the  $\lambda$  repressor has a "recognition helix" ( $\alpha$ -helix-3) that makes contacts in the major groove of DNA, while the other helix ( $\alpha$ -helix-2) lies at an angle across the DNA. The homeodomain can be organized into three potential helical regions; the sequences of three examples are compared in **Figure 22.24**. The best conserved part of the sequence lies in the third helix. The difference between these structures and the prokaryotic repressor structures lies in the length of the helix that recognizes DNA, helix-3, which is 17 amino acids long in the homeodomain, compared to 9 residues long in the  $\lambda$  repressor.

**Figure 22.24** The homeodomain of the *Antennapedia* gene represents the major group of genes containing homeoboxes in *Drosophila*; *engrailed* (*en*) represents another type of homeotic gene; and the mammalian factor Oct-2 represents a distantly related group of transcription factors. The homeodomain is conventionally numbered from 1 to 60. It starts with the N-terminal arm, and the three helical regions occupy residues 10-22, 28-38, and 42-58. Amino acids in red are conserved in all three examples.

The structure of the homeodomain of the *D. melanogaster* Engrailed protein is represented schematically in **Figure 22.25**. Helix 3 binds in the major groove of DNA and makes the majority of the contacts between protein and nucleic acid. Many of the contacts that orient the helix in the major groove are made with the phosphate backbone, so they are not specific for DNA sequence. They lie largely on one face of the double helix, and flank the bases with which specific contacts are made. The remaining contacts are made by the N-terminal arm of the homeodomain, the sequence that just precedes the first helix. It projects into the minor groove. So the N-terminal and C-terminal regions of the homeodomain are primarily responsible for contacting DNA (678).

**Figure 22.25** Helix 3 of the homeodomain binds in the major groove of DNA, with helices 1 and 2 lying outside the double helix. Helix 3 contacts both the phosphate backbone and specific bases. The N-terminal arm lies in the minor groove, and makes additional contacts.

A striking demonstration of the generality of this model derives from a comparison of the crystal structure of the homeodomain of engrailed with that of the  $\alpha 2$  mating protein of yeast. The DNA-binding domain of this protein resembles a homeodomain, and can form three similar helices: its structure in the DNA groove can be superimposed almost exactly on that of the engrailed homeodomain. These similarities suggest that all homeodomains bind to DNA in the same manner. This means that a relatively small number of residues in helix-3 and in the N-terminal arm are responsible for specificity of contacts with DNA (for review see 239).

One group of homeodomain-containing proteins is the set of Hox proteins (see **Figure 31.39**). They bind to DNA with rather low sequence specificity, and it has been puzzling how these proteins can have different specificities. It turns out that Hox proteins often bind to DNA as heterodimers with a partner (called Exd in flies and Pbx in vertebrates). The heterodimer has a more restricted specificity *in vitro* than an individual Hox protein; typically it binds the 10 bp sequence TGATNNATNN. Still this is not enough to account for the differences in the specificities of Hox proteins. A third protein, Hth, which is necessary to localize Exd in the nucleus, also forms part of the complex that binds DNA, and may restrict the binding sites further. But since the same partners (Exd and Hth) are present together with each Hox protein in the trimeric complex, it remains puzzling how each Hox protein has sufficient specificity.

Homeodomain proteins can be either transcriptional activators or repressors. The nature of the factor depends on the other domain(s) – the homeodomain is responsible solely for binding to DNA. The activator or repressor domains both act by influencing the basal apparatus. Activator domains may interact with coactivators that in turn bind to components of the basal apparatus. Repressor domains also interact with the transcription apparatus (that is, they do not act by blocking access to DNA as such). The repressor Eve, for example, interacts directly with TF<sub>II</sub>D (674).

## ACTIVATING TRANSCRIPTION

### 5.22.15 Helix-loop-helix proteins interact by combinatorial association

---

#### Key Terms

The **helix-loop-helix (HLH)** motif is responsible for dimerization of a class of transcription factors called HLH proteins. A bHLH protein has a basic DNA-binding sequence close to the dimerization motif.

A **bHLH protein** has a basic DNA-binding region adjacent to the helix-loop-helix motif.

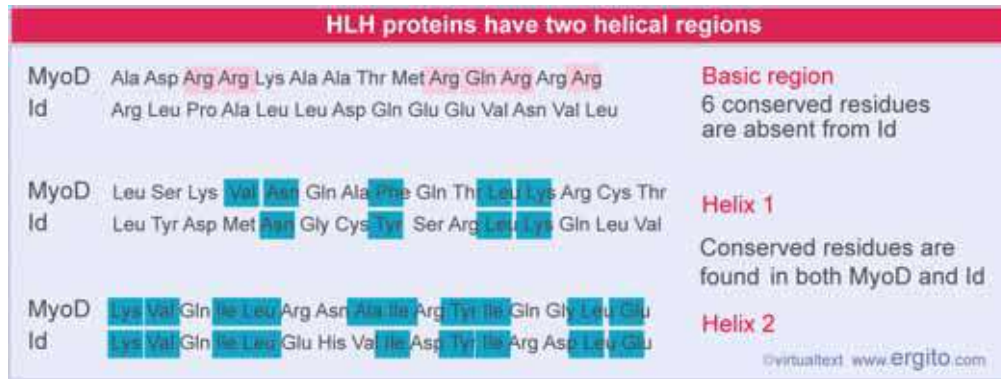

#### Key Concepts

- Helix-loop-helix proteins have a motif of 40-50 amino acids that comprises two amphipathic  $\alpha$ -helices of 15-16 residues separated by a loop.
- The helices are responsible for dimer formation.
- bHLH proteins have a basic sequence adjacent to the HLH motif that is responsible for binding to DNA.
- Class A bHLH proteins are ubiquitously expressed. Class B bHLH proteins are tissue specific.
- A class B protein usually forms a heterodimer with a class A protein.
- HLH proteins that lack the basic region prevent a bHLH partner in a heterodimer from binding to DNA.
- HLH proteins form combinatorial associations that may be changed during development by the addition or removal of specific proteins.

---

Two common features in DNA-binding proteins are the presence of helical regions that bind DNA, and the ability of the protein to dimerize. Both features are represented in the group of **helix-loop-helix** proteins that share a common type of sequence motif: a stretch of 40-50 amino acids contains two amphipathic  $\alpha$ -helices separated by a linker region (the loop) of varying length. (An amphipathic helix forms two faces, one presenting hydrophobic amino acids, the other presenting charged amino acids.) The proteins in this group form both homodimers and heterodimers by means of interactions between the hydrophobic residues on the corresponding faces of the two helices (675). The helical regions are 15-16 amino acids long, and each contains several conserved residues. Two examples are compared in **Figure 22.26**. The ability to form dimers resides with these amphipathic helices, and is common to all HLH proteins. The loop is probably important only for allowing the freedom for the two helical regions to interact independently of one another.

**Figure 22.26** All HLH proteins have regions corresponding to helix 1 and helix 2, separated by a loop of 10-24 residues. Basic HLH proteins have a region with conserved positive charges immediately adjacent to helix 1.

Most HLH proteins contain a region adjacent to the HLH motif itself that is highly basic, and which is needed for binding to DNA. There are ~6 conserved residues in a stretch of 15 amino acids (see **Figure 22.26**). Members of the group with such a region are called **bHLH proteins**. A dimer in which both subunits have the basic region can bind to DNA. The HLH domains probably correctly orient the two basic regions contributed by the individual subunits.

The bHLH proteins fall into two general groups. Class A consists of proteins that are ubiquitously expressed, including mammalian E12/E47. Class B consists of proteins that are expressed in a tissue-specific manner, including mammalian MyoD, myogenin, and Myf-5 (a group of activators that are involved in myogenesis [muscle formation]). A common *modus operandi* for a tissue-specific bHLH protein is to form a heterodimer with a ubiquitous partner. There is also a group of gene products that specify development of the nervous system in *D. melanogaster* (where *Ac-S* is the tissue-specific component and *da* is the ubiquitous component). The Myc proteins (which are the cellular counterparts of oncogene products and are involved in growth regulation) form a separate class of bHLH proteins, whose partners and targets are different.

Dimers formed from bHLH proteins differ in their abilities to bind to DNA. For example, E47 homodimers, E12-E47 heterodimers, and MyoD-E47 heterodimers all form efficiently and bind strongly to DNA; E12 homodimerizes well but binds DNA poorly, while MyoD homodimerizes only poorly. So both dimer formation and DNA binding may represent important regulatory points. At this juncture, it is possible to define groups of HLH proteins whose members form various pairwise combinations, but not to predict from the sequences the strengths of dimer formation or DNA binding. All of the dimers in this group that bind DNA recognize the same consensus sequence, but we do not know yet whether different homodimers and heterodimers have preferences for slightly different target sites that are related to their functions.

Differences in DNA-binding result from properties of the region in or close to the HLH motif; for example, E12 differs from E47 in possessing an inhibitory region just by the basic region, which prevents DNA binding by homodimers. Some HLH proteins lack the basic region and/or contain proline residues that appear to disrupt its function. The example of the protein Id is shown in **Figure 22.26**. Proteins of this type have the same capacity to dimerize as bHLH proteins, but a dimer that contains

one subunit of this type can no longer bind to DNA specifically. This is a forceful demonstration of the importance of doubling the DNA-binding motif in DNA-binding proteins (670; 671; 675).

The importance of the distinction between the nonbasic HLH and bHLH proteins is suggested by the properties of two pairs of HLH proteins: the *da-Ac-S/emc* pair and the MyoD/Id pair. A model for their functions in forming a regulatory network is illustrated in **Figure 22.27**.

**Figure 22.27** An HLH dimer in which both subunits are of the bHLH type can bind DNA, but a dimer in which one subunit lacks the basic region cannot bind DNA.

In *D. melanogaster*, the gene *emc* (*extramacrochaetae*) is required to establish the normal spatial pattern of adult sensory organs. It functions by *suppressing* the functions of several genes, including *da* (*daughterless*) and the *achaete-scute* complex (*Ac-S*). *Ac-S* and *da* are genes of the bHLH type. The suppressor *emc* codes for an HLH protein that lacks the basic region. We suppose that, in the absence of *emc* function, the *da* and *Ac-S* proteins form dimers that activate transcription of appropriate target genes, but the production of *emc* protein causes the formation of heterodimers that cannot bind to DNA. So production of *emc* protein in the appropriate cells is necessary to suppress the function of *Ac-S/da*.

The formation of muscle cells is triggered by a change in the transcriptional program that requires several bHLH proteins, including MyoD. MyoD is produced specifically in myogenic cells; and, indeed, overexpression of MyoD in certain other cells can induce them to commence a myogenic program. The trigger for muscle differentiation is probably a heterodimer consisting of MyoD-E12 or MyoD-E47, rather than a MyoD homodimer. Before myogenesis begins, a member of the nonbasic HLH type, the Id protein, may bind to MyoD and/or E12 and E47 to form heterodimers that cannot bind to DNA. It binds to E12/E47 better than to MyoD, and so might function by sequestering the ubiquitous bHLH partner. Overexpression of Id can prevent myogenesis. So the removal of Id could be the trigger that releases

MyoD to initiate myogenesis (668; 669; for review see 236).

A bHLH activator such as MyoD can be controlled in several ways. It is prevented from binding to DNA when it is sequestered by an HLH partner such as Id. It can activate transcription when bound to bHLH partner such as E12 or E47. It can also act as a site-specific repressor when bound to another partner; the bHLH protein MyoR forms a MyoD-MyoR dimer in proliferating myoblasts that represses transcription (at the same target loci at which MyoD-E12/E47 activate transcription).

The behavior of the HLH proteins therefore illustrates two general principles of transcriptional regulation. A small number of proteins form combinatorial associations. Particular combinations have different functions with regard to DNA binding and transcriptional regulation. Differentiation may depend either on the presence or on the removal of particular partners.

## ACTIVATING TRANSCRIPTION

### 5.22.16 Leucine zippers are involved in dimer formation

#### Key Terms

The **leucine zipper** is a dimerization motif adjacent to a basic DNA-binding region that is found in a class of transcription factors.

A **bZIP** protein has a basic DNA-binding region adjacent to a leucine zipper dimerization motif.

#### Key Concepts

- The leucine zipper is an amphipathic helix that dimerizes.
- The zipper is adjacent to a basic region that binds DNA.
- Dimerization forms the bZIP motif in which the two basic regions symmetrically bind inverted repeats in DNA.

Interactions between proteins are a common theme in building a transcription complex, and a motif found in several activators (and other proteins) is involved in both homo- and heteromeric interactions. The **leucine zipper** is a stretch of amino acids rich in leucine residues that provide a dimerization motif. Dimer formation itself has emerged as a common principle in the action of proteins that recognize specific DNA sequences, and in the case of the leucine zipper, its relationship to DNA binding is especially clear, because we can see how dimerization juxtaposes the DNA-binding regions of each subunit. The reaction is depicted diagrammatically in **Figure 22.28** (673).

**Figure 22.28** The basic regions of the bZIP motif are held together by the dimerization at the adjacent zipper region when the hydrophobic faces of two leucine zippers interact in parallel orientation.

An amphipathic  $\alpha$ -helix has a structure in which the hydrophobic groups (including leucine) face one side, while charged groups face the other side. A leucine zipper forms an amphipathic helix in which the leucines of the zipper on one protein could protrude from the  $\alpha$ -helix and interdigitate with the leucines of the zipper of another protein in parallel to form a coiled coil. The two right-handed helices wind around each other, with 3.5 residues per turn, so the pattern repeats integrally every 7 residues.

How is this structure related to DNA binding? The region adjacent to the leucine repeats is highly basic in each of the zipper proteins, and could comprise a DNA-binding site. The two leucine zippers in effect form a Y-shaped structure, in which the zippers comprise the stem, and the two basic regions stick out to form the arms that bind to DNA. This is known as the **bZIP** structural motif. It explains why the target sequences for such proteins are inverted repeats with no separation (676).

Zippers may be used to sponsor formation of homodimers or heterodimers. They are lengthy motifs. Leucine (or another hydrophobic amino acid) occupies every seventh residue in the potential zipper. There are 4 repeats of the zipper (Leu-X<sub>6</sub>) in the protein C/EBP (a factor that binds as a dimer to both the CAAT box and the SV40 core enhancer), and 5 repeats in the factors Jun and Fos (which form the heterodimeric activator, AP1).

AP1 was originally identified by its binding to a DNA sequence in the SV40 enhancer (see **Figure 21.24**). The active preparation of AP1 includes several polypeptides. A major component is Jun, the product of the gene *c-jun*, which was identified by its relationship with the oncogene *v-jun* carried by an avian sarcoma virus (see *Molecular Biology 6.30.18 Oncoproteins may regulate gene expression*). The mouse genome contains a family of related genes, *c-jun* (the original isolate) and *junB* and *junD* (identified by sequence homology with *jun*). There are considerable sequence similarities in the three Jun proteins; they have leucine zippers that can interact to form homodimers or heterodimers.

The other major component of AP1 is the product of another gene with an oncogenic counterpart. The *c-fos* gene is the cellular homologue to the oncogene *v-fos* carried by a murine sarcoma virus. Expression of *c-fos* activates genes whose promoters or enhancers possess an AP1 target site. The *c-fos* product is a nuclear phosphoprotein that is one of a group of proteins. The others are described as Fos-related antigens (FRA); they constitute a family of Fos-like proteins.

Fos also has a leucine zipper. Fos cannot form homodimers, but can form a heterodimer with Jun. A leucine zipper in each protein is required for the reaction. The ability to form dimers is a crucial part of the interaction of these factors with DNA. Fos cannot by itself bind to DNA, possibly because of its failure to form a dimer. But the Jun-Fos heterodimer can bind to DNA with same target specificity as the Jun-Jun dimer; and this heterodimer binds to the AP1 site with an affinity  $\sim 10\times$  that of the Jun homodimer.

## ACTIVATING TRANSCRIPTION

### 5.22.17 Summary

---

Transcription factors include basal factors, activators, and coactivators. Basal factors interact with RNA polymerase at the startpoint. Activators bind specific short response elements (REs) located in promoters or enhancers. Activators function by making protein-protein interactions with the basal apparatus. Some activators interact directly with the basal apparatus; others require coactivators to mediate the interaction. Activators often have a modular construction, in which there are independent domains responsible for binding to DNA and for activating transcription. The main function of the DNA-binding domain may be to tether the activating domain in the vicinity of the initiation complex. Some response elements are present in many genes and are recognized by ubiquitous factors; others are present in a few genes and are recognized by tissue-specific factors.

Promoters for RNA polymerase II contain a variety of short *cis*-acting elements, each of which is recognized by a *trans*-acting factor. The *cis*-acting elements are located upstream of the TATA box and may be present in either orientation and at a variety of distances with regard to the startpoint. The upstream elements are recognized by activators that interact with the basal transcription complex to determine the efficiency with which the promoter is used. Some activators interact directly with components of the basal apparatus; others interact via intermediaries called coactivators. The targets in the basal apparatus are the TAFs of TF<sub>II</sub>D, or TF<sub>II</sub>B or TF<sub>II</sub>A. The interaction stimulates assembly of the basal apparatus.

Several groups of transcription factors have been identified by sequence homologies. The homeodomain is a 60 residue sequence found in genes that regulate development in insects and worms and in mammalian transcription factors. It is related to the prokaryotic helix-turn-helix motif and provides the motif by which the factors bind to DNA.

Another motif involved in DNA-binding is the zinc finger, which is found in proteins that bind DNA or RNA (or sometimes both). A finger has cysteine residues that bind zinc. One type of finger is found in multiple repeats in some transcription factors; another is found in single or double repeats in others.

Steroid receptors were the first members identified of a group of transcription factors in which the protein is activated by binding a small hydrophobic hormone. The activated factor becomes localized in the nucleus, and binds to its specific response element, where it activates transcription. The DNA-binding domain has zinc fingers. The receptors are homodimers or heterodimers. The homodimers all recognize palindromic response elements with the same consensus sequence; the difference between the response elements is the spacing between the inverted repeats. The heterodimers recognize direct repeats, again being distinguished by the spacing between the repeats. The DNA-binding motif of these receptors includes two zinc fingers; the first determines which consensus sequence is recognized, and the second responds to the spacing between the repeats.

The leucine zipper contains a stretch of amino acids rich in leucine that are involved

in dimerization of transcription factors. An adjacent basic region is responsible for binding to DNA.

HLH (helix-loop-helix) proteins have amphipathic helices that are responsible for dimerization, adjacent to basic regions that bind to DNA. bHLH proteins have a basic region that binds to DNA, and fall into two groups: ubiquitously expressed and tissue-specific. An active protein is usually a heterodimer between two subunits, one from each group. When a dimer has one subunit that does not have the basic region, it fails to bind DNA, so such subunits can prevent gene expression. Combinatorial associations of subunits form regulatory networks.

Many transcription factors function as dimers, and it is common for there to be multiple members of a family that form homodimers and heterodimers. This creates the potential for complex combinations to govern gene expression. In some cases, a family includes inhibitory members, whose participation in dimer formation prevents the partner from activating transcription.

## CONTROLLING CHROMATIN STRUCTURE

### 5.23.1 Introduction

---

#### Key Terms

**Epigenetic** changes influence the phenotype without altering the genotype. They consist of changes in the properties of a cell that are inherited but that do not represent a change in genetic information.

A **prion** is a proteinaceous infectious agent, which behaves as an inheritable trait, although it contains no nucleic acid. Examples are PrP<sup>Sc</sup>, the agent of scrapie in sheep and bovine spongiform encephalopathy, and Psi, which confers an inherited state in yeast.

---

When transcription is treated in terms of interactions involving DNA and individual transcription factors and RNA polymerases, we get an accurate description of the events that occur *in vitro*, but this lacks an important feature of transcription *in vivo*. The cellular genome is organized as nucleosomes, but initiation of transcription generally is prevented if the promoter region is packaged into nucleosomes. In this sense, histones function as generalized repressors of transcription (a rather old idea), although we see in this Chapter that they are also involved in more specific interactions. Activation of a gene requires changes in the state of chromatin: the essential issue is how the transcription factors gain access to the promoter DNA.

Local chromatin structure is an integral part of controlling gene expression. Genes may exist in either of two structural conditions. Genes are found in an "active" state only in the cells in which they are expressed. The change of structure precedes the act of transcription, and indicates that the gene is "transcribable." This suggests that acquisition of the "active" structure must be the first step in gene expression. Active genes are found in domains of euchromatin with a preferential susceptibility to nucleases (see *Molecular Biology 5.20.16 Domains define regions that contain active genes*). Hypersensitive sites are created at promoters before a gene is activated (see *Molecular Biology 5.20.15 DNAase hypersensitive sites change chromatin structure*).

More recently it has turned out that there is an intimate and continuing connection between initiation of transcription and chromatin structure. Some activators of gene transcription directly modify histones; in particular, acetylation of histones is associated with gene activation. Conversely, some repressors of transcription function by deacetylating histones. So a reversible change in histone structure in the vicinity of the promoter is involved in the control of gene expression. This may be part of the mechanism by which a gene is maintained in an active or inactive state.

The mechanisms by which local regions of chromatin are maintained in an inactive (silent) state are related to the means by which an individual promoter is repressed. The proteins involved in the formation of heterochromatin act on chromatin via the histones, and modifications of the histones may be an important feature in the interaction. Once established, such changes in chromatin may persist through cell divisions, creating an **epigenetic** state in which the properties of a gene are

determined by the self-perpetuating structure of chromatin. The name epigenetic reflects the fact that a gene may have an inherited condition (it may be active or may be inactive) which does not depend on its sequence. Yet a further insight into epigenetic properties is given by the self-perpetuating structures of **prions** (proteinaceous infectious agents).

**CONTROLLING CHROMATIN STRUCTURE****5.23.2 Chromatin can have alternative states****Key Concepts**

- Chromatin structure is stable and cannot be changed by altering the equilibrium of transcription factors and histones.

Two types of model have been proposed to explain how the state of expression of DNA is changed: equilibrium and discontinuous change-of-state.

**Figure 23.1** shows the equilibrium model. Here the only pertinent factor is the concentration of the repressor or activator protein, which drives an equilibrium between free form and DNA-bound form. When the concentration of the protein is high enough, its DNA-binding site is occupied, and the state of expression of the DNA is affected. (Binding might either repress or activate any particular target sequence.) This type of model explains the regulation of transcription in bacterial cells, where gene expression is determined exclusively by the actions of individual repressor and activator proteins (see *Molecular Biology 3.10 The operon*). Whether a bacterial gene is transcribed can be predicted from the sum of the concentrations of the various factors that either activate or repress the individual gene. Changes in these concentrations *at any time* will change the state of expression accordingly. In most cases, the protein binding is cooperative, so that once the concentration becomes high enough, there is a rapid association with DNA, resulting in a switch in gene expression.

**Figure 23.1** In an equilibrium model, the state of a binding site on DNA depends on the concentration of the protein that binds to it.

A different situation applies with eukaryotic chromatin. Early *in vitro* experiments showed that either an active or inactive state can be established, but this is not affected by the subsequent addition of other components. The transcription factor TF<sub>m</sub>A, required for RNA polymerase III to transcribe 5S rRNA genes, cannot activate its target genes *in vitro* if they are complexed with histones. However, if the factor is presented with free DNA, it forms a transcription complex, and then the addition of histones does not prevent the gene from remaining active. Once the factor has bound, it remains at the site, allowing a succession of RNA polymerase molecules to initiate transcription. Whether the factor or histones get to the control

site first may be the critical factor (680; for review see 227; 228).

**Figure 23.2** illustrates the two types of condition that can exist at a eukaryotic promoter. In the inactive state, nucleosomes are present, and they prevent basal factors and RNA polymerase from binding. In the active state, the basal apparatus occupies the promoter, and histone octamers cannot bind to it. Each type of state is stable.

**Figure 23.2** If nucleosomes form at a promoter, transcription factors (and RNA polymerase) cannot bind. If transcription factors (and RNA polymerase) bind to the promoter to establish a stable complex for initiation, histones are excluded.

A similar situation is seen with the TF<sub>II</sub>D complex at promoters for RNA polymerase II. A plasmid containing an adenovirus promoter can be transcribed *in vitro* by RNA polymerase II in a reaction that requires TF<sub>II</sub>D and other transcription factors. The template can be assembled into nucleosomes by the addition of histones. If the histones are added *before* the TF<sub>II</sub>D, transcription cannot be initiated. But if the TF<sub>II</sub>D is added first, the template still can be transcribed in its chromatin form. So TF<sub>II</sub>D can recognize free DNA, but either cannot recognize or cannot function on nucleosomal DNA. Only the TF<sub>II</sub>D must be added before the histones; the other transcription factors and RNA polymerase can be added later. This suggests that binding of TF<sub>II</sub>D to the promoter creates a structure to which the other components of the transcription apparatus can bind (681).

It is important to note that these *in vitro* systems use disproportionate quantities of components, which may create unnatural situations. The major importance of these results, therefore, is not that they demonstrate the mechanism used *in vivo*, but that they establish the principle that *transcription factors or nucleosomes may form stable structures that cannot be changed merely by changing the equilibrium with free*

*components.*

## CONTROLLING CHROMATIN STRUCTURE

### 5.23.3 Chromatin remodeling is an active process

---

#### Key Terms

**Chromatin remodeling** describes the energy-dependent displacement or reorganization of nucleosomes that occurs in conjunction with activation of genes for transcription.

**SWI/SNF** is a chromatin remodeling complex; it uses hydrolysis of ATP to change the organization of nucleosomes.

#### Key Concepts

- There are several chromatin remodeling complexes that use energy provided by hydrolysis of ATP.
- The SWI/SNF, RSC, and NURF complexes all are very large; there are some common subunits.
- A remodeling complex does not itself have specificity for any particular target site, but must be recruited by a component of the transcription apparatus.

---

The general process of inducing changes in chromatin structure is called **chromatin remodeling**. This consists of mechanisms for displacing histones that depend on the input of energy. Many protein-protein and protein-DNA contacts need to be disrupted to release histones from chromatin. There is no free ride: the energy must be provided to disrupt these contacts. **Figure 23.3** illustrates the principle of a *dynamic model* by a factor that hydrolyzes ATP. When the histone octamer is released from DNA, other proteins (in this case transcription factors and RNA polymerase) can bind.

**Figure 23.3** The dynamic model for transcription of chromatin relies upon factors that can use energy provided by hydrolysis of ATP to displace nucleosomes from specific DNA sequences.

**Figure 23.4** summarizes the types of remodeling changes in chromatin that can be characterized *in vitro*:

**Figure 23.4** Remodeling complexes can cause nucleosomes to slide along DNA, can displace nucleosomes from DNA, or can reorganize the spacing between nucleosomes.

- Histone octamers may slide along DNA, changing the relationship between the nucleic acid and protein. This alters the position of a particular sequence on the nucleosomal surface.
- The spacing between histone octamers may be changed, again with the result that the positions of individual sequences are altered relative to protein.
- And the most extensive change is that an octamer(s) may be displaced entirely from DNA to generate a nucleosome-free gap.

The most common use of chromatin remodeling is to change the organization of nucleosomes at the promoter of a gene that is to be transcribed. This is required to allow the transcription apparatus to gain access to the promoter. The remodeling most often takes the form of displacing one or more histone octamers. This can be detected by a change in the micrococcal nuclease ladder where protection against cleavage has been lost. It often results in the creation of a site that is hypersensitive to cleavage with DNAase I (see *Molecular Biology 5.20.15 DNAase hypersensitive sites change chromatin structure*). Sometimes there are less dramatic changes, for example, involving a change in rotational positioning of a single nucleosome; this may be detected by loss of the DNAaseI 10 base ladder. So changes in chromatin structure may extend from altering the positions of nucleosomes to removing them altogether (for review see 234; 237).

Chromatin remodeling is undertaken by large complexes that use ATP hydrolysis to provide the energy for remodeling. The heart of the remodeling complex is its ATPase subunit. Remodeling complexes are usually classified according to the type of ATPase subunit – those with related ATPase subunits are considered to belong to the same family (usually some other subunits are common also). **Figure 23.5** keeps the names straight (for review see 3007). The two major types of complex are SWI/SNF and ISW (ISW stands for imitation SWI). Yeast has two complexes of each type. Complexes of both types are also found in fly and in Man (for review see 1969; 2413). Each type of complex may undertake a different range of remodeling activities (for review see 3252; 3432).

There are several types of remodeling complexes			
Type of complex	SWI/SNF	ISW	Other
Yeast	SWI/SNF RSC	ISW1 ISW2	
Fly	dSWI/SNF (Brahma)	NURF CHRAC ACF	
Human	hSWI/SNF	RSF hACF/WCFR hCHRAC	NuRD
Frog			Mi-2

©virtualtext www.ergito.com

**Figure 23.5** Remodeling complexes can be classified by their ATPase subunits.

**SWI/SNF** was the first remodeling complex to be identified. Its name reflects the fact that many of its subunits are coded by genes originally identified by *SWI* or *SNF* mutations in *S. cerevisiae*. Mutations in these loci are pleiotropic, and the range of defects is similar to those shown by mutants that have lost the CTD tail of RNA polymerase II. These mutations also show genetic interactions with mutations in genes that code for components of chromatin, in particular *SIN1*, which codes for a nonhistone protein, and *SIN2*, which codes for histone H3. The *SWI* and *SNF* genes are required for expression of a variety of individual loci (~120 or 2% of *S. cerevisiae* genes are affected). Expression of these loci may require the SWI/SNF complex to remodel chromatin at their promoters (684; 682; 685).

SWI/SNF acts catalytically *in vitro* (1971), and there are only ~150 complexes per yeast cell. All of the genes encoding the SWI/SNF subunits are nonessential, which implies that yeast must also have other ways of remodeling chromatin (1974; 1975). The RSC complex is more abundant and also is essential. It acts at ~ 700 target loci (2495).

SWI/SNF complexes can remodel chromatin *in vitro* without overall loss of histones or can displace histone octamers (1972; 1973). Both types of reaction may pass through the same intermediate in which the structure of the target nucleosome is altered, leading either to reformation of a (remodeled) nucleosome on the original DNA or to displacement of the histone octamer to a different DNA molecule. The SWI/SNF complex alters nucleosomal sensitivity to DNAase I at the target site, and induces changes in protein-DNA contacts that persist after it has been released from the nucleosomes (688; 694). The SWI2 subunit is the ATPase that provides the energy for remodeling by SWI/SNF.

There are many contacts between DNA and a histone octamer – 14 are identified in the crystal structure. All of these contacts must be broken for an octamer to be released or for it to move to a new position. How is this achieved? Some obvious mechanisms can be excluded because we know that single-stranded DNA is not generated during remodeling (and there are no helicase activities associated with the

complexes). Present thinking is that remodeling complexes in the SWI and ISW classes use the hydrolysis of ATP to twist DNA on the nucleosomal surface. Indirect evidence suggests that this creates a mechanical force that allows a small region of DNA to be released from the surface and then repositioned (3008).

One important reaction catalyzed by remodeling complexes involves nucleosome sliding. It was first observed that the ISW family affects nucleosome positioning without displacing octamers (1974; 1975). This is achieved by a sliding reaction, in which the octamer moves along DNA. Sliding is prevented if the N-terminal tail of histone H4 is removed, but we do not know exactly how the tail functions in this regard (2218). SWI/SNF complexes have the same capacity; the reaction is prevented by the introduction of a barrier in the DNA, which suggests that a sliding reaction is involved, in which the histone octamer moves more or less continuously along DNA without ever losing contact with it (3253).

One puzzle about the action of the SWI/SNF complex is its sheer size. It has 11 subunits with a combined molecular weight  $\sim 2 \times 10^6$ . It dwarfs RNA polymerase and the nucleosome, making it difficult to understand how all of these components could interact with DNA retained on the nucleosomal surface. However, a transcription complex with full activity, called RNA polymerase II holoenzyme, can be found that contains the RNA polymerase itself, all the TF<sub>II</sub> factors except TBP and TF<sub>II</sub>A, and the SWI/SNF complex, which is associated with the CTD tail of the polymerase. In fact, virtually all of the SWI/SNF complex may be present in holoenzyme preparations. This suggests that the remodeling of chromatin and recognition of promoters is undertaken in a coordinated manner by a single complex (689).

## CONTROLLING CHROMATIN STRUCTURE

### 5.23.4 Nucleosome organization may be changed at the promoter

---

#### Key Concepts

- Remodeling complexes are recruited to promoters by sequence-specific activators.
- The factor may be released once the remodeling complex has bound.
- The MMTV promoter requires a change in rotational positioning of a nucleosome to allow an activator to bind to DNA on the nucleosome.

---

How are remodeling complexes targeted to specific sites on chromatin? They do not themselves contain subunits that bind specific DNA sequences. This suggests the model shown in **Figure 23.6** in which they are recruited by activators or (sometimes) by repressors (1864; 1970).

**Figure 23.6** A remodeling complex binds to chromatin via an activator (or repressor).

The interaction between transcription factors and remodeling complexes gives a key insight into their modus operandi. The transcription factor Swi5p activates the *HO* locus in yeast. (Note that Swi5p is not a member of the SWI/SNF complex.) Swi5p enters nuclei toward the end of mitosis and binds to the *HO* promoter. It then recruits SWI/SNF to the promoter. Then Swi5p is released, leaving SWI/SNF at the promoter (1966). This means that a transcription factor can activate a promoter by a "hit and run" mechanism, in which its function is fulfilled once the remodeling complex has bound.

The involvement of remodeling complexes in gene activation was discovered because the complexes are necessary for the ability of certain transcription factors to activate their target genes. One of the first examples was the GAGA factor, which activates the *hsp70* *Drosophila* promoter *in vitro*. Binding of GAGA to four (CT)<sub>n</sub>-rich sites on the promoter disrupts the nucleosomes, creates a hypersensitive

region, and causes the adjacent nucleosomes to be rearranged so that they occupy preferential instead of random positions. Disruption is an energy-dependent process that requires the NURF remodeling complex. The organization of nucleosomes is altered so as to create a boundary that determines the positions of the adjacent nucleosomes (691). During this process, GAGA binds to its target sites and DNA, and its presence fixes the remodeled state.

The *PHO* system was one of the first in which it was shown that a change in nucleosome organization is involved in gene activation (for review see 1976). At the *PHO5* promoter, the bHLH regulator PHO4 responds to phosphate starvation by inducing the disruption of four precisely positioned nucleosomes. This event is independent of transcription (it occurs in a TATA<sup>-</sup> mutant) and independent of replication. There are two binding sites for PHO4 at the promoter, one located between nucleosomes, which can be bound by the isolated DNA-binding domain of PHO4, and the other within a nucleosome, which cannot be recognized. Disruption of the nucleosome to allow DNA binding at the second site is necessary for gene activation. This action requires the presence of the transcription-activating domain. The activator sequence of VP16 can substitute for the PHO4 activator sequence in nucleosome disruption. This suggests that disruption occurs by protein-protein interactions that involve the same region that makes protein-protein contacts to activate transcription (605). In this case, it is not known which remodeling complex is involved in executing the effects.

It is not always the case, however, that nucleosomes must be excluded in order to permit initiation of transcription. Some activators can bind to DNA on a nucleosomal surface. Nucleosomes appear to be precisely positioned at some steroid hormone response elements in such a way that receptors can bind. Receptor binding may alter the interaction of DNA with histones, and even lead to exposure of new binding sites. The exact positioning of nucleosomes could be required either because the nucleosome "presents" DNA in a particular rotational phase or because there are protein-protein interactions between the activators and histones or other components of chromatin. So we have now moved some way from viewing chromatin exclusively as a repressive structure to considering which interactions between activators and chromatin can be required for activation.

The MMTV promoter presents an example of the need for specific nucleosomal organization. It contains an array of 6 partly palindromic sites, each bound by one dimer of hormone receptor (HR), which constitute the HRE. It also has a single binding site for the factor NF1, and two adjacent sites for the factor OTF. HR and NF1 cannot bind simultaneously to their sites in free DNA. **Figure 23.7** shows how the nucleosomal structure controls binding of the factors.

**Figure 23.7** Hormone receptor and NF1 cannot bind simultaneously to the MMTV promoter in the form of linear DNA, but can bind when the DNA is presented on a nucleosomal surface.

The HR protects its binding sites at the promoter when hormone is added, but does not affect the micrococcal nuclease-sensitive sites that mark either side of the nucleosome. This suggests that HR is binding to the DNA on the nucleosomal surface. However, the rotational positioning of DNA on the nucleosome prior to hormone addition allows access to only two of the four sites. Binding to the other two sites requires a change in rotational positioning on the nucleosome. This can be detected by the appearance of a sensitive site at the axis of dyad symmetry (which is in the center of the binding sites that constitute the HRE). NF1 can be footprinted on the nucleosome after hormone induction, so these structural changes may be necessary to allow NF1 to bind, perhaps because they expose DNA and abolish the steric hindrance by which HR blocks NF1 binding to free DNA (687; 690).

## CONTROLLING CHROMATIN STRUCTURE

### 5.23.5 Histone modification is a key event

---

#### Key Terms

**Silencing** describes the repression of gene expression in a localized region, usually as the result of a structural change in chromatin.

**Heterochromatin** describes regions of the genome that are highly condensed, are not transcribed, and are late-replicating. Heterochromatin is divided into two types, which are called constitutive and facultative.

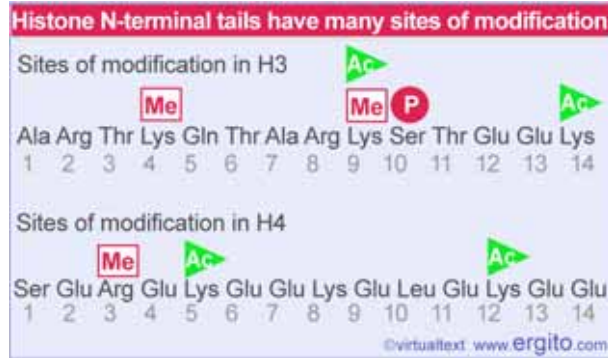

---

Whether a gene is expressed depends on the structure of chromatin both locally (at the promoter) and in the surrounding domain. Chromatin structure correspondingly can be regulated by individual activation events or by changes that affect a wide chromosomal region. The most localized events concern an individual target gene, where changes in nucleosomal structure and organization occur in the immediate vicinity of the promoter. More general changes may affect regions as large as a whole chromosome.

Changes that affect large regions control the potential of a gene to be expressed. The term **silencing** is used to refer to repression of gene activity in a local chromosomal region. The term **heterochromatin** is used to describe chromosomal regions that are large enough to be seen to have a physically more compact structure in the microscope. The basis for both types of change is the same: additional proteins bind to chromatin and either directly or indirectly prevent transcription factors and RNA polymerase from activating promoters in the region.

Changes at an individual promoter control whether transcription is initiated for a particular gene. These changes may be either activating or repressing.

All of these events depend on interactions with histones. Changes in chromatin structure are initiated by modifying the N-terminal tails of the histones, especially H3 and H4. The histone tails consist of the N-terminal 20 amino acids, and extend from the nucleosome between the turns of DNA (see **Figure 20.25** in *Molecular Biology 5.20.8 Organization of the histone octamer*). **Figure 23.8** shows that they can be modified at several sites, by methylation, acetylation, or phosphorylation (see *Molecular Biology 5.20.9 The N-terminal tails of histones are modified*). The modifications reduce positive charge. The histone modifications may directly affect nucleosome structure or create binding sites for the attachment of nonhistone proteins that change the properties of chromatin.

**Figure 23.8** The N-terminal tails of histones H3 and H4 can be acetylated, methylated, or phosphorylated at several positions.

The range of nucleosomes that is targeted for modification can vary. Modification can be a local event, for example, restricted to nucleosomes at the promoter. Or it can be a general event, extending for example to an entire chromosome. **Figure 23.9** shows that there is a general correlation in which acetylation is associated with active chromatin while methylation is associated with inactive chromatin. However, this is not a simple rule, and the particular sites that are modified, as well as combinations of specific modifications may be important, so there are certainly exceptions in which (for example) histones methylated at a certain position are found in active chromatin. Mutations in one of the histone acetylase complexes of yeast have the opposite effect from usual (they prevent silencing of some genes), emphasizing the lack of a uniform effect of acetylation (2228).

**Figure 23.9** Acetylation of H3 and H4 is associated with active chromatin, while methylation is associated with inactive chromatin.

The specificity of the modifications is indicated by the fact that many of the modifying enzymes have individual target sites in specific histones. **Figure 23.10** summarizes the effects of some of the modifications. Most modified sites are subject to only a single type of modification. In some cases, modification of one site may activate or inhibit modification of another site. The idea that combinations of signals may be used to define chromatin types has sometimes been called the *histone code* (for review see 2033).

Histone modification affects the structure and function of chromatin			
Histone	Site	Modification	Function
H3	Lys-4	methylation	chromatin condensation required for DNA methylation
H3	Lys-9	methylation	
"	"	acetylation	
H3	Ser-10	phosphorylation	prevents methylation at Lys-9 telomeric silencing
H3	Lys-14	acetylation	
H3	Lys-79	methylation	
H4	Arg-3	methylation	nucleosome assembly fly X activation
H4	Lys-5	acetylation	
H4	Lys-12	acetylation	
H4	Lys-16	acetylation

## CONTROLLING CHROMATIN STRUCTURE

### 5.23.6 Histone acetylation occurs in two circumstances

---

#### Key Concepts

- Histone acetylation occurs transiently at replication.
  - Histone acetylation is associated with activation of gene expression.
- 

All the core histones can be acetylated. The major targets for acetylation are lysines in the N-terminal tails of histones H3 and H4. Acetylation occurs in two different circumstances:

- during DNA replication;
- and when genes are activated.

When chromosomes are replicated, during the S phase of the cell cycle, histones are transiently acetylated (1980; for review see 1978). **Figure 23.11** shows that this acetylation occurs before the histones are incorporated into nucleosomes. We know that histones H3 and H4 are acetylated at the stage when they are associated with one another in the H<sub>3</sub><sub>2</sub>·H<sub>4</sub><sub>2</sub> tetramer. The tetramer is then incorporated into nucleosomes. Quite soon after, the acetyl groups are removed.

**Figure 23.11** Acetylation at replication occurs on histones before they are incorporated into nucleosomes.

The importance of the acetylation is indicated by the fact that preventing acetylation of both histones H3 and H4 during replication causes loss of viability in yeast (1977). The two histones are redundant as substrates, since yeast can manage perfectly well so long as they can acetylate either one of these histones during S phase. There are two possible roles for the acetylation: it could be needed for the histones to be recognized by factors that incorporate them into nucleosomes; or it could be required for the assembly and/or structure of the new nucleosome.

The factors that are known to be involved in chromatin assembly do not distinguish between acetylated and nonacetylated histones, suggesting that the modification is more likely to be required for subsequent interactions (1979). It has been thought for a long time that acetylation might be needed to help control protein-protein interactions that occur as histones are incorporated into nucleosomes. Some evidence for such a role is that the yeast SAS histone acetylase complex binds to chromatin assembly complexes at the replication fork, where it acetylates <sup>16</sup>Lys of histone H4 (2008; 2007). This may be part of the system that establishes the histone acetylation patterns after replication.

Outside of S phase, acetylation of histones in chromatin is generally correlated with the state of gene expression. The correlation was first noticed because histone acetylation is increased in a domain containing active genes, and acetylated chromatin is more sensitive to DNAase I and (possibly) to micrococcal nuclease. **Figure 23.12** shows that this involves the acetylation of histone tails in nucleosomes. We now know that this occurs largely because of acetylation of the nucleosomes in the vicinity of the promoter when a gene is activated.

**Figure 23.12** Acetylation associated with gene activation occurs by directly modifying histones in nucleosomes.

In addition to events at individual promoters, widescale changes in acetylation occur on sex chromosomes. This is part of the mechanism by which the activities of genes on the X chromosome are altered to compensate for the presence of two X chromosomes in one species but only one X chromosome (in addition to the Y chromosome) in the other species (see *Molecular Biology 5.23.17 X chromosomes undergo global changes*). The inactive X chromosome in female mammals has underacetylated H4. The super-active X chromosome in *Drosophila* males has increased acetylation of H4 (616). This suggests that the presence of acetyl groups may be a prerequisite for a less condensed, active structure. In male *Drosophila*, the X chromosome is acetylated specifically at  $^{16}\text{Lys}$  of histone H4. The HAT that is responsible is an enzyme called MOF that is recruited to the chromosome as part of a large protein complex (1229). This "dosage compensation" complex is responsible for introducing general changes in the X chromosome that enable it to be more highly expressed. The increased acetylation is only one of its activities.

## CONTROLLING CHROMATIN STRUCTURE

### 5.23.7 Acetylases are associated with activators

---

#### Key Terms

**Histone acetyltransferase (HAT)** enzymes modify histones by addition of acetyl groups; some transcriptional coactivators have HAT activity.

A **deacetylase** is an enzyme that removes acetyl groups from proteins.

**Histone deacetyltransferase (HDAC)** enzymes remove acetyl groups from histones; they may be associated with repressors of transcription.

#### Key Concepts

- Deacetylated chromatin may have a more condensed structure.
- Transcription activators are associated with histone acetylase activities in large complexes.
- Histone acetylases vary in their target specificity.
- Acetylation could affect transcription in a quantitative or qualitative way.

---

Acetylation is reversible. Each direction of the reaction is catalyzed by a specific type of enzyme. Enzymes that can acetylate histones are called **histone acetyltransferases** or **HATs**; the acetyl groups are removed by histone **deacetylases** or **HDACs**. There are two groups of HAT enzymes: group A describes those that are involved with transcription; group B describes those involved with nucleosome assembly.

Two inhibitors have been useful in analyzing acetylation. Trichostatin and butyric acid inhibit histone deacetylases, and cause acetylated nucleosomes to accumulate. The use of these inhibitors has supported the general view that acetylation is associated with gene expression; in fact, the ability of butyric acid to cause changes in chromatin resembling those found upon gene activation was one of the first indications of the connection between acetylation and gene activity.

The breakthrough in analyzing the role of histone acetylation was provided by the characterization of the acetylating and deacetylating enzymes, and their association with other proteins that are involved in specific events of activation and repression. A basic change in our view of histone acetylation was caused by the discovery that HATs are not necessarily dedicated enzymes associated with chromatin: rather it turns out that known activators of transcription have HAT activity.

The connection was established when the catalytic subunit of a group A HAT was identified as a homologue of the yeast regulator protein GCN5. Then it was shown that GCN5 itself has HAT activity (with histones H3 and H4 as substrates). GCN5 is part of an adaptor complex that is necessary for the interaction between certain enhancers and their target promoters. Its HAT activity is required for activation of

the target gene (693).

This enables us to redraw our picture for the action of coactivators as shown in **Figure 23.13**, where RNA polymerase is bound at a hypersensitive site and coactivators are acetylating histones on the nucleosomes in the vicinity (692). Many examples are now known of interactions of this type.

**Figure 23.13** Coactivators may have HAT activities that acetylate the tails of nucleosomal histones.

GCN5 leads us into one of the most important acetylase complexes. In yeast, GCN5 is part of the 1.8 MDa SAGA complex, which contains several proteins that are involved in transcription (for review see 1969). Among these proteins are several TAF<sub>II</sub>s (696). Also, the TAF<sub>145</sub> subunit of TF<sub>II</sub>D is an acetylase. There are some functional overlaps between TF<sub>II</sub>D and SAGA, most notably that yeast can manage with either TAF<sub>145</sub> or GCN5, but is damaged by the deletion of both. This suggests that an acetylase activity is essential for gene expression, but can be provided by either TF<sub>II</sub>D or SAGA (1062). As might be expected from the size of the SAGA complex, acetylation is only one of its functions, although its other functions in gene activation are less well characterized.

One of the first general activators to be characterized as an HAT was p300/CBP. (Actually, p300 and CBP are different proteins, but they are so closely related that they are often referred to as a single type of activity.) p300/CBP is a coactivator that links an activator to the basal apparatus (see **Figure 22.8**). p300/CBP interacts with various activators, including hormone receptors, AP-1 (c-Jun and c-Fos), and MyoD. The interaction is inhibited by the viral regulator proteins adenovirus E1A and SV40 T antigen, which bind to p300/CBP to prevent the interaction with transcription factors; this explains how these viral proteins inhibit cellular transcription. (This inhibition is important for the ability of the viral proteins to contribute to the tumorigenic state; see *Molecular Biology 6.30.18 Oncoproteins may regulate gene*

expression).

p300/CBP acetylates the N-terminal tails of H4 in nucleosomes. Another coactivator, called PCAF, preferentially acetylates H3 in nucleosomes. p300/CBP and PCAF form a complex that functions in transcriptional activation. In some cases yet another HAT is involved: the coactivator ACTR, which functions with hormone receptors, is itself an HAT that acts on H3 and H4, and also recruits both p300/CBP and PCAF to form a coactivating complex. One explanation for the presence of multiple HAT activities in a coactivating complex is that each HAT has a different specificity, and that multiple different acetylation events are required for activation.

A general feature of acetylation is that an HAT is part of a large complex. **Figure 23.14** shows a simplified model for their behavior. Typically the complex will contain a targeting subunit(s) that determines the binding sites on DNA. This determines the target for the HAT. The complex also contains effector subunits that affect chromatin structure or act directly on transcription. Probably at least some of the effectors require the acetylation event in order to act. Deacetylation, catalyzed by an HDAC, may work in a similar way.

**Figure 23.14** Complexes that modify chromatin structure or activity have targeting subunits that determine their sites of action, HAT or HDAC enzymes that acetylate or deacetylate histones, and effector subunits that have other actions on chromatin or DNA.

Acetylation occurs at both replication (when it is transient) and at transcription (when it is maintained while the gene is active). Is it playing the same role in each case? One possibility is that the important effect is on nucleosome structure. Acetylation may be necessary to "loosen" the nucleosome core. At replication, acetylation of histones could be necessary to allow them to be incorporated into new cores more easily. At transcription, a similar effect could be necessary to allow a related change in structure, possibly even to allow the histone core to be displaced from DNA. Alternatively, acetylation could generate binding sites for other proteins that are required for transcription. In either case, deacetylation would reverse the effect.

Is the effect of acetylation quantitative or qualitative? One possibility is that a certain number of acetyl groups are required to have an effect, and the exact positions at which they occur are largely irrelevant. An alternative is that individual acetylation events have specific effects. We might interpret the existence of complexes containing multiple HAT activities in either way – if individual enzymes have different specificities, we may need multiple activities either to acetylate a sufficient

number of different positions or because the individual events are necessary for different effects upon transcription. At replication, it appears, at least with respect to histone H4, that acetylation at any two of three available positions is adequate, favoring a quantitative model in this case. Where chromatin structure is changed to affect transcription, acetylation at specific positions may be important (see *Molecular Biology 5.23.15 Heterochromatin depends on interactions with histones*).

**CONTROLLING CHROMATIN STRUCTURE****5.23.8 Deacetylases are associated with repressors****Key Concepts**

- Deacetylation is associated with repression of gene activity.
- Deacetylases are present in complexes with repressor activity.

In yeast, mutations in *SIN3* and *Rpd3* behave as though these loci repress a variety of genes. The proteins form a complex with the DNA-binding protein Ume6, which binds to the *URS1* element. The complex represses transcription at the promoters containing *URS1*, as illustrated in **Figure 23.15** (3312). Rpd3 has histone deacetylase activity; we do not know whether the function of Sin3 is just to bring Rpd3 to the promoter or whether it has an additional role in repression.

**Figure 23.15** A repressor complex contains three components: a DNA binding subunit, a corepressor, and a histone deacetylase.

A similar system for repression is found in mammalian cells (3313; 3314). The bHLH family of transcription regulators includes activators that function as heterodimers, including MyoD (see *Molecular Biology 5.22.15 Helix-loop-helix proteins interact by combinatorial association*). It also includes repressors, in particular the heterodimer Mad:Max, where Mad can be any one of a group of closely related proteins. The Mad:Max heterodimer (which binds to specific DNA sites) interacts with a homologue of Sin3 (called mSin3 in mouse and hSin3 in man). mSin3 is part of a repressive complex that includes histone binding proteins and the histone deacetylases HDAC1 and HDAC2. Deacetylase activity is required for repression. The modular nature of this system is emphasized by other means of

employment: a corepressor (SMRT), which enables retinoid hormone receptors to repress certain target genes, functions by binding mSin3, which in turns brings the HDAC activities to the site. Another means of bringing HDAC activities to the site may be a connection with MeCP2, a protein that binds to methylated cytosines (see *Molecular Biology 5.21.19 CpG islands are regulatory targets*).

Absence of histone acetylation is also a feature of heterochromatin. This is true of both constitutive heterochromatin (typically involving regions of centromeres or telomeres) and facultative heterochromatin (regions that are inactivated in one cell although they may be active in another). Typically the N-terminal tails of histones H3 and H4 are not acetylated in heterochromatic regions (for review see 2414).

## CONTROLLING CHROMATIN STRUCTURE

### 5.23.9 Methylation of histones and DNA is connected

---

#### Key Concepts

- Methylation of both DNA and histones is a feature of inactive chromatin.
  - The two types of methylation event may be connected.
- 

Methylation of both histones and DNA is associated with inactivity (for review see 2414). Sites that are methylated in histones include two lysines in the tail of H3 and an arginine in the tail of H4.

Methylation of H3<sup>9</sup>Lys is a feature of condensed regions of chromatin, including heterochromatin as seen in bulk and also smaller regions that are known not to be expressed. The histone methyltransferase enzyme that targets this lysine is called SUV39H1 (2014). (We see the origin of this peculiar name in *Molecular Biology 5.23.14 Some common motifs are found in proteins that modify chromatin*). Its catalytic site has a region called the SET domain. Other histone methyltransferases act on arginine (for review see 2237). In addition, methylation may occur on <sup>79</sup>Lys in the globular core region of H3; this may be necessary for the formation of heterochromatin at telomeres (3215).

Most of the methylation sites in DNA are CpG islands (see *Molecular Biology 5.21.19 CpG islands are regulatory targets*). CpG sequences in heterochromatin are usually methylated. Conversely, it is necessary for the CpG islands located in promoter regions to be unmethylated in order for a gene to be expressed (see *Molecular Biology 5.21.18 Gene expression is associated with demethylation*).

Methylation of DNA and methylation of histones may be connected. Some histone methyltransferase enzymes contain potential binding sites for the methylated CpG doublet, raising the possibility that a methylated DNA sequence may cause a histone methyltransferase to bind. A possible connection in the opposite direction is indicated by the fact that in the fungus *Neurospora*, the methylation of DNA is prevented by a mutation in a gene coding for a histone methylase that acts on <sup>9</sup>Lys of histone H3 (2183). This suggests that methylation of the histone is a signal involved in recruiting the DNA methylase to chromatin. The important point is not the detailed order of events – which remains to be worked out – but the fact that one type of modification can be the trigger for another.

**CONTROLLING CHROMATIN STRUCTURE****5.23.10 Chromatin states are interconverted by modification****Key Concepts**

- Acetylation of histones is associated with gene activation.
- Methylation of DNA and of histones is associated with heterochromatin.

**Figure 23.16** summarizes three types of differences that are found between active chromatin and inactive chromatin:

**Figure 23.16** Acetylation of histones activates chromatin, and methylation of DNA and histones inactivates chromatin.

- Active chromatin is acetylated on the tails of histones H3 and H4.
- Inactive chromatin is methylated on <sup>9</sup>Lys of histone H3.
- Inactive chromatin is methylated on cytosines of CpG doublets.

The reverse types of events occur if we compare the activation of a promoter with the generation of heterochromatin. The actions of the enzymes that modify chromatin

ensure that activating events are mutually exclusive with inactivating events. Methylation of H3<sup>9</sup>Lys and acetylation of H3<sup>14</sup>Lys are mutually antagonistic.

Acetylases and deacetylases may trigger the initiating events. Deacetylation allows methylation to occur, which causes formation of a heterochromatic complex (see *Molecular Biology 5.23.15 Heterochromatin depends on interactions with histones*). Acetylation marks a region as active (see *Molecular Biology 5.23.11 Promoter activation involves an ordered series of events*).

## CONTROLLING CHROMATIN STRUCTURE

### 5.23.11 Promoter activation involves an ordered series of events

---

#### Key Concepts

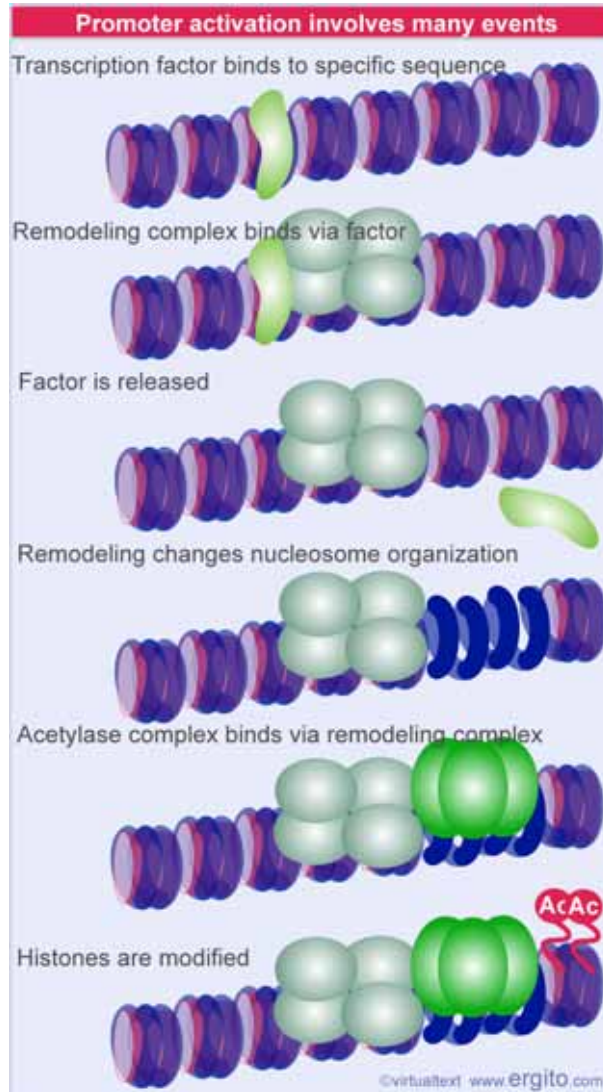

- The remodeling complex may recruit the acetylating complex.
  - Acetylation of histones may be the event that maintains the complex in the activated state.
- 

How are acetylases (or deacetylases) recruited to their specific targets? As we have seen with remodeling complexes, the process is likely to be indirect. A sequence-specific activator (or repressor) may interact with a component of the acetylase (or deacetylase) complex to recruit it to a promoter.

There may also be direct interactions between remodeling complexes and histone-modifying complexes. Binding by the SWI/SNF remodeling complex may lead in turn to binding by the SAGA acetylase complex (1966). Acetylation of histones may then in fact stabilize the association with the SWI/SNF complex, making a mutual reinforcement of the changes in the components at the promoter (1967).

We can connect all of the events at the promoter into the series summarized in **Figure 23.17**. The initiating event is binding of a sequence-specific component (which is able to find its target DNA sequence in the context of chromatin). This recruits a remodeling complex. Changes occur in nucleosome structure. An acetylating complex binds, and the acetylation of target histones provides a covalent mark that the locus has been activated.

**Figure 23.17** Promoter activation involves binding of a sequence-specific activator, recruitment and action of a remodeling complex, and recruitment and action of an acetylating complex.

Modification of DNA also occurs at the promoter. Methylation of cytosine at CpG doublets is associated with gene inactivity (see *Molecular Biology 5.21.18 Gene expression is associated with demethylation*). The basis for recognition of DNA as a target for methylation is not very well established (see *Molecular Biology 5.23.20 DNA methylation is responsible for imprinting*).

It is clear that chromatin remodeling at the promoter requires a variety of changes that affect nucleosomes, including acetylation, but what changes are required within the gene to allow an RNA polymerase to traverse it? We know that RNA polymerase can transcribe DNA *in vitro* at rates comparable to the *in vivo* rate (~25 nucleotides per second) only with template of free DNA. Several proteins have been characterized for their abilities to improve the speed with which RNA polymerase transcribes chromatin *in vivo* (1427; 1428; 1429). The common feature is that they

act on chromatin (for review see 1426). A current model for their action is that they associate with RNA polymerase and travel with it along the template, modifying nucleosome structure by acting on histones. Among these factors are histone acetylases. One possibility is that the first RNA polymerase to transcribe a gene is a pioneer polymerase carrying factors that change the structure of the transcription unit so as to make it easier for subsequent polymerases.

## CONTROLLING CHROMATIN STRUCTURE

### 5.23.12 Histone phosphorylation affects chromatin structure

---

#### Key Concepts

- At least two histones are targets for phosphorylation, possibly with opposing effects.
- 

Histones are phosphorylated in two circumstances:

- cyclically during the cell cycle;
- and in association with chromatin remodeling.

It has been known for a very long time that histone H1 is phosphorylated at mitosis, and more recently it was discovered that H1 is an extremely good substrate for the Cdc2 kinase that controls cell division. This led to speculations that the phosphorylation might be connected with the condensation of chromatin, but so far no direct effect of this phosphorylation event has been demonstrated, and we do not know whether it plays a role in cell division (see *Molecular Biology 6.29.7 Protein phosphorylation and dephosphorylation control the cell cycle*).

Loss of a kinase that phosphorylates histone H3 on <sup>10</sup>Ser has devastating effects on chromatin structure. **Figure 23.18** compares the usual extended structure of the polytene chromosome set of *D. melanogaster* (upper photograph) with the structure that is found in a null mutant that has no JIL-1 kinase (lower photograph). The absence of JIL-1 is lethal, but the chromosomes can be visualized in the larvae before they die (2192).

**Figure 23.18** Polytene chromosomes of flies that have no JIL-1 kinase have abnormal polytene chromosomes that are condensed instead of extended. Photograph kindly provided by Kristen M. Johansen.

The cause of the disruption of structure is most likely the failure to phosphorylate histone H3 (of course, JIL-1 may also have other targets). This suggests that H3 phosphorylation is required to generate the more extended chromosome structure of euchromatic regions. Evidence supporting the idea that JIL-1 acts directly on chromatin is that it associates with the complex of proteins that binds to the X chromosome to increase its gene expression in males (see *Molecular Biology 5.23.17 X chromosomes undergo global changes*).

This leaves us with somewhat conflicting impressions of the roles of histone phosphorylation. If it is important in the cell cycle, it is likely to be as a signal for condensation. Its effect in chromatin remodeling appears to be the opposite. It is of course possible that phosphorylation of different histones, or even of different amino acid residues in one histone, has opposite effects on chromatin structure.

## CONTROLLING CHROMATIN STRUCTURE

### 5.23.13 Heterochromatin propagates from a nucleation event

---

#### Key Terms

**Epigenetic** changes influence the phenotype without altering the genotype. They consist of changes in the properties of a cell that are inherited but that do not represent a change in genetic information.

**Position effect variegation (PEV)** is silencing of gene expression that occurs as the result of proximity to heterochromatin.

**Telomeric silencing** describes the repression of gene activity that occurs in the vicinity of a telomere.

#### Key Concepts

- Heterochromatin is nucleated at a specific sequence and the inactive structure propagates along the chromatin fiber.
- Genes within regions of heterochromatin are inactivated.
- Because the length of the inactive region varies from cell to cell, inactivation of genes in this vicinity causes position effect variegation.
- Similar spreading effects occur at telomeres and at the silent cassettes in yeast mating type.

---

An interphase nucleus contains both euchromatin and heterochromatin. The condensation state of heterochromatin is close to that of mitotic chromosomes. Heterochromatin is inert. It remains condensed in interphase, is transcriptionally repressed, replicates late in S phase, and may be localized to the nuclear periphery. Centromeric heterochromatin typically consists of satellite DNAs. However, the formation of heterochromatin is not rigorously defined by sequence. When a gene is transferred, either by a chromosomal translocation or by transfection and integration, into a position adjacent to heterochromatin, it may become inactive as the result of its new location, implying that it has become heterochromatic.

Such inactivation is the result of an **epigenetic** effect (see *Molecular Biology 5.23.22 Epigenetic effects can be inherited*). It may differ between individual cells in an animal, and results in the phenomenon of **position effect variegation (PEV)**, in which genetically identical cells have different phenotypes. This has been well characterized in *Drosophila*. **Figure 23.19** shows an example of position effect variegation in the fly eye, in which some regions lack color while others are red, because the *white* gene is inactivated by adjacent heterochromatin in some cells, while it remained active in other cells.

**Figure 23.19** Position effect variegation in eye color results when the *white* gene is integrated near heterochromatin. Cells in which *white* is inactive give patches of white eye, while cells in which *white* is active give red patches. The severity of the effect is determined by the closeness of the integrated gene to heterochromatin. Photograph kindly provided by Steve Henikoff.

The explanation for this effect is shown in **Figure 23.20**. Inactivation spreads from heterochromatin into the adjacent region for a variable distance. In some cells it goes far enough to inactivate a nearby gene, but in others it does not. This happens at a certain point in embryonic development, and after that point the state of the gene is inherited by all the progeny cells. Cells descended from an ancestor in which the gene was inactivated form patches corresponding to the phenotype of loss-of-function (in the case of *white*, absence of color).

**Figure 23.20** Extension of heterochromatin inactivates genes. The probability that a gene will be inactivated depends on its distance from the heterochromatin region.

The closer a gene lies to heterochromatin, the higher the probability that it will be inactivated. This suggests that the formation of heterochromatin may be a two-stage process: a *nucleation* event occurs at a specific sequence; and then the inactive structure *propagates* along the chromatin fiber. The distance for which the inactive structure extends is not precisely determined, and may be stochastic, being influenced by parameters such as the quantities of limiting protein components. One factor that may affect the spreading process is the activation of promoters in the region; an active promoter may inhibit spreading (2191).

Genes that are closer to heterochromatin are more likely to be inactivated, and will therefore be inactive in a greater proportion of cells. On this model, the boundaries of a heterochromatic region might be terminated by exhausting the supply of one of the proteins that is required.

The effect of **telomeric silencing** in yeast is analogous to position effect variegation in *Drosophila*; genes translocated to a telomeric location show the same sort of variable loss of activity. This results from a spreading effect that propagates from the telomeres.

A second form of silencing occurs in yeast. Yeast mating type is determined by the activity of a single active locus (*MAT*), but the genome contains two other copies of the mating type sequences (*HML* and *HMR*), which are maintained in an inactive form. The silent loci *HML* and *HMR* share many properties with heterochromatin, and could be regarded as constituting regions of heterochromatin in miniature (see *Molecular Biology 4.18.7 Silent cassettes at HML and HMR are repressed*).

## CONTROLLING CHROMATIN STRUCTURE

### 5.23.14 Some common motifs are found in proteins that modify chromatin

---

#### Key Concepts

- The chromo domain is found in several chromatin proteins that have either activating or repressing effects on gene expression
  - The SET domain is part of the catalytic site of protein methyltransferases.
- 

Our insights into the molecular mechanisms for controlling the structure of chromatin start with mutants that affect position effect variegation. Some 30 genes have been identified in *Drosophila*. They are named systematically as *Su(var)* for genes whose products act to suppress variegation and *E(var)* for genes whose products enhance variegation. Remember that the genes were named for the behavior of the mutant loci. *Su(var)* mutations lie in genes whose products are needed for the formation of heterochromatin. They include enzymes that act on chromatin, such as histone deacetylases, and proteins that are localized to heterochromatin. *E(var)* mutations lie in genes whose products are needed to activate gene expression. They include members of the SWI/SNF complex. We see immediately from these properties that modification of chromatin structure is important for controlling the formation of heterochromatin. The universality of these mechanisms is indicated by the fact that many of these loci have homologues in yeast that display analogous properties. Some of the homologues in *S. pombe* are *clr* (cryptic loci regulator) genes, in which mutations affect silencing.

Many of the *Su(var)* and *E(var)* proteins have a common protein motif of 60 amino acids called the chromo domain. The fact that this domain is found in proteins of both groups suggests that it represents a motif that participates in protein-protein interactions with targets in chromatin (for summary see 2026). Chromo domain(s) are mostly responsible for targeting proteins to heterochromatin. They function by recognizing methylated lysines in histone tails (see *Molecular Biology 5.23.15 Heterochromatin depends on interactions with histones* and *Molecular Biology 5.23.16 Polycomb and trithorax are antagonistic repressors and activators*)

*Su(var)3-9* has a chromo domain and also a SET domain, a motif that is found in several *Su(var)* proteins. Its mammalian homologues localize to centromeric heterochromatin. It is the histone methyltransferase that acts on <sup>9</sup>Lys of histone H3 (see *Molecular Biology 5.23.9 Methylation of histones and DNA is connected*). The SET domain is part of the active site, and in fact is a marker for the methylase activity.

The bromo domain is found in a variety of proteins that interact with chromatin, including histone acetylases. The crystal structure shows that it has a binding site for acetylated lysine (2028). The bromo domain itself recognizes only a very short sequence of 4 amino acids including the acetylated lysine, so specificity for target

recognition must depend on interactions involving other regions (2032). Besides the acetylases, the bromo domain is found in a range of proteins that interact with chromatin, including components of the transcription apparatus. This implies that it is used to recognize acetylated histones, which means that it is likely to be found in proteins that are involved with gene activation.

Although there is a general correlation in which active chromatin is acetylated while inactive chromatin is methylated on histones, there are some exceptions to the rule. The best characterized is that acetylation of <sup>12</sup>Lys of H4 is associated with heterochromatin (616).

Multiple modifications may occur on the same histone tail, and one modification may influence another. Phosphorylation of a lysine at one position may be necessary for acetylation of a lysine at another position. **Figure 23.21** shows the situation in the tail of H3, which can exist in either of two alternative states. The inactive state has Methyl-<sup>9</sup>Lys. The active state has Acetyl-<sup>9</sup>Lys and Phospho-<sup>10</sup>Ser. These states can be maintained over extended regions of chromatin (2025). The phosphorylation of <sup>10</sup>Ser and the methylation of <sup>9</sup>Lys are mutually inhibitory, suggesting the order of events shown in the figure. This situation may cause the tail to flip between the active and inactive states.

**Figure 23.21** Multiple modifications in the H3 tail affect chromatin activity.

## CONTROLLING CHROMATIN STRUCTURE

### 5.23.15 Heterochromatin depends on interactions with histones

---

#### Key Concepts

- HP1 is the key protein in forming mammalian heterochromatin, and acts by binding to methylated H3 histone.
  - RAP1 initiates formation of heterochromatin in yeast by binding to specific target sequences in DNA.
  - The targets of RAP1 include telomeric repeats and silencers at *HML* and *HMR*.
  - RAP1 recruits SIR3/SIR4, which interact with the N-terminal tails of H3 and H4.
- 

Inactivation of chromatin occurs by the addition of proteins to the nucleosomal fiber. The inactivation may be due to a variety of effects, including condensation of chromatin to make it inaccessible to the apparatus needed for gene expression, addition of proteins that directly block access to regulatory sites, or proteins that directly inhibit transcription.

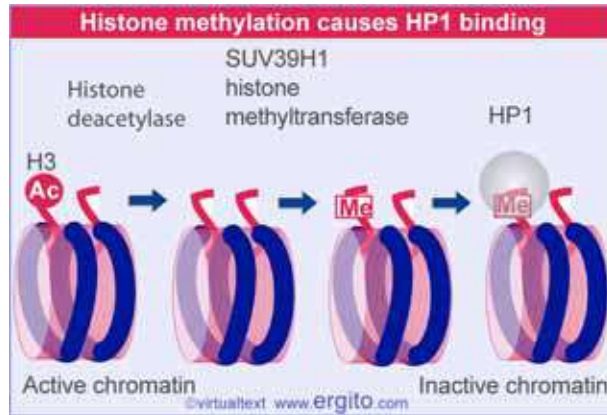

Two systems that have been characterized at the molecular level involve HP1 in mammals and the SIR complex in yeast (for review see 2420). Although there are no detailed similarities between the proteins involved in each system, the general mechanism of reaction is similar: the points of contact in chromatin are the N-terminal tails of the histones.

HP1 (heterochromatin protein 1) is one of most important Su(var) proteins. This was originally identified as a protein that is localized to heterochromatin by staining polytene chromosomes with an antibody directed against the protein (2021). It was later shown to be the product of the gene *Su(var)2-5* (2022). Its homologue in the yeast *S. pombe* is coded by *swi6*. The original protein identified as HP1 is now called HP1  $\alpha$ , since two related proteins, HP1  $\beta$  and HP1  $\gamma$ , have since been found.

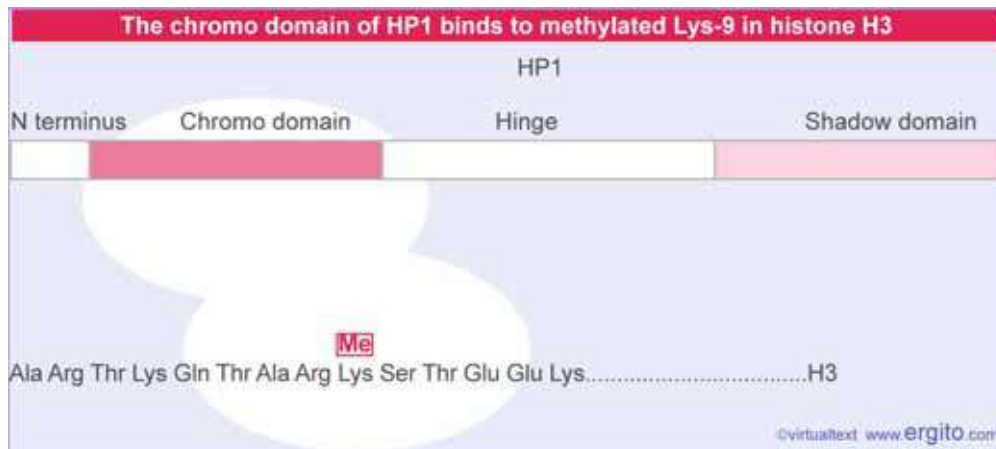

HP1 contains a chromo domain near the N-terminus, and another domain that is related to it, called the chromo-shadow domain, at the C-terminus (see **Figure 23.23**). The importance of the chromo domain is indicated by the fact that it is the location of many of the mutations in HP1 (2023).

Mutation of a deacetylase that acts on the H3 Ac-<sup>14</sup>Lys prevents the methylation at <sup>9</sup>Lys (2238). H3 that is methylated at <sup>9</sup>Lys binds the protein HP1 via the chromo domain (2016, 2015, (4178, 4180). This suggests the model for initiating formation of heterochromatin shown in **Figure 23.22**. First the deacetylase acts to remove the modification at <sup>14</sup>Lys. Then the SUV39H1 methylase acts on the histone H3 tail to create the methylated signal to which HP1 will bind. **Figure 23.23** expands the reaction to show that the interaction occurs between the chromo domain and the methylated lysine. This is a trigger for forming inactive chromatin. **Figure 23.24**

shows that the inactive region may then be extended by the ability of further HP1 molecules to interact with one another (for review see 2237).

**Figure 23.22** SUV39H1 is a histone methyltransferase that acts on <sup>9</sup>Lys of histone H3. HP1 binds to the methylated histone.

**Figure 23.23** Methylation of histone H3 creates a binding site for HP1.

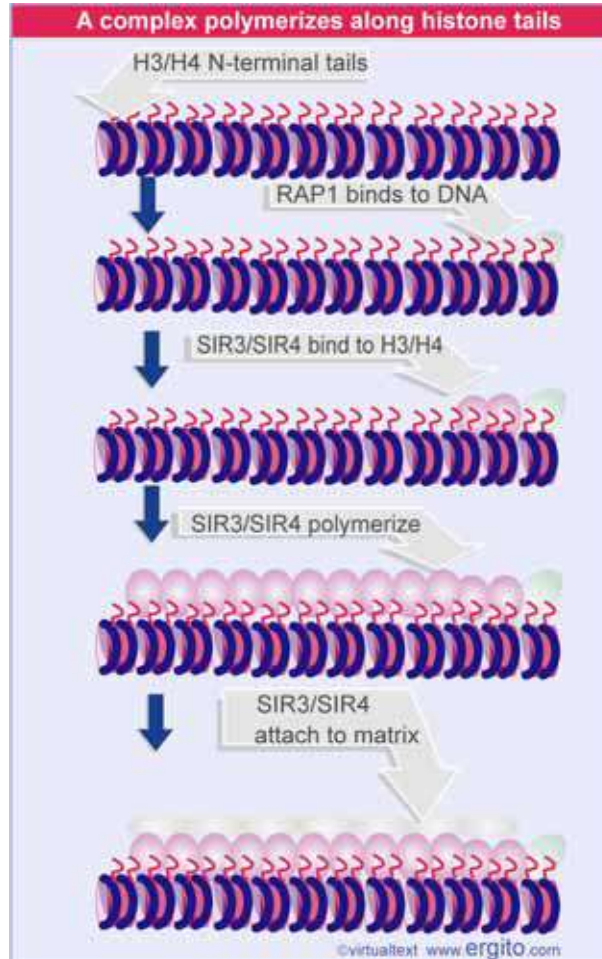

**Figure 23.24** Binding of HP1 to methylated histone H3 forms a trigger for silencing because further molecules of HP1 aggregate on the nucleosome chain.

The existence of a common basis for silencing in yeast is suggested by its reliance on a common set of genetic loci. Mutations in any one of a number of genes cause *HML* and *HMR* to become activated, and also relieve the inactivation of genes that have been integrated near telomeric heterochromatin. The products of these loci therefore function to maintain the inactive state of both types of heterochromatin (for review see 210, 4530).

**Figure 23.25** proposes a model for actions of these proteins. Only one of them is a sequence-specific DNA-binding protein. This is RAP1, which binds to the C<sub>1</sub>-A repeats at the telomeres, and also binds to the *cis*-acting silencer elements that are needed for repression of *HML* and *HMR* (619). The proteins SIR3 and SIR4 interact with RAP1 and also with one another (they may function as a heteromultimer). SIR3/SIR4 interact with the N-terminal tails of the histones H3 and H4. [In fact, the first evidence that histones might be involved directly in formation of heterochromatin was provided by the discovery that mutations abolishing silencing at *HML/HMR* map to genes coding for H3 and H4 (620; for review see 209)].

**Figure 23.25** Formation of heterochromatin is initiated when RAP1 binds to DNA. SIR3/4 bind to RAP1 and also to histones H3/H4. The complex polymerizes along chromatin and may connect telomeres to the nuclear matrix.

RAP1 has the crucial role of identifying the DNA sequences at which heterochromatin forms. It recruits SIR3/SIR4, and they interact directly with the histones H3/H4 (622; 1214). Once SIR3/SIR4 have bound to histones H3/H4, the complex may polymerize further, and spread along the chromatin fiber. This may inactivate the region, either because coating with SIR3/SIR4 itself has an inhibitory effect, or because binding to histones H3/H4 induces some further change in structure. We do not know what limits the spreading of the complex. The C-terminus of SIR3 has a similarity to nuclear lamin proteins (constituents of the nuclear matrix) and may be responsible for tethering heterochromatin to the nuclear periphery (621; 623).

A similar series of events forms the silenced regions at HMR and HML (see also *Molecular Biology 4.18.7 Silent cassettes at HML and HMR are repressed*). Three sequence-specific factors are involved in triggering formation of the complex: RAP1, ABF1 (a transcription factor), and ORC (the origin replication complex). In this case, SIR1 binds to a sequence-specific factor and recruits SIR2,3,4 to form the repressive structure. SIR2 is a histone deacetylase (2416; 2418; 2419). The deacetylation

reaction is necessary to maintain binding of the SIR complex to chromatin (for review see 2420).

How does a silencing complex repress chromatin activity? It could condense chromatin so that regulator proteins cannot find their targets. The simplest case would be to suppose that the presence of a silencing complex is mutually incompatible with the presence of transcription factors and RNA polymerase. The cause could be that silencing complexes block remodeling (and thus indirectly prevent factors from binding) or that they directly obscure the binding sites on DNA for the transcription factors. However, the situation may not be this simple, because transcription factors and RNA polymerase can be found at promoters in silenced chromatin (1963). This could mean that the silencing complex prevents the factors from working rather than from binding as such. In fact, there may be competition between gene activators and the repressing effects of chromatin, so that activation of a promoter inhibits spread of the silencing complex (2191).

Another specialized chromatin structure forms at the centromere. Its nature is suggested by the properties of an *S. cerevisiae* mutation, *cse4*, that disrupts the structure of the centromere. Cse4p is a protein that is related to histone H3. A mammalian centromeric protein, CENP-A, has a related sequence. Genetic interactions between *cse4* and CDE-II, and between *cse4* and a mutation in the H4 histone gene, suggest that a histone octamer may form around a core of Cse4p-H4, and then the centromeric complexes CBF1 and CBF3 may attach to form the centromere (591; 624).

The centromere may then be associated with the formation of heterochromatin in the region. In human cells, the centromere-specific protein CENP-B is required to initiate modifications of histone H3 (deacetylation of <sup>9</sup>Lys and <sup>14</sup>Lys, followed by methylation of <sup>9</sup>Lys) that trigger an association with the protein Swi6 that leads to the formation of heterochromatin in the region (3218).

## CONTROLLING CHROMATIN STRUCTURE

### 5.23.16 Polycomb and trithorax are antagonistic repressors and activators

---

#### Key Concepts

- Polycomb group proteins (Pc-G) perpetuate a state of repression through cell divisions.
  - The PRE is a DNA sequence that is required for the action of Pc-G.
  - The PRE provides a nucleation center from which Pc-G proteins propagate an inactive structure.
  - No individual Pc-G protein has yet been found that can bind the PRE.
  - Trithorax group proteins antagonize the actions of the Pc-G.
- 

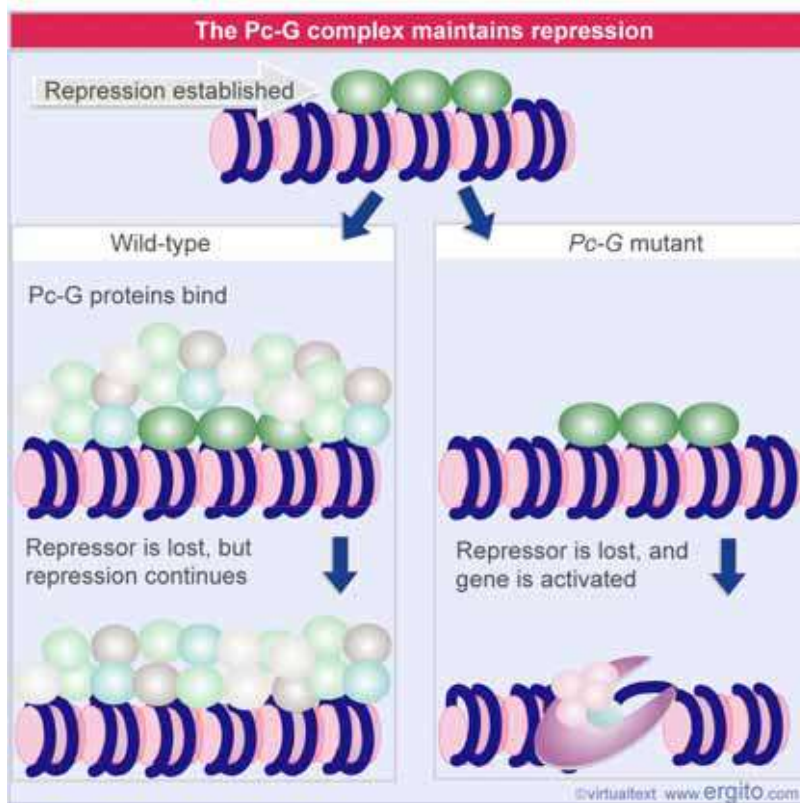

Heterochromatin provides one example of the specific repression of chromatin. Another is provided by the genetics of homeotic genes in *Drosophila*, which have led to the identification of a protein complex that may maintain certain genes in a repressed state. *Pc* mutants show transformations of cell type that are equivalent to gain-of-function mutations in the genes *Antennapedia* (*Antp*) or *Ultrabithorax*, because these genes are expressed in tissues in which usually they are repressed. This implicates *Pc* in regulating transcription. Furthermore, *Pc* is the prototype for a class of loci called the *Pc* group (*Pc-G*); mutations in these genes generally have the same result of derepressing homeotic genes, suggesting the possibility that the group of proteins has some common regulatory role. A connection between chromatin remodeling and repression is indicated by the properties of *brahma*, a fly counterpart to *SWI2*, which codes for component of the SWI/SNF remodeling complex. Loss of *brahma* function suppresses mutations in *Polycomb*.

Consistent with the pleiotropy of *Pc* mutations, Pc is a nuclear protein that can be visualized at ~80 sites on polytene chromosomes. These sites include the *Antp* gene. Another member of the *Pc-G*, *polyhomeotic*, is visualized at a set of polytene chromosome bands that are identical with those bound by Pc. The two proteins coimmunoprecipitate in a complex of  $\sim 2.5 \times 10^6$  D that contains 10-15 polypeptides. The relationship between these proteins and the products of the ~30 *Pc-G* genes remains to be established. One possibility is that some of these gene products form a general repressive complex, and then some of the other proteins associate with it to determine its specificity (683; 697).

The Pc-G proteins are not conventional repressors. They are not responsible for determining the initial pattern of expression of the genes on which they act. In the absence of Pc-G proteins, these genes are initially repressed as usual, but later in development the repression is lost without Pc-G group functions. This suggests that *the Pc-G proteins in some way recognize the state of repression when it is established, and they then act to perpetuate it through cell division of the daughter*

cells. **Figure 23.26** shows a model in which Pc-G proteins bind in conjunction with a repressor, but the Pc-G proteins remain bound after the repressor is no longer available. This is necessary to maintain repression, so that if Pc-G proteins are absent, the gene becomes activated (698).

**Figure 23.26** Pc-G proteins do not initiate repression, but are responsible for maintaining it.

A region of DNA that is sufficient to enable the response to the *Pc-G* genes is called a PRE (*Polycomb* response element). It can be defined operationally by the property that it maintains repression in its vicinity throughout development. The assay for a PRE is to insert it close to a reporter gene that is controlled by an enhancer that is repressed in early development, and then to determine whether the reporter becomes expressed subsequently in the descendants. An effective PRE will prevent such re-expression (700).

The PRE is a complex structure, ~10 kb. No individual member of the Pc-G proteins has yet been shown to bind to specific sequences in the PRE, so the basis for the assembly of the complex is still unknown. When a locus is repressed by Pc-G proteins, however, the proteins appear to be present over a much larger length of DNA than the PRE itself. Polycomb is found locally over a few kilobases of DNA surrounding a PRE.

This suggests that the PRE may provide a nucleation center, from which a structural state depending on Pc-G proteins may propagate. This model is supported by the observation of effects related to position effect variegation (see **Figure 23.20**), that

is, a gene near to a locus whose repression is maintained by Pc-G may become heritably inactivated in some cells but not others. In one typical situation, crosslinking experiments *in vivo* showed that Pc protein is found over large regions of the *bithorax* complex that are inactive, but the protein is excluded from regions that contain active genes. The idea that this could be due to cooperative interactions within a multimeric complex is supported by the existence of mutations in *Pc* that change its nuclear distribution and abolish the ability of other *Pc-G* members to localize in the nucleus. The role of Pc-G proteins in maintaining, as opposed to establishing, repression must mean that the formation of the complex at the PRE also depends on the local state of gene expression (699).

A connection between the Pc-G complex and more general structural changes in chromatin is suggested by the inclusion of a chromo domain in Pc. (In fact, the chromo domain was first identified as a region of homology between Pc and the protein HP1 found in heterochromatin.) Since variegation is caused by the spreading of inactivity from constitutive heterochromatin, it is likely that the chromo domain is used by Pc and HP1 in a similar way to induce the formation of heterochromatic or inactive structures (see *Molecular Biology 5.23.14 Some common motifs are found in proteins that modify chromatin*). The chromo domain of Pc binds to <sup>27</sup>Lys on H3 (4179) (analogous to HP1's use of its chromo domain to bind to <sup>9</sup>Lys). This model implies that similar mechanisms are used to repress individual loci or to create heterochromatin. This is probably how the PRC-1 (Polycomb-repressive complex) works. Another complex that contains Polycomb, the Esc-E(z) complex, has a histone methyltransferase activity, carried by E(z), which may target the complex by methylating H3 in the appropriate chromatin locations.

The *trithorax* group (*trxG*) of proteins have the opposite effect to the Pc-G proteins: they act to maintain genes in an active state. There may be some similarities in the actions of the two groups: mutations in some loci prevent both Pc-G and *trx* from functioning, suggesting that they could rely on common components. A factor coded by the *trithorax-like* gene, called GAGA because it binds to GA-rich consensus sequences, has binding sites in the PRE. In fact, the sites where Pc binds to DNA coincide with the sites where GAGA factor binds (704, 702).

What does this mean? GAGA is probably needed for activating factors, including *trxG* members, to bind to DNA. Is it also needed for PcG proteins to bind and exercise repression? This is not yet clear, but such a model would demand that something other than GAGA determines which of the alternative types of complex subsequently assemble at the site.

## CONTROLLING CHROMATIN STRUCTURE

### 5.23.17 X chromosomes undergo global changes

---

#### Key Terms

**Dosage compensation** describes mechanisms employed to compensate for the discrepancy between the presence of two X chromosomes in one sex but only one X chromosome in the other sex.

**Constitutive heterochromatin** describes the inert state of permanently nonexpressed sequences, usually satellite DNA.

**Facultative heterochromatin** describes the inert state of sequences that also exist in active copies—for example, one mammalian X chromosome in females.

The **single X hypothesis** describes the inactivation of one X chromosome in female mammals.

The **n-1 rule** states that only one X chromosome is active in female mammalian cells; any other(s) are inactivated.

#### Key Concepts

- One of the two X chromosomes is inactivated at random in each cell during embryogenesis of eutherian mammals.
- In exceptional cases where there are >2 X chromosomes, all but one are inactivated.
- The *Xic* (X inactivation center) is a *cis*-acting region on the X chromosome that is necessary and sufficient to ensure that only one X chromosome remains active.
- *Xic* includes the *Xist* gene which codes for an RNA that is found only on inactive X chromosomes.
- The mechanism that is responsible for preventing *Xist* RNA from accumulating on the active chromosome is unknown.

---

Sex presents an interesting problem for gene regulation, because of the variation in the number of X chromosomes. If X-linked genes were expressed equally well in each sex, females would have twice as much of each product as males. The importance of avoiding this situation is shown by the existence of **dosage compensation**, which equalizes the level of expression of X-linked genes in the two sexes. Mechanisms used in different species are summarized in **Figure 23.27**:

**Figure 23.27** Different means of dosage compensation are used to equalize X chromosome expression in male and female.

- In mammals, one of the two female X chromosomes is inactivated completely. The result is that females have only one active X chromosome, which is the same situation found in males. The active X chromosome of females and the single X chromosome of males are expressed at the same level.
- In *Drosophila*, the expression of the single male X chromosome is doubled relative to the expression of each female X chromosome.
- In *C. elegans*, the expression of each female X chromosome is halved relative to the expression of the single male X chromosome.

The common feature in all these mechanisms of dosage compensation is that *the entire chromosome is the target for regulation*. A global change occurs that quantitatively affects all of the promoters on the chromosome. We know most about the inactivation of the X chromosome in mammalian females, where the entire chromosome becomes heterochromatic.

The twin properties of heterochromatin are its condensed state and associated inactivity. It can be divided into two types:

- **Constitutive heterochromatin** contains specific sequences that have no coding function. Typically these include satellite DNAs, and are often found at the centromeres. These regions are invariably heterochromatic because of their intrinsic nature.
- **Facultative heterochromatin** takes the form of entire chromosomes that are inactive in one cell lineage, although they can be expressed in other lineages. The example *par excellence* is the mammalian X chromosome. The inactive X chromosome is perpetuated in a heterochromatic state, while the active X chromosome is part of the euchromatin. So *identical DNA sequences are involved in both states*. Once the inactive state has been established, it is inherited by descendant cells. This is an example of epigenetic inheritance, because it does not depend on the DNA sequence.

Our basic view of the situation of the female mammalian X chromosomes was formed by the **single X hypothesis** in 1961 (see *Great Experiments 11.10 The*

discovery of X-chromosome inactivation). Female mice that are heterozygous for X-linked coat color mutations have a variegated phenotype in which some areas of the coat are wild-type, but others are mutant. **Figure 23.28** shows that this can be explained if one of the two X chromosomes is inactivated at random in each cell of a small precursor population. Cells in which the X chromosome carrying the wild-type gene is inactivated give rise to progeny that express only the mutant allele on the active chromosome. Cells derived from a precursor where the other chromosome was inactivated have an active wild-type gene. In the case of coat color, cells descended from a particular precursor stay together and thus form a patch of the same color, creating the pattern of visible variegation. In other cases, individual cells in a population will express one or the other of X-linked alleles; for example, in heterozygotes for the X-linked locus G6PD, any particular red blood cell will express only one of the two allelic forms. [Random inactivation of one X chromosome occurs in eutherian mammals. In marsupials, the choice is directed: it is always the X chromosome inherited from the father that is inactivated (625).]

**Figure 23.28** X-linked variegation is caused by the random inactivation of one X chromosome in each precursor cell. Cells in which the + allele is on the active chromosome have wild phenotype; but cells in which the - allele is on the active chromosome have mutant phenotype.

Inactivation of the X chromosome in females is governed by the **n-1 rule**: however many X chromosomes are present, all but one will be inactivated. In normal females there are of course 2 X chromosomes, but in rare cases where nondisjunction has generated a 3X or greater genotype, only one X chromosome remains active. This suggests a general model in which a specific event is limited to one X chromosome and protects it from an inactivation mechanism that applies to all the others.

A single locus on the X chromosome is sufficient for inactivation. When a translocation occurs between the X chromosome and an autosome, this locus is present on only one of the reciprocal products, and only that product can be inactivated. By comparing different translocations, it is possible to map this locus, which is called the *Xic* (X-inactivation center). A cloned region of 450 kb contains all the properties of the *Xic*. When this sequence is inserted as a transgene on to an autosome, the autosome becomes subject to inactivation (in a cell culture system) (627).

*Xic* is a *cis*-acting locus that contains the information necessary to count X chromosomes and inactivate all copies but one. Inactivation spreads from *Xic* along the entire X chromosome. When *Xic* is present on an X chromosome-autosome translocation, inactivation spreads into the autosomal regions (although the effect is not always complete).

*Xic* contains a gene, called *Xist*, that is expressed only on the *inactive* X chromosome. The behavior of this gene is effectively the opposite from all other loci on the chromosome, which are turned off. Deletion of *Xist* prevents an X chromosome from being inactivated. However, it does not interfere with the counting mechanism (because other X chromosomes can be inactivated). So we can distinguish two features of *Xic*: an unidentified element(s) required for counting; and the *Xist* gene required for inactivation.

**Figure 23.29** illustrates the role of *Xist* RNA in X-inactivation (for review see 3237). *Xist* codes for an RNA that lacks open reading frames. The *Xist* RNA "coats" the X chromosome from which it is synthesized, suggesting that it has a structural role. Prior to X-inactivation, it is synthesized by both female X chromosomes. Following inactivation, the RNA is found only on the inactive X chromosome. The transcription rate remains the same before and after inactivation, so the transition depends on post-transcriptional events (626).

**Figure 23.29** X-inactivation involves stabilization of *Xist* RNA, which coats the inactive chromosome.

Prior to X-inactivation, *Xist* RNA decays with a half life of ~2 hr. X-inactivation is mediated by stabilizing the *Xist* RNA on the inactive X chromosome. The *Xist* RNA shows a punctate distribution along the X chromosome, suggesting that association with proteins to form particulate structures may be the means of stabilization. We do not know yet what other factors may be involved in this reaction and how the *Xist* RNA is limited to spreading in *cis* along the chromosome. The characteristic features of the inactive X chromosome, which include a lack of acetylation of histone H4, and methylation of CpG sequences (see *Molecular Biology* 5.21.19 *CpG islands are regulatory targets*), presumably occur later as part of the mechanism of inactivation (628; 617).

The n-1 rule suggests that stabilization of *Xist* RNA is the "default," and that some blocking mechanism prevents stabilization at one X chromosome (which will be the active X). This means that, although *Xic* is necessary and sufficient for a chromosome to be *inactivated*, the products of other loci may be necessary for the establishment of an *active* X chromosome.

Silencing of *Xist* expression is necessary for the active X. Deletion of the gene for DNA methyltransferase prevents silencing of *Xist*, probably because methylation at the *Xist* promoter is necessary for cessation of transcription.

## CONTROLLING CHROMATIN STRUCTURE

### 5.23.18 Chromosome condensation is caused by condensins

---

#### Key Terms

**Structural maintenance of chromosomes (SMC)** describes a group of proteins that include the cohesins, which hold sister chromatids together, and the condensins, which are involved in chromosome condensation.

**Condensin** proteins are components of a complex that binds to chromosomes to cause condensation for meiosis or mitosis. They are members of the SMC family of proteins.

**Cohesin** proteins form a complex that holds sister chromatids together. They include some SMC proteins.

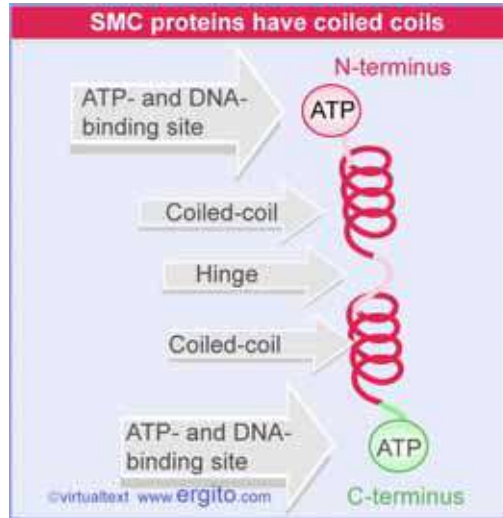

#### Key Concepts

- SMC proteins are ATPases that include the condensins and the cohesins.
- A heterodimer of SMC proteins associates with other subunits.
- The condensins cause chromatin to be more tightly coiled by introducing positive supercoils into DNA.
- Condensins are responsible for condensing chromosomes at mitosis.
- Chromosome-specific condensins are responsible for condensing inactive X chromosomes in *C. elegans*.

---

The structures of entire chromosomes are influenced by interactions with proteins of the **SMC** (structural maintenance of chromosome) family. They are ATPases that fall into two functional groups (for review see 3445). **Condensins** are involved with the control of overall structure, and are responsible for the condensation into compact chromosomes at mitosis. **Cohesins** are concerned with connections between sister chromatids that must be released at mitosis (see *Molecular Biology 6.29.19 Cohesins hold sister chromatids together*). Both consist of dimers formed by SMC proteins. Condensins form complexes that have a core of the heterodimer SMC2-SMC4 associated with other (non SMC) proteins. Cohesins have a similar organization based on the heterodimeric core of SMC1-SMC3.

**Figure 23.31** shows that an SMC protein has a coiled-coil structure in its center, interrupted by a flexible hinge region. Both the amino and carboxyl termini have ATP- and DNA-binding motifs. Different models have been proposed for the actions of these proteins depending on whether they dimerize by intra- or inter-molecular interactions.

**Figure 23.31** An SMC protein has a "Walker module" with an ATP-binding motif and DNA-binding site at each end, connected by coiled coils that are linked by a hinge region.

Experiments with the bacterial homologues of the SMC proteins suggest that a dimer is formed by an antiparallel interaction between the coiled coils, so that the N-terminus of one subunit bonds to the C-terminus of the other subunit. The existence of a flexible hinge region could allow cohesins and condensins to depend on a different mode of action by the dimer. **Figure 23.33** shows that cohesins have a V-shaped structure, with the arms separated by an  $86^\circ$  angle, whereas condensins are more sharply bent back, with only  $6^\circ$  between the arms. This enables cohesins to hold sister chromatids together, while condensins instead condense an individual chromosome (for review see 2323; 2262; 2375). **Figure 23.30** shows that a cohesin could take the form of an extended dimer that cross-links two DNA molecules. **Figure 23.32** shows that a condensin could take the form of a V-shaped dimer – essentially bent at the hinge – that pulls together distant sites on the same DNA molecule, causing it to condense.

**Figure 23.30** SMC proteins dimerize by anti-parallel interactions between the central coiled coils. Both terminal regions of each subunit have ATP- and DNA-binding motifs. Cohesins may form an extended structure that allows two different DNA molecules to be linked.

**Figure 23.32** Condensins may form a compact structure by bending at the hinge, causing DNA to become compacted.

**Figure 23.33** The two halves of a condensin are folded back at an angle of 6°. Cohesins have a more open conformation with an angle of 86° between the two halves.

An alternative model is suggested by experiments to suggest that the yeast proteins dimerize by intramolecular interactions, that is, a homodimer is formed solely by interaction between two identical subunits (2860). Dimers of two different proteins (in this case, SMC1 and SMC3) may then interact at both their head and hinge regions to form a circular structure as illustrated in **Figure 23.35**. Instead of binding directly to DNA, a structure of this type could hold DNA molecules together by encircling them (for review see 2859).

**Figure 23.35** Cohesins may dimerize by intramolecular connections, then forming multimers that are connected at the heads and at the hinge. Such a structure could hold two molecules of DNA together by surrounding them.

Visualization of mitotic chromosomes shows that condensins are located all along the length of the chromosome, as can be seen in **Figure 23.34**. (By contrast, cohesins are found at discrete locations; see **Figure 29.34**).

**Figure 23.34** Condensins are located along the entire length of a mitotic chromosome. DNA is red; condensins are yellow. Photograph kindly provided by Ana Losada and Tatsuya Hirano.

The condensin complex was named for its ability to cause chromatin to condense *in vitro* (2463). It has an ability to introduce positive supercoils into DNA in an action that uses hydrolysis of ATP and depends on the presence of topoisomerase I. This ability is controlled by the phosphorylation of the non-SMC subunits, which occurs at mitosis. We do not know yet how this connects with other modifications of chromatin, for example, the phosphorylation of histones. The activation of the condensin complex specifically at mitosis makes it questionable whether it is also involved in the formation of interphase heterochromatin.

Global changes occur in other types of dosage compensation. In *Drosophila*, a complex of proteins is found in males, where it localizes on the X chromosome. In *C. elegans*, a protein complex associates with both X chromosomes in XX embryos, but the protein components remain diffusely distributed in the nuclei of XO embryos. The protein complex contains an SMC core, and is similar to the condensin complexes that are associated with mitotic chromosomes in other species. This suggests that it has a structural role in causing the chromosome to take up a more condensed, inactive state. Multiple sites on the X chromosome may be needed for the complex to be fully distributed along it. The complex binds to these sites, and then spreads along the chromosome to cover it more thoroughly (4844).

Changes affecting all the genes on a chromosome, either negatively (mammals and *C. elegans*) or positively (*Drosophila*) are therefore a common feature of dosage compensation. However, the components of the dosage compensation apparatus may vary as well as the means by which it is localized to the chromosome, and of course its mechanism of action is different in each case.

**CONTROLLING CHROMATIN STRUCTURE****5.23.19 DNA methylation is perpetuated by a maintenance methylase**

---

**Key Terms**

A **fully methylated** site is a palindromic sequence that is methylated on both strands of DNA.

A **hemi-methylated** site is a palindromic sequence that is methylated on only one strand of DNA.

A **demethylase** is a casual name for an enzyme that removes a methyl group, typically from DNA, RNA, or protein.

A **methyltransferase (Methylase)** is an enzyme that adds a methyl group to a substrate, which can be a small molecule, a protein, or a nucleic acid.

A **de novo methylase** adds a methyl group to an unmethylated target sequence on DNA.

A **maintenance methylase** adds a methyl group to a target site that is already hemimethylated.

**Key Concepts**

- Most methyl groups in DNA are found on cytosine on both strands of the CpG doublet.
- Replication converts a fully methylated site to a hemi-methylated site.
- Hemi-methylated sites are converted to fully methylated sites by a maintenance methylase.

---

Methylation of DNA occurs at specific sites. In bacteria, it is associated with identifying the particular bacterial strain, and also with distinguishing replicated and nonreplicated DNA (see *Molecular Biology 4.15.24 Controlling the direction of mismatch repair*). In eukaryotes, its principal known function is connected with the control of transcription; methylation is associated with gene inactivation (see *Molecular Biology 5.21.18 Gene expression is associated with demethylation*).

From 2-7% of the cytosines of animal cell DNA are methylated (the value varies with the species). Most of the methyl groups are found in CG "doublets," and, in fact, the majority of the CG sequences are methylated. Usually the C residues on both strands of this short palindromic sequence are methylated, giving the structure

Such a site is described as **fully methylated**. But consider the consequences of

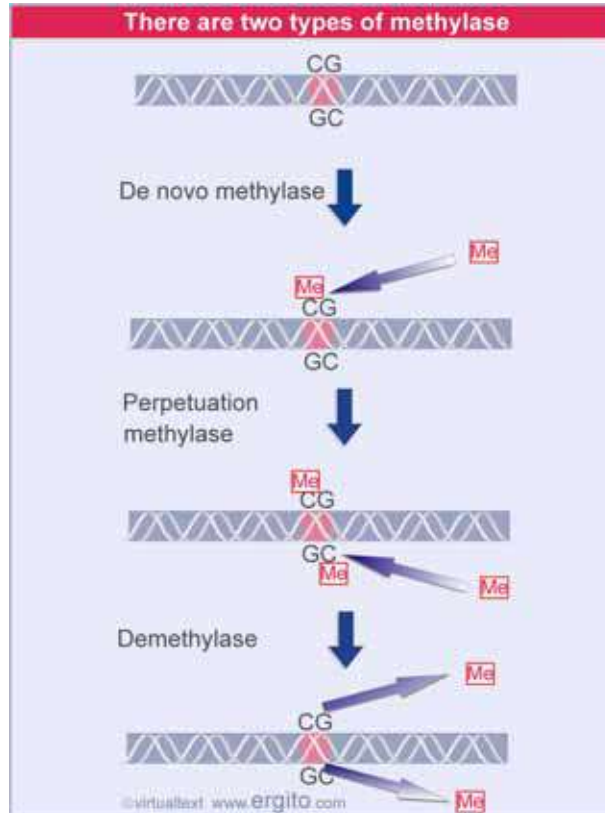

replicating this site. **Figure 23.36** shows that each daughter duplex has one methylated strand and one unmethylated strand. Such a site is called **hemi-methylated** (for review see 217).

**Figure 23.36** The state of methylated sites could be perpetuated by an enzyme that recognizes only hemimethylated sites as substrates.

The perpetuation of the methylated site now depends on what happens to hemimethylated DNA. If methylation of the unmethylated strand occurs, the site is restored to the fully methylated condition. However, if replication occurs first, the hemimethylated condition will be perpetuated on one daughter duplex, but the site will become unmethylated on the other daughter duplex. **Figure 23.37** shows that the state of methylation of DNA is controlled by **methylases**, which add methyl groups to the 5 position of cytosine, and **demethylases**, which remove the methyl groups. (The more formal name for the enzymes uses **methyltransferase** as the description.)

**Figure 23.37** The state of methylation is controlled by three types of enzyme. *De novo* and perpetuation methylases are known, but demethylases have not been identified.

There are two types of DNA methylase, whose actions are distinguished by the state of the methylated DNA. To modify DNA at a new position requires the action of the **de novo methylase**, which recognizes DNA by virtue of a specific sequence. It acts *only* on nonmethylated DNA, to add a methyl group to one strand. There are two *de novo* methylases (Dnmt3A and Dnmt3B) in mouse; they have different target sites, and both are essential for development (941).

A **maintenance methylase** acts constitutively *only on hemimethylated sites* to convert them to fully methylated sites. Its existence means that any methylated site is perpetuated after replication. There is one maintenance methylase (Dnmt1) in mouse, and it is essential: mouse embryos in which its gene has been disrupted do not survive past early embryogenesis (942).

Maintenance methylation is virtually 100% efficient, ensuring that the situation shown on the left of **Figure 23.36** usually prevails *in vivo*. The result is that, if a *de novo* methylation occurs on one allele but not on the other, this difference will be perpetuated through ensuing cell divisions, maintaining a difference between the alleles that does not depend on their sequences.

Methylation has various types of targets. Gene promoters are the most common target. The promoters are methylated when the gene is inactive, but unmethylated when it is active. The absence of Dnmt1 in mouse causes widespread demethylation

at promoters, and we assume this is lethal because of the uncontrolled gene expression. Satellite DNA is another target. Mutations in Dnmt3B prevent methylation of satellite DNA, which causes centromere instability at the cellular level. Mutations in the corresponding human gene cause a disease (1964). The importance of methylation is emphasized by another human disease, which is caused by mutation of the gene for the protein McCP2 that binds methylated CpG sequences (1965).

The methylases are conventional enzymes that act on a DNA target. However, there may also be a methylation system that uses a short RNA sequence to target a corresponding DNA sequence for methylation (see *Molecular Biology 3.11.18 Antisense RNA can be used to inactivate gene expression*) Nothing is known about the mechanism of operation of this system (for review see 2077; 2078).

How are demethylated regions established and maintained? If a DNA site has not been methylated, a protein that recognizes the unmethylated sequence could protect it against methylation. Once a site has been methylated, there are two possible ways to generate demethylated sites. One is to block the maintenance methylase from acting on the site when it is replicated. After a second replication cycle, one of the daughter duplexes will be unmethylated (as shown on the right side of **Figure 23.36**). The other is actively to demethylate the site, as shown in **Figure 23.38**, either by removing the methyl group directly from cytosine, or by excising the methylated cytosine or cytidine from DNA for replacement by a repair system. We know that active demethylation can occur to the paternal genome soon after fertilization, but we do not know what mechanism is used (for review see 2424).

**Figure 23.38** DNA could be demethylated by removing the methyl group, the base, or the nucleotide. Removal of the base or nucleotide would require its replacement by a repair system.

## CONTROLLING CHROMATIN STRUCTURE

### 5.23.20 DNA methylation is responsible for imprinting

---

#### Key Terms

**Imprinting** describes a change in a gene that occurs during passage through the sperm or egg with the result that the paternal and maternal alleles have different properties in the very early embryo. May be caused by methylation of DNA.

#### Key Concepts

- Paternal and maternal alleles may have different patterns of methylation at fertilization.
- Methylation is usually associated with inactivation of the gene.
- When genes are differentially imprinted, survival of the embryo may require that the functional allele is provided by the parent with the unmethylated allele.
- Survival of heterozygotes for imprinted genes is different depending on the direction of the cross.
- Imprinted genes occur in clusters and may depend on a local control site where *de novo* methylation occurs unless specifically prevented.

---

The pattern of methylation of germ cells is established in each sex during gametogenesis by a two stage process: first the existing pattern is erased by a genome-wide demethylation; then the pattern specific for each sex is imposed.

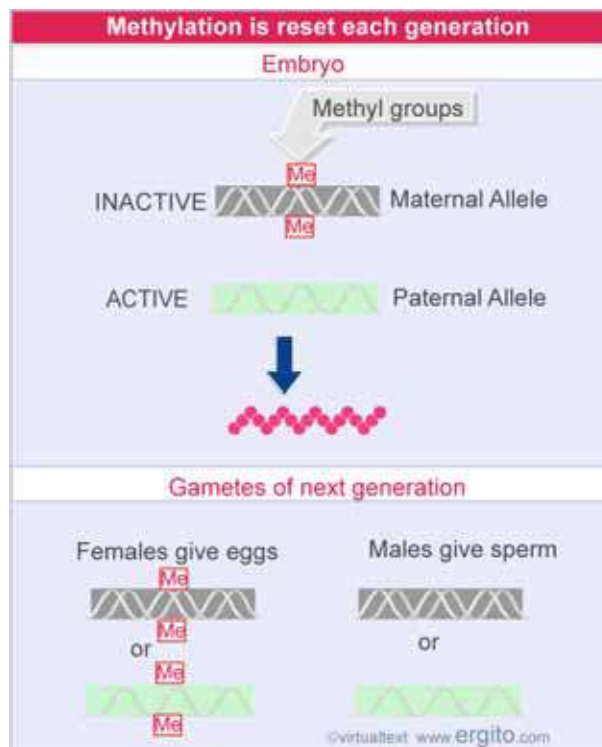

All allelic differences are lost when primordial germ cells develop in the embryo; irrespective of sex, the previous patterns of methylation are erased, and a typical gene is then unmethylated. In males, the pattern develops in two stages. The methylation pattern that is characteristic of mature sperm is established in the spermatocyte. But further changes are made in this pattern after fertilization. In females, the maternal pattern is imposed during oogenesis, when oocytes mature through meiosis after birth.

As may be expected from the inactivity of genes in gametes, the typical state is to be methylated. However, there are cases of differences between the two sexes, where a locus is unmethylated in one sex. A major question is how the specificity of methylation is determined in the male and female gametes.

Systematic changes occur in early embryogenesis. Some sites will continue to be methylated, but others will be specifically unmethylated in cells in which a gene is expressed. From the pattern of changes, we may infer that individual sequence-specific demethylation events occur during somatic development of the organism as particular genes are activated (629).

The specific pattern of methyl groups in germ cells is responsible for the phenomenon of **imprinting**, which describes a difference in behavior between the alleles inherited from each parent. The expression of certain genes in mouse embryos depends upon the sex of the parent from which they were inherited. For example, the allele coding for IGF-II (insulin-like growth factor II) that is inherited from the father is expressed, but the allele that is inherited from the mother is not expressed. The IGF-II gene of oocytes is methylated, but the IGF-II gene of sperm is not methylated, so that the two alleles behave differently in the zygote. This is the most common pattern, but the dependence on sex is reversed for some genes. In fact, the opposite pattern (expression of maternal copy) is shown for IGF-IIR, the receptor for IGF-II (for review see 215).

This sex-specific mode of inheritance requires that the pattern of methylation is established specifically during each gametogenesis. The fate of a hypothetical locus in a mouse is illustrated in **Figure 23.39**. In the early embryo, the paternal allele is nonmethylated and expressed, and the maternal allele is methylated and silent. What happens when this mouse itself forms gametes? If it is a male, the allele contributed to the sperm must be nonmethylated, irrespective of whether it was originally methylated or not. So when the maternal allele finds itself in a sperm, it must be demethylated. If the mouse is a female, the allele contributed to the egg must be methylated; so if it was originally the paternal allele, methyl groups must be added.

**Figure 23.39** The typical pattern for imprinting is that a methylated locus is inactive. If this is the maternal allele, only the paternal allele is active, and will be essential for viability. The methylation pattern is reset when gametes are formed, so that all sperm have the paternal type, and all oocytes have the maternal type.

The consequence of imprinting is that an embryo requires a paternal allele for this gene. So in the case of a heterozygous cross where the allele of one parent has an inactivating mutation, the embryo will survive if the wild-type allele comes from the father, but will die if the wild-type allele is from the mother. This type of dependence on the directionality of the cross (in contrast with Mendelian genetics) is an example of epigenetic inheritance, where some factor other than the sequences of the genes themselves influences their effects (see *Molecular Biology 5.23.22 Epigenetic effects can be inherited*). Although the paternal and maternal alleles have identical sequences, they display different properties, depending on which parent provided them. These properties are inherited through meiosis and the subsequent somatic mitoses.

Imprinted genes are sometimes clustered. More than half of the 17 known imprinted genes in mouse are contained in two particular regions, each containing both maternally and paternally expressed genes. This suggests the possibility that imprinting mechanisms may function over long distances. Some insights into this possibility come from deletions in the human population that cause the Prader-Willi and Angelman diseases. Most cases are caused by the same 4 Mb deletion, but the syndromes are different, depending on which parent contributed the deletion. The reason is that the deleted region contains at least one gene that is paternally imprinted and at least one that is maternally imprinted. There are some rare cases, however, with much smaller deletions. Prader-Willi syndrome can be caused by a 20 kb deletion that silences genes that are distant on either side of it. The basic effect of the deletion is to prevent a father from resetting the paternal mode to a chromosome inherited from his mother. The result is that these genes remain in maternal mode, so that the paternal as well as maternal alleles are silent in the offspring. The inverse effect is found in some small deletions that cause Angelman's syndrome. The implication is that this region comprises some sort of "imprint center" that acts at a distance to switch one parental type to the other.

**CONTROLLING CHROMATIN STRUCTURE****5.23.21 Oppositely imprinted genes can be controlled by a single center****Key Concepts**

- Imprinted genes are controlled by methylation of *cis*-acting sites.
- Methylation may be responsible for either inactivating or activating a gene.

Imprinting is determined by the state of methylation of a *cis*-acting site near a target gene or genes. These regulatory sites are known as DMDs (differentially methylated domains) or ICRs (imprinting control regions). Deletion of these sites removes imprinting, and the target loci then behave the same in both maternal and paternal genomes.

The behavior of a region containing two genes, *Igf2* and *H19*, illustrates the ways in which methylation can control gene activity. **Figure 23.40** shows that these two genes react oppositely to the state of methylation at a site located between them, called the ICR. The ICR is methylated on the paternal allele. *H19* shows the typical response of inactivation. However, *Igf2* is expressed. The reverse situation is found on a maternal allele, where the ICR is not methylated. *H19* now becomes expressed, but *Igf2* is inactivated.

**Figure 23.40** ICR is methylated on the paternal allele, where *Igf2* is active and *H19* is inactive. ICR is unmethylated on the maternal allele, where *Igf2* is inactive and *H19* is active.

The control of *Igf2* is exercised by an insulator function of the ICR. **Figure 23.41** shows that when the ICR is unmethylated, it binds the protein CTCF. This creates an insulator function that blocks an enhancer from activating the *Igf2* promoter (2048; 2052). This is an unusual effect in which methylation indirectly activates a gene by blocking an insulator.

**Figure 23.41** The ICR is an insulator that prevents an enhancer from activating Igf2. The insulator functions only when it binds CTCF to unmethylated DNA.

The regulation of *H19* shows the more usual direction of control in which methylation creates an inactive imprinted state. This could reflect a direct effect of methylation on promoter activity.

## CONTROLLING CHROMATIN STRUCTURE

### 5.23.22 Epigenetic effects can be inherited

---

#### Key Terms

**Epigenetic** changes influence the phenotype without altering the genotype. They consist of changes in the properties of a cell that are inherited but that do not represent a change in genetic information.

#### Key Concepts

- Epigenetic effects can result from modification of a nucleic acid after it has been synthesized or by the perpetuation of protein structures.

---

**Epigenetic** inheritance describes the ability of different states, which may have different phenotypic consequences, to be inherited without any change in the sequence of DNA. How can this occur?

We can divide epigenetic mechanisms into two general classes:

- DNA may be modified by the covalent attachment of a moiety that is then perpetuated. Two alleles with the same sequence may have different states of methylation that confer different properties.
- Or a self-perpetuating protein state may be established. This might involve assembly of a protein complex, modification of specific protein(s), or establishment of an alternative protein conformation.

Methylation establishes epigenetic inheritance so long as the maintenance methylase acts constitutively to restore the methylated state after each cycle of replication, as shown in **Figure 23.36**. A state of methylation can be perpetuated through an indefinite series of somatic mitoses. This is probably the "default" situation. Methylation can also be perpetuated through meiosis: for example, in the fungus *Ascobolus* there are epigenetic effects that can be transmitted through both mitosis and meiosis by maintaining the state of methylation. In mammalian cells, epigenetic effects are created by resetting the state of methylation differently in male and female meioses.

Situations in which epigenetic effects appear to be maintained by means of protein states are less well understood in molecular terms. Position effect variegation shows that constitutive heterochromatin may extend for a variable distance, and the structure is then perpetuated through somatic divisions. Since there is no methylation of DNA in *Saccharomyces* and a vanishingly small amount in *Drosophila*, the inheritance of epigenetic states of position effect variegation or telomeric silencing in these organisms is likely to be due to the perpetuation of protein structures.

**Figure 23.42** considers two extreme possibilities for the fate of a protein complex at

replication.

**Figure 23.42** What happens to protein complexes on chromatin during replication?

- A complex could perpetuate itself if it splits symmetrically, so that half complexes associate with each daughter duplex. If the half complexes have the capacity to nucleate formation of full complexes, the original state will be restored. This is basically analogous to the maintenance of methylation. The problem with this model is that there is no evident reason why protein complexes should behave in this way.
- A complex could be maintained as a unit and segregate to one of the two daughter duplexes. The problem with this model is that it requires a new complex to be assembled *de novo* on the other daughter duplex, and it is not evident why this should happen.

Consider now the need to perpetuate a heterochromatic structure consisting of protein complexes. Suppose that a protein is distributed more or less continuously along a stretch of heterochromatin, as implied in **Figure 23.20**. If individual subunits are distributed at random to each daughter duplex at replication, the two daughters will continue to be marked by the protein, although its density will be reduced to half of the level before replication. If the protein has a self-assembling property that causes new subunits to associate with it, the original situation may be restored. *Basically, the existence of epigenetic effects forces us to the view that a protein responsible for such a situation must have some sort of self-templating or*

*self-assembling capacity.*

In some cases, it may be the state of protein modification, rather than the presence of the protein *per se*, that is responsible for an epigenetic effect. There is a general correlation between the activity of chromatin and the state of acetylation of the histones, in particular the acetylation of histones H3 and H4, which occurs on their N-terminal tails. Activation of transcription is associated with acetylation in the vicinity of the promoter; and repression of transcription is associated with deacetylation (see *Molecular Biology 5.23.7 Acetylases are associated with activators*). The most dramatic correlation is that the inactive X chromosome in mammalian female cells is underacetylated on histone H4.

The inactivity of constitutive heterochromatin may require that the histones are not acetylated. If a histone acetyltransferase is tethered to a region of telomeric heterochromatin in yeast, silenced genes become active. When yeast is exposed to trichostatin (an inhibitor of deacetylation), centromeric heterochromatin becomes acetylated, and silenced genes in centromeric regions may become active. *The effect may persist even after trichostatin has been removed.* In fact, it may be perpetuated through mitosis and meiosis. This suggests that an epigenetic effect has been created by changing the state of histone acetylation.

How might the state of acetylation be perpetuated? Suppose that the H<sub>3</sub><sub>2</sub>·H<sub>4</sub><sub>2</sub> tetramer is distributed at random to the two daughter duplexes. This creates the situation shown in **Figure 23.43**, in which each daughter duplex contains some histone octamers that are fully acetylated on the H3 and H4 tails, while others are completely unacetylated. To account for the epigenetic effect, we could suppose that the presence of some fully acetylated histone octamers provides a signal that causes the unacetylated octamers to be acetylated.

**Figure 23.43** Acetylated cores are conserved and distributed at random to the daughter chromatin fibers at replication. Each daughter fiber has a mixture of old (acetylated) cores and new (unacetylated) cores.

(The actual situation is probably more complicated than shown in the figure, because transient acetylations occur during replication. If they are simply reversed following deposition of histones into nucleosomes, they may be irrelevant. An alternative possibility is that the usual deacetylation is prevented, instead of, or as well as, inducing acetylation.)

## CONTROLLING CHROMATIN STRUCTURE

### 5.23.23 Yeast prions show unusual inheritance

---

#### Key Terms

A **prion** is a proteinaceous infectious agent, which behaves as an inheritable trait, although it contains no nucleic acid. Examples are PrP<sup>Sc</sup>, the agent of scrapie in sheep and bovine spongiform encephalopathy, and Psi, which confers an inherited state in yeast.

#### Key Concepts

- The Sup35 protein in its wild-type soluble form is a termination factor for translation.
- It can also exist in an alternative form of oligomeric aggregates, in which it is not active in protein synthesis.
- The presence of the oligomeric form causes newly synthesized protein to acquire the inactive structure.
- Conversion between the two forms is influenced by chaperones.
- The wild-type form has the recessive genetic state  $psi^-$  and the mutant form has the dominant genetic state  $PSI^+$ .

---

One of the clearest cases of the dependence of epigenetic inheritance on the condition of a protein is provided by the behavior of **prions** – proteinaceous infectious agents. They have been characterized in two circumstances: by genetic effects in yeast; and as the causative agents of neurological diseases in mammals, including man. A striking epigenetic effect is found in yeast, where two different states can be inherited that map to a single genetic locus, *although the sequence of the gene is the same in both states*. The two different states are  $[psi^-]$  and  $[PSI^+]$ . A switch in condition occurs at a low frequency as the result of a spontaneous transition between the states (for review see 211; 212).

The *psi* genotype maps to the locus *sup35*, which codes for a translation termination factor. **Figure 23.44** summarizes the effects of the Sup35 protein in yeast. In wild-type cells, which are characterized as  $[psi^-]$ , the gene is active, and Sup35 protein terminates protein synthesis. In cells of the mutant  $[PSI^+]$  type, the factor does not function, causing a failure to terminate protein synthesis properly. (This was originally detected by the lethal effects of the enhanced efficiency of suppressors of ochre codons in  $[PSI^+]$  strains.)

**Figure 23.44** The state of the Sup35 protein determines whether termination of translation occurs.

$[PSI^+]$  strains have unusual genetic properties. When a  $[\psi^-]$  strain is crossed with a  $[PSI^+]$  strain, *all of the progeny are  $[PSI^+]$* . This is a pattern of inheritance that would be expected of an extrachromosomal agent, but the  $[PSI^+]$  trait cannot be mapped to any such nucleic acid. The  $[PSI^+]$  trait is metastable, which means that, although it is inherited by most progeny, it is lost at a higher rate than is consistent with mutation. Similar behavior is shown also by the locus *URE2*, which codes for a protein required for nitrogen-mediated repression of certain catabolic enzymes. When a yeast strain is converted into an alternative state, called  $[URE3]$ , the Ure2 protein is no longer functional (637).

The  $[PSI^+]$  state is determined by the conformation of the Sup35 protein. In a wild-type  $[\psi^-]$  cell, the protein displays its normal function. But in a  $[PSI^+]$  cell, the protein is present in an alternative conformation in which its normal function has been lost. To explain the unilateral dominance of  $[PSI^+]$  over  $[\psi^-]$  in genetic crosses, we must suppose that *the presence of protein in the  $[PSI^+]$  state causes all the protein in the cell to enter this state*. This requires an interaction between the  $[PSI^+]$  protein and newly synthesized protein, probably reflecting the generation of an oligomeric state in which the  $[PSI^+]$  protein has a nucleating role, as illustrated in **Figure 23.45** (for review see 997).

**Figure 23.45** Newly synthesized Sup35 protein is converted into the  $[\text{PSI}^+]$  state by the presence of pre-existing  $[\text{PSI}^+]$  protein.

A feature common to both the Sup35 and Ure2 proteins is that each consists of two domains that function independently. The C-terminal domain is sufficient for the activity of the protein. The N-terminal domain is sufficient for formation of the structures that make the protein inactive. So yeast in which the N-terminal domain of Sup35 has been deleted cannot acquire the  $[\text{PSI}^+]$  state; and the presence of an  $[\text{PSI}^+]$  N-terminal domain is sufficient to maintain Sup35 protein in the  $[\text{PSI}^+]$  condition (639). The critical feature of the N-terminal domain is that it is rich in glutamine and asparagine residues.

Loss of function in the  $[\text{PSI}^+]$  state is due to the sequestration of the protein in an oligomeric complex. Sup35 protein in  $[\text{PSI}^+]$  cells is clustered in discrete foci, whereas the protein in  $[\psi^-]$  cells is diffused in the cytosol. Sup35 protein from  $[\text{PSI}^+]$  cells forms amyloid fibers *in vitro* – these have a characteristic high content of  $\beta$  sheet structures (640).

The involvement of protein conformation (rather than covalent modification) is suggested by the effects of conditions that affect protein structure. Denaturing treatments cause loss of the  $[\text{PSI}^+]$  state. And in particular, the chaperone Hsp104 is

involved in inheritance of  $[PSI^+]$ . Its effects are paradoxical. Deletion of *HSP104* prevents maintenance of the  $[PSI^+]$  state. And overexpression of Hsp104 also causes loss of the  $[PSI^+]$  state. This suggests that Hsp104 is required for some change in the structure of Sup35 that is necessary for acquisition of the  $[PSI^+]$  state, but that must be transitory (638; for review see 213).

Using the ability of Sup35 to form the inactive structure *in vitro*, it is possible to provide biochemical proof for the role of the protein. **Figure 23.46** illustrates a striking experiment in which the protein was converted to the inactive form *in vitro*, put into liposomes (when in effect the protein is surrounded by an artificial membrane), and then introduced directly into cells by fusing the liposomes with  $[psi^-]$  yeast (1069). The yeast cells were converted to  $[PSI^+]$ ! This experiment refutes all of the objections that were raised to the conclusion that the protein has the ability to confer the epigenetic state. Experiments in which cells are mated, or in which extracts are taken from one cell to treat another cell, always are susceptible to the possibility that a nucleic acid has been transferred. But when the protein by itself does not convert target cells, but protein converted to the inactive state can do so, the only difference is the treatment of the protein – which must therefore be responsible for the conversion.

**Figure 23.46** Purified protein can convert the  $[psi^-]$  state of yeast to  $[PSI^+]$ .

The ability of yeast to form the  $[PSI^+]$  prion state depends on the genetic background. The yeast must be  $[PIN^+]$  in order for the  $[PSI^+]$  state to form. The  $[PIN^+]$  condition itself is an epigenetic state (1953). It can be created by the formation of prions from any one of several different proteins (1954). These proteins share the characteristic of Sup35 that they have Gln/Asn-rich domains. Overexpression of these domains in yeast stimulates formation of the  $[PSI^+]$  state (1955). This suggests that there is a common model for the formation of the prion state that involves aggregation of the Gln/Asn domains.

How does the presence of one Gln/Asn protein influence the formation of prions by another? We know that the formation of Sup35 prions is specific to Sup35 protein, that is, it does not occur by cross-aggregation with other proteins. This suggests that the yeast cell may contain soluble proteins that antagonize prion formation. These proteins are not specific for any one prion. As a result, the introduction of any Gln/Asn domain protein that interacts with these proteins will reduce the concentration. This will allow other Gln/Asn proteins to aggregate more easily.

## CONTROLLING CHROMATIN STRUCTURE

### 5.23.24 Prions cause diseases in mammals

---

#### Key Terms

**Scrapie** is an infective agent made of protein.

**Kuru** is a human neurological disease caused by prions. It may be caused by eating infected brains.

#### Key Concepts

- The protein responsible for scrapie exists in two forms, the wild-type noninfectious form PrP<sup>C</sup> which is susceptible to proteases, and the disease-causing form PrP<sup>Sc</sup> which is resistant to proteases.
- The neurological disease can be transmitted to mice by injecting the purified PrP<sup>Sc</sup> protein into mice.
- The recipient mouse must have a copy of the *PrP* gene coding for the mouse protein.
- The PrP<sup>Sc</sup> protein can perpetuate itself by causing the newly synthesized PrP protein to take up the PrP<sup>Sc</sup> form instead of the PrP<sup>C</sup> form.
- Multiple strains of PrP<sup>Sc</sup> may have different conformations of the protein.

---

Prion diseases have been found in sheep and Man, and, more recently, in cows. The basic phenotype is an ataxia – a neurodegenerative disorder that is manifested by an inability to remain upright. The name of the disease in sheep, **scrapie**, reflects the phenotype: the sheep rub against walls in order to stay upright. Scrapie can be perpetuated by inoculating sheep with tissue extracts from infected animals. The disease **kuru** was found in New Guinea, where it appeared to be perpetuated by cannibalism, in particular the eating of brains. Related diseases in Western populations with a pattern of genetic transmission include Gerstmann-Straussler syndrome; and the related Creutzfeldt-Jakob disease (CJD) occurs sporadically. Most recently, a disease resembling CJD appears to have been transmitted by consumption of meat from cows suffering from "mad cow" disease (634).

When tissue from scrapie-infected sheep is inoculated into mice, the disease occurs in a period ranging from 75-150 days. The active component is a protease-resistant protein. The protein is coded by a gene that is normally expressed in brain. The form of the protein in normal brain, called PrP<sup>C</sup>, is sensitive to proteases. Its conversion to the resistant form, called PrP<sup>Sc</sup>, is associated with occurrence of the disease. The infectious preparation has no detectable nucleic acid, is sensitive to UV irradiation at wave lengths that damage protein, and has a low infectivity (1 infectious unit / 10<sup>5</sup> PrP<sup>Sc</sup> proteins). This corresponds to an epigenetic inheritance in which there is no change in genetic information, because normal and diseased cells have the same *PrP* gene sequence, but the PrP<sup>Sc</sup> form of the protein is the infectious agent, whereas PrP<sup>C</sup> is harmless (383; 384; 385; for review see 203).

The basis for the difference between the PrP<sup>Sc</sup> and PrP<sup>C</sup> forms appears to lie with a change in conformation rather than with any covalent alteration. Both proteins are glycosylated and linked to the membrane by a GPI-linkage. No changes in these modifications have been found. The PrP<sup>Sc</sup> form has a high content of  $\beta$  sheets, which is absent from the PrP<sup>C</sup> form.

The assay for infectivity in mice allows the dependence on protein sequence to be tested. **Figure 23.47** illustrates the results of some critical experiments. In the normal situation, PrP<sup>Sc</sup> protein extracted from an infected mouse will induce disease (and ultimately kill) when it is injected into a recipient mouse. If the *PrP* gene is "knocked out", a mouse becomes resistant to infection. This experiment demonstrates two things. First, the endogenous protein is necessary for an infection, presumably because it provides the raw material that is converted into the infectious agent. Second, the cause of disease is not the removal of the PrP<sup>C</sup> form of the protein, because a mouse with no PrP<sup>C</sup> survives normally: the disease is caused by a gain-of-function in PrP<sup>Sc</sup> (386).

**Figure 23.47** A PrpSc protein can only infect an animal that has the same type of endogenous PrPC protein.

The existence of species barriers allows hybrid proteins to be constructed to delineate the features required for infectivity. The original preparations of scrapie were perpetuated in several types of animal, but these cannot always be transferred readily. For example, mice are resistant to infection from prions of hamsters. This means that hamster-PrP<sup>Sc</sup> cannot convert mouse-PrP<sup>C</sup> to PrP<sup>Sc</sup>. However, the situation changes if the mouse *PrP* gene is replaced by a hamster *PrP* gene. (This can be done by introducing the hamster *PrP* gene into the *PrP* knockout mouse.) A mouse with a hamster *PrP* gene is sensitive to infection by hamster PrP<sup>Sc</sup>. This suggests that the conversion of cellular PrP<sup>C</sup> protein into the Sc state requires that the PrP<sup>Sc</sup> and PrP<sup>C</sup> proteins have matched sequences.

There are different "strains" of PrP<sup>Sc</sup>, which are distinguished by characteristic incubation periods upon inoculation into mice. This implies that the protein is not restricted solely to alternative states of PrP<sup>C</sup> and PrP<sup>Sc</sup>, but that there may be multiple Sc states. These differences must depend on some self-propagating property of the protein other than its sequence. If conformation is the feature that distinguishes PrP<sup>Sc</sup> from PrP<sup>C</sup>, then there must be multiple conformations, each of which has a self-templating property when it converts PrP<sup>C</sup> (636; for review see 214).

The probability of conversion from PrP<sup>C</sup> to PrP<sup>Sc</sup> is affected by the sequence of PrP. Gerstmann-Straussler syndrome in man is caused by a single amino acid change in PrP. This is inherited as a dominant trait. If the same change is made in the mouse PrP gene, mice develop the disease. This suggests that the mutant protein has an increased probability of spontaneous conversion into the Sc state. Similarly, the sequence of the PrP gene determines the susceptibility of sheep to develop the disease spontaneously; the combination of amino acids at three positions (codons 136, 154, and 171) determines susceptibility.

The prion offers an extreme case of epigenetic inheritance, in which the infectious agent is a protein that can adopt multiple conformations, each of which has a self-templating property. This property is likely to involve the state of aggregation of the protein.

## CONTROLLING CHROMATIN STRUCTURE

### 5.23.25 Summary

---

The existence of a preinitiation complex signals that the gene is in an "active" state, ready to be transcribed. The complex is stable, and may remain in existence through many cycles of replication. The ability to form a preinitiation complex could be a general regulatory mechanism. By binding to a promoter to make it possible for RNA polymerase in turn to bind, the factor in effect switches the gene on.

The variety of situations in which hypersensitive sites occur suggests that their existence reflects a general principle. *Sites at which the double helix initiates an activity are kept free of nucleosomes.* A transcription factor, or some other nonhistone protein concerned with the particular function of the site, modifies the properties of a short region of DNA so that nucleosomes are excluded. The structures formed in each situation need not necessarily be similar (except that each, by definition, creates a site hypersensitive to DNAase I).

Genes whose control regions are organized in nucleosomes usually are not expressed. In the absence of specific regulatory proteins, promoters and other regulatory regions are organized by histone octamers into a state in which they cannot be activated. This may explain the need for nucleosomes to be precisely positioned in the vicinity of a promoter, so that essential regulatory sites are appropriately exposed. Some transcription factors have the capacity to recognize DNA on the nucleosomal surface, and a particular positioning of DNA may be required for initiation of transcription.

Active chromatin and inactive chromatin are not in equilibrium. Sudden, disruptive events are needed to convert one to the other. Chromatin remodeling complexes have the ability to displace histone octamers by a mechanism that involves hydrolysis of ATP. Remodeling complexes are large and are classified according to the type of the ATPase subunit. Two common types are SWI/SNF and ISW. A typical form of this chromatin remodeling is to displace one or more histone octamers from specific sequences of DNA, creating a boundary that results in the precise or preferential positioning of adjacent nucleosomes. Chromatin remodeling may also involve changes in the positions of nucleosomes, sometimes involving sliding of histone octamers along DNA.

Acetylation of histones occurs at both replication and transcription and could be necessary to form a less compact chromatin structure. Some coactivators, which connect transcription factors to the basal apparatus, have histone acetylase activity. Conversely, repressors may be associated with deacetylases. The modifying enzymes are usually specific for particular amino acids in particular histones. The most common sites for modification are located in the N-terminal tails of histones H3 and H4, which extrude from nucleosomes between the turns of DNA. The activating (or repressing) complexes are usually large and often contain several activities that undertake different modifications of chromatin. Some common motifs found in proteins that modify chromatin are the chromo domain (concerned with protein-protein interactions), the bromo domain (which targets acetylated lysine), and the SET domain (part of the active sites of histone methyltransferases).

The formation of heterochromatin occurs by proteins that bind to specific chromosomal regions (such as telomeres) and that interact with histones. The formation of an inactive structure may propagate along the chromatin thread from an initiation center. Similar events occur in silencing of the inactive yeast mating type loci. Repressive structures that are required to maintain the inactive states of particular genes are formed by the Pc-G protein complex in *Drosophila*. They share with heterochromatin the property of propagating from an initiation center.

Formation of heterochromatin may be initiated at certain sites and then propagated for a distance that is not precisely determined. When a heterochromatic state has been established, it is inherited through subsequent cell divisions. This gives rise to a pattern of epigenetic inheritance, in which two identical sequences of DNA may be associated with different protein structures, and therefore have different abilities to be expressed. This explains the occurrence of position effect variegation in *Drosophila*.

Modification of histone tails is a trigger for chromatin reorganization. Acetylation is generally associated with gene activation. Histone acetylases are found in activating complexes, and histone deacetylases are found in inactivating complexes. Histone methylation is associated with gene inactivation. Some histone modifications may be exclusive or synergistic with others.

Inactive chromatin at yeast telomeres and silent mating type loci appears to have a common cause, and involves the interaction of certain proteins with the N-terminal tails of histones H3 and H4. Formation of the inactive complex may be initiated by binding of one protein to a specific sequence of DNA; the other components may then polymerize in a cooperative manner along the chromosome.

Inactivation of one X chromosome in female (eutherian) mammals occurs at random. The *Xic* locus is necessary and sufficient to count the number of X chromosomes. The n-1 rule ensures that all but one X chromosome are inactivated. *Xic* contains the gene *Xist*, which codes for an RNA that is expressed only on the inactive X chromosome. Stabilization of *Xist* RNA is the mechanism by which the inactive X chromosome is distinguished.

Methylation of DNA is inherited epigenetically. Replication of DNA creates hemimethylated products, and a maintenance methylase restores the fully methylated state. Some methylation events depend on parental origin. Sperm and eggs contain specific and different patterns of methylation, with the result that paternal and maternal alleles are differently expressed in the embryo. This is responsible for imprinting, in which the nonmethylated allele inherited from one parent is essential because it is the only active allele; the allele inherited from the other parent is silent. Patterns of methylation are reset during gamete formation in every generation.

Prions are proteinaceous infectious agents that are responsible for the disease of scrapie in sheep and for related diseases in man. The infectious agent is a variant of a normal cellular protein. The PrP<sup>Sc</sup> form has an altered conformation that is self-templating: the normal PrP<sup>C</sup> form does not usually take up this conformation, but does so in the presence of PrP<sup>Sc</sup>. A similar effect is responsible for inheritance of the *PSI* element in yeast.

## RNA SPLICING AND PROCESSING

### 5.24.1 Introduction

---

#### Key Terms

**Pre-mRNA** is used to describe the nuclear transcript that is processed by modification and splicing to give an mRNA.

**RNA splicing** is the process of excising the sequences in RNA that correspond to introns, so that the sequences corresponding to exons are connected into a continuous mRNA.

**Heterogeneous nuclear RNA (hnRNA)** comprises transcripts of nuclear genes made by RNA polymerase II; it has a wide size distribution and low stability.

An **hnRNP** is the ribonucleoprotein form of hnRNA (heterogeneous nuclear RNA), in which the hnRNA is complexed with proteins. Since pre-mRNAs are not exported until processing is complete, hnRNPs are found only in the nucleus.

---

Interrupted genes are found in all classes of organisms. They represent a minor proportion of the genes of the very lowest eukaryotes, but the vast majority of genes in higher eukaryotic genomes. Genes vary widely according to the numbers and lengths of introns, but a typical mammalian gene has 7-8 exons spread out over ~16 kb. The exons are relatively short (~100-200 bp), and the introns are relatively long (>1 kb) (see *Molecular Biology 1.2.7 Genes show a wide distribution of sizes*).

The discrepancy between the interrupted organization of the gene and the uninterrupted organization of its mRNA requires processing of the primary transcription product. The primary transcript has the same organization as the gene, and is sometimes called the **pre-mRNA**. Removal of the introns from pre-mRNA leaves a typical messenger of ~2.2 kb. The process by which the introns are removed is called **RNA splicing**.

Removal of introns is a major part of the production of RNA in all eukaryotes. (Although interrupted genes are relatively rare in lower eukaryotes such as yeast, the overall proportion underestimates the importance of introns, because most of the genes that are interrupted code for relatively abundant proteins. Splicing is therefore involved in the production of a greater proportion of total mRNA than would be apparent from analysis of the genome, perhaps as much as 50%.)

One of the first clues about the nature of the discrepancy in size between nuclear genes and their products in higher eukaryotes was provided by the properties of nuclear RNA. Its average size is much larger than mRNA, it is very unstable, and it has a much greater sequence complexity. Taking its name from its broad size distribution, it was called **heterogeneous nuclear RNA (hnRNA)**. It includes pre-mRNA, but could also include other transcripts (that is, which are not ultimately processed to mRNA; for review see 17).

The physical form of hnRNA is a ribonucleoprotein particle (**hnRNP**), in which the

hnRNA is bound by proteins. As characterized *in vitro*, an hnRNP particle takes the form of beads connected by a fiber. The structure is summarized in **Figure 24.1**. The most abundant proteins in the particle are the core proteins, but other proteins are present at lower stoichiometry, making a total of ~20 proteins. The proteins typically are present at  $\sim 10^8$  copies per nucleus, compared with  $\sim 10^6$  molecules of hnRNA. Some of the proteins may have a structural role in packaging the hnRNA; several are known to shuttle between the nucleus and cytoplasm, and play roles in exporting the RNA or otherwise controlling its activity (for review see 249; 3428).

**Figure 24.1** hnRNA exists as a ribonucleoprotein particle organized as a series of beads.

Splicing occurs in the nucleus, together with the other modifications that are made to newly synthesized RNAs. The process of expressing an interrupted gene is reviewed in **Figure 24.2**. The transcript is capped at the 5' end (see *Molecular Biology 2.5.9 The 5' end of eukaryotic mRNA is capped*), has the introns removed, and is polyadenylated at the 3' end (see *Molecular Biology 2.5.10 The 3' terminus is polyadenylated*). The RNA is then transported through nuclear pores to the cytoplasm, where it is available to be translated.

**Figure 24.2** RNA is modified in the nucleus by additions to the 5' and 3' ends and by splicing to remove the introns. The splicing event requires breakage of the exon-intron junctions and joining of the ends of the exons. Mature mRNA is transported through nuclear pores to the cytoplasm, where it is translated.

With regard to the various processing reactions that occur in the nucleus, we should like to know at what point splicing occurs *vis-à-vis* the other modifications of RNA. Does splicing occur at a particular location in the nucleus; and is it connected with other events, for example, nucleocytoplasmic transport? Does the lack of splicing make an important difference in the expression of uninterrupted genes?

With regard to the splicing reaction itself, one of the main questions is how its specificity is controlled. What ensures that the ends of each intron are recognized in pairs so that the correct sequence is removed from the RNA? Are introns excised from a precursor in a particular order? Is the maturation of RNA used to *regulate* gene expression by discriminating among the available precursors or by changing the pattern of splicing?

We can identify several types of splicing systems:

- Introns are removed from the nuclear pre-mRNAs of higher eukaryotes by a

system that recognizes only short consensus sequences conserved at exon-intron boundaries and within the intron. This reaction requires a large splicing apparatus, which takes the form of an array of proteins and ribonucleoproteins that functions as a large particulate complex (the spliceosome). The mechanism of splicing involves transesterifications, and the catalytic center includes RNA as well as proteins.

- Certain RNAs have the ability to excise their introns autonomously. Introns of this type fall into two groups, as distinguished by secondary/tertiary structure. Both groups use transesterification reactions in which the RNA is the catalytic agent (see *Molecular Biology* 5.26 *Catalytic RNA*).
- The removal of introns from yeast nuclear tRNA precursors involves enzymatic activities that handle the substrate in a way resembling the tRNA processing enzymes, in which a critical feature is the conformation of the tRNA precursor. These splicing reactions are accomplished by enzymes that use cleavage and ligation.

## RNA SPLICING AND PROCESSING

### 5.24.2 Nuclear splice junctions are short sequences

#### Key Terms

**Splice sites** are the sequences immediately surrounding the exon-intron boundaries.

The **GT-AG rule** describes the presence of these constant dinucleotides at the first two and last two positions of introns of nuclear genes.

#### Key Concepts

- Splice sites are the sequences immediately surrounding the exon-intron boundaries. They are named for their positions relative to the intron.
- The 5' splice site at the 5' (left) end of the intron includes the consensus sequence GU.
- The 3' splice site at the 3' (right) end of the intron includes the consensus sequence AG.
- The GU-AG rule (originally called the GT-AG rule in terms of DNA sequence) describes the requirement for these constant dinucleotides at the first two and last two positions of introns in pre-mRNAs.

To focus on the molecular events involved in nuclear intron splicing, we must consider the nature of the **splice sites**, the two exon-intron boundaries that include the sites of breakage and reunion.

By comparing the nucleotide sequence of mRNA with that of the structural gene, the junctions between exons and introns can be assigned. There is no extensive homology or complementarity between the two ends of an intron. However, the junctions have well conserved, though rather short, consensus sequences.

It is possible to assign a specific end to every intron by relying on the conservation of exon-intron junctions. They can all be aligned to conform to the consensus sequence given in **Figure 24.3**.

**Figure 24.3** The ends of nuclear introns are defined by the GU-AG rule.

The subscripts indicate the percent occurrence of the specified base at each consensus position. High conservation is found only *immediately within the intron* at the presumed junctions. This identifies the sequence of a generic intron as:

GU##AG

Because the intron defined in this way starts with the dinucleotide GU and ends with the dinucleotide AG, the junctions are often described as conforming to the **GT-AG rule**. (This reflects the fact that the sequences were originally analyzed in terms of DNA, but of course the GT in the coding strand sequence of DNA becomes a GU in the RNA.)

Note that the two sites have different sequences and so they define the ends of the intron *directionally*. They are named proceeding from left to right along the intron as the 5' splice site (sometimes called the left or donor site) and the 3' splice site (also called the right or acceptor site). The consensus sequences are implicated as the sites recognized in splicing by point mutations that prevent splicing *in vivo* and *in vitro* (for review see 242; 243).

## RNA SPLICING AND PROCESSING

### 5.24.3 Splice junctions are read in pairs

#### Key Concepts

- Splicing depends only on recognition of pairs of splice junctions.
- All 5' splice sites are functionally equivalent, and all 3' splice sites are functionally equivalent.

A typical mammalian mRNA has many introns. The basic problem of pre-mRNA splicing results from the simplicity of the splice sites, and is illustrated in **Figure 24.4**: what ensures that the correct pairs of sites are spliced together? The corresponding GU-AG pairs must be connected across great distances (some introns are >10 kb long). We can imagine two types of principle that might be responsible for pairing the appropriate 5' and 3' sites:

**Figure 24.4** Splicing junctions are recognized only in the correct pairwise combinations.

- It could be an *intrinsic property* of the RNA to connect the sites at the ends of a particular intron. This would require matching of specific sequences or structures.
- Or all 5' sites may be functionally equivalent and all 3' sites may be similarly indistinguishable, but splicing could follow *rules* that ensure a 5' site is always connected to the 3' site that comes next in the RNA.

Neither the splice sites nor the surrounding regions have any sequence complementarity, which excludes models for complementary base pairing between

intron ends. And experiments using hybrid RNA precursors show that any 5' splice site can in principle be connected to any 3' splice site. For example, when the first exon of the early SV40 transcription unit is linked to the third exon of mouse  $\beta$  globin, the hybrid intron can be excised to generate a perfect connection between the SV40 exon and the  $\beta$ -globin exon. Indeed, this interchangeability is the basis for the exon-trapping technique described previously in **Figure 2.12**. Such experiments make two general points:

- *Splice sites are generic:* they do not have specificity for individual RNA precursors, and individual precursors do not convey specific information (such as secondary structure) that is needed for splicing.
- *The apparatus for splicing is not tissue specific;* an RNA can usually be properly spliced by any cell, whether or not it is usually synthesized in that cell. (We discuss exceptions in which there are tissue-specific alternative splicing patterns in *Molecular Biology 5.24.12 Alternative splicing involves differential use of splice junctions.*)

Here is a paradox. Probably all 5' splice sites look similar to the splicing apparatus, and all 3' splice sites look similar to it. *In principle any 5' splice site may be able to react with any 3' splice site.* But in the usual circumstances splicing occurs only between the 5' and 3' sites of the *same* intron. *What rules ensure that recognition of splice sites is restricted so that only the 5' and 3' sites of the same intron are spliced?*

Are introns removed in a specific *order* from a particular RNA? Using RNA blotting, we can identify nuclear RNAs that represent intermediates from which some introns have been removed. **Figure 24.5** shows a blot of the precursors to ovomucoid mRNA. There is a discrete series of bands, which suggests that splicing occurs via definite pathways. (If the seven introns were removed in an entirely random order, there would be more than 300 precursors with different combinations of introns, and we should not see discrete bands.)

**Figure 24.5** Northern blotting of nuclear RNA with an ovomucoid probe identifies discrete precursors to mRNA. The contents of the more prominent bands are indicated. Photograph kindly provided by Bert O#Malley.

There does not seem to be a *unique* pathway, since intermediates can be found in which different combinations of introns have been removed. However, there is evidence for a *preferred* pathway or pathways. When only one intron has been lost, it is virtually always 5 or 6. But either can be lost first. When two introns have been lost, 5 and 6 are again the most frequent, but there are other combinations. Intron 3 is never or very rarely lost at one of the first three splicing steps. From this pattern, we see that there is a preferred pathway in which introns are removed in the order 5/6, 7/4, 2/1, 3. But there are other pathways, since (for example), there are some molecules in which 4 or 7 is lost last. A caveat in interpreting these results is that we do not have proof that all these intermediates actually lead to mature mRNA.

The general conclusion suggested by this analysis is that the conformation of the RNA influences the accessibility of the splice sites. As particular introns are removed, the conformation changes, and new pairs of splice sites become available.

But the ability of the precursor to remove its introns in more than one order suggests that alternative conformations are available at each stage. Of course, the longer the molecule, the more structural options become available; and when we consider larger genes, it becomes difficult to see how specific secondary structures could control the reaction. One important conclusion of this analysis is that *the reaction does not proceed sequentially along the precursor*.

A simple model to control recognition of splice sites would be for the splicing apparatus to act in a processive manner. Having recognized a 5' site, the apparatus might scan the RNA in the appropriate direction until it meets the next 3' site. This would restrict splicing to adjacent sites. But this model is excluded by experiments that show that splicing can occur in *trans* as an intermolecular reaction under special circumstances (see *Molecular Biology 5.24.13 trans-splicing reactions use small RNAs*) or in RNA molecules in which part of the nucleotide chain is replaced by a chemical linker. This means that there cannot be a requirement for strict scanning along the RNA from the 5' splice site to the 3' splice site. Another problem with the scanning model is that it cannot explain the existence of alternative splicing patterns, where (for example) a common 5' site is spliced to more than one 3' site. The basis for proper recognition of correct splice site pairs remains incompletely defined.

## RNA SPLICING AND PROCESSING

### 5.24.4 pre-mRNA splicing proceeds through a lariat

---

#### Key Terms

The **lariat** is an intermediate in RNA splicing in which a circular structure with a tail is created by a 5' -2' bond.

The **branch site** is a short sequence just before the end of an intron at which the lariat intermediate is formed in splicing by joining the 5' nucleotide of the intron to the 2' position of an Adenosine.

A **transesterification** reaction breaks and makes chemical bonds in a coordinated transfer so that no energy is required.

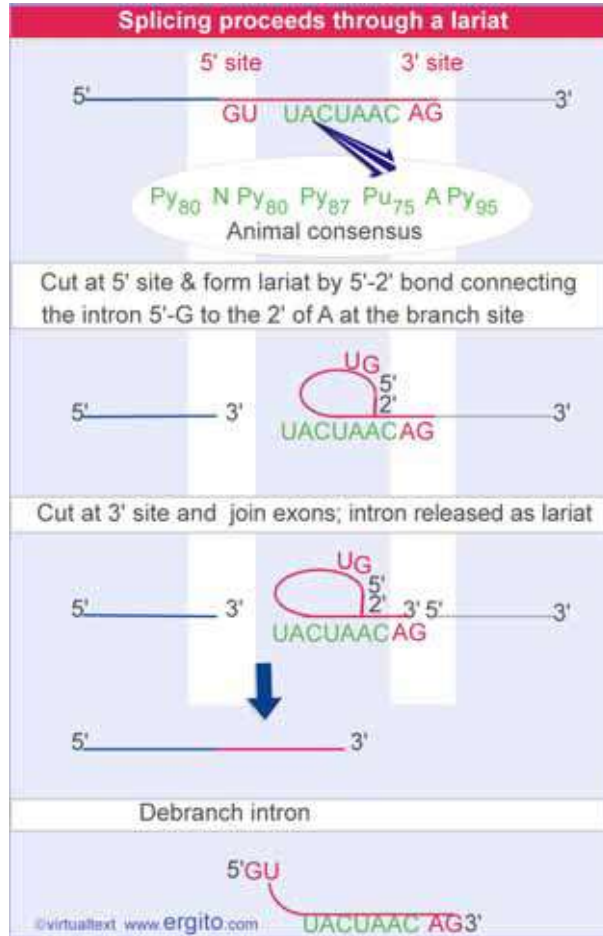

#### Key Concepts

- Splicing requires the 5' and 3' splice sites and a branch site just upstream of the 3' splice site.
- The branch sequence is conserved in yeast but less well conserved in higher eukaryotes.
- A lariat is formed when the intron is cleaved at the 5' splice site, and the 5' end is joined to a 2' position at an A at the branch site in the intron.
- The intron is released as a lariat when it is cleaved at the 3' splice site, and the left and right exons are then ligated together.
- The reactions occur by transesterifications in which a bond is transferred from one location to another.

---

The mechanism of splicing has been characterized *in vitro*, using systems in which introns can be removed from RNA precursors. Nuclear extracts can splice purified RNA precursors, which shows that the action of splicing is not linked to the process of transcription. Splicing can occur to RNAs that are neither capped nor polyadenylated. However, although the splicing reaction as such is independent of transcription or modification to the RNA, these events normally occur in a coordinated manner, and the efficiency of splicing may be influenced by other processing events.

The stages of splicing *in vitro* are illustrated in the pathway of **Figure 24.6**. We discuss the reaction in terms of the individual RNA species that can be identified, but remember that *in vivo* the species containing exons are not released as free molecules, but remain held together by the splicing apparatus (for review see 253).

**Figure 24.6** Splicing occurs in two stages. First the 5' exon is cleaved off; then it is joined to the 3' exon.

The first step is to make a cut at the 5' splice site, separating the left exon and the right intron-exon molecule. The left exon takes the form of a linear molecule. The right intron-exon molecule forms a **lariat**, in which the 5' terminus generated at the end of the intron becomes linked by a 5'–2' bond to a base within the intron. The target base is an A in a sequence that is called the **branch site** (712).

Cutting at the 3' splice site releases the free intron in lariat form, while the right exon is ligated (spliced) to the left exon. The cleavage and ligation reactions are shown separately in the figure for illustrative purposes, but actually occur as one coordinated transfer.

The lariat is then "debranched" to give a linear excised intron, which is rapidly degraded.

*The sequences needed for splicing are the short consensus sequences at the 5' and 3' splice sites and at the branch site.* Together with the knowledge that most of the sequence of an intron can be deleted without impeding splicing, this indicates that there is no demand for specific conformation in the intron (or exon).

The branch site plays an important role in identifying the 3' splice site. The branch site in yeast is highly conserved, and has the consensus sequence UACUAAC. The branch site in higher eukaryotes is not well conserved, but has a preference for purines or pyrimidines at each position and retains the target A nucleotide (see **Figure 24.6**) (717).

The branch site lies 18-40 nucleotides upstream of the 3' splice site. Mutations or deletions of the branch site in yeast prevent splicing. In higher eukaryotes, the relaxed constraints in its sequence result in the ability to use related sequences (called cryptic sites) when the authentic branch is deleted. Proximity to the 3' splice site appears to be important, since the cryptic site is always close to the authentic site. A cryptic site is used only when the branch site has been inactivated. When a cryptic branch sequence is used in this manner, splicing otherwise appears to be normal; and the exons give the same products as wild type. *The role of the branch site therefore is to identify the nearest 3' splice site as the target for connection to the 5' splice site* (713). This can be explained by the fact that an interaction occurs between protein complexes that bind to these two sites.

The bond that forms the lariat goes from the 5' position of the invariant G that was at the 5' end of the intron to the 2' position of the invariant A in the branch site. This corresponds to the third A residue in the yeast UACUAAC box.

The chemical reactions proceed by **transesterification**: a bond is in effect *transferred* from one location to another. **Figure 24.7** shows that the first step is a nucleophilic attack by the 2'-OH of the invariant A of the UACUAAC sequence on the 5' splice site. In the second step, the free 3'-OH of the exon that was released by the first reaction now attacks the bond at the 3' splice site. Note that the number of phosphodiester bonds is conserved. There were originally two 5'-3' bonds at the exon-intron splice sites; one has been replaced by the 5'-3' bond between the exons, and the other has been replaced by the 5'-2' bond that forms the lariat (for review see 251).

**Figure 24.7** Nuclear splicing occurs by two transesterification reactions in which an OH group attacks a phosphodiester bond.

## RNA SPLICING AND PROCESSING

### 5.24.5 snRNAs are required for splicing

---

#### Key Terms

A **small nuclear RNA (snRNA)** is one of many small RNA species confined to the nucleus; several of the snRNAs are involved in splicing or other RNA processing reactions.

**Small cytoplasmic RNAs (scRNA)** are present in the cytoplasm and (sometimes are also found in the nucleus).

**snRNPs (snurp)** are small nuclear ribonucleoproteins (snRNAs associated with proteins).

**scRNPs (scyrp)** are small cytoplasmic ribonucleoproteins (scRNAs associated with proteins).

The **spliceosome** is a complex formed by the snRNPs that are required for splicing together with additional protein factors.

**Anti-Sm** is an autoimmune antiserum that defines the Sm epitope that is common to a group of proteins found in snRNPs that are involved in RNA splicing.

#### Key Concepts

- The five snRNPs involved in splicing are U1, U2, U5, U4, and U6.
- Together with some additional proteins, the snRNPs form the spliceosome.
- All the snRNPs except U6 contain a conserved sequence that binds the Sm proteins that are recognized by antibodies generated in autoimmune disease.

---

The 5' and 3' splice sites and the branch sequence are recognized by components of the splicing apparatus that assemble to form a large complex. This complex brings together the 5' and 3' splice sites before any reaction occurs, explaining why a deficiency in any one of the sites may prevent the reaction from initiating. The complex assembles sequentially on the pre-mRNA, and several intermediates can be recognized by fractionating complexes of different sizes. Splicing occurs only after all the components have assembled (719).

The splicing apparatus contains both proteins and RNAs (in addition to the pre-mRNA). The RNAs take the form of small molecules that exist as ribonucleoprotein particles. Both the nucleus and cytoplasm of eukaryotic cells contain many discrete small RNA species. They range in size from 100-300 bases in higher eukaryotes, and extend in length to ~1000 bases in yeast. They vary considerably in abundance, from  $10^5$ - $10^6$  molecules per cell to concentrations too low to be detected directly.

Those restricted to the nucleus are called **small nuclear RNAs (snRNA)**; those found in the cytoplasm are called **small cytoplasmic RNAs (scRNA)**. In their natural state, they exist as ribonucleoprotein particles (snRNP and scRNP).

Colloquially, they are sometimes known as **snurps** and **scyrps**. There is also a class of small RNAs found in the nucleolus, called snoRNAs, which are involved in processing ribosomal RNA (see *Molecular Biology 5.24.22 Small RNAs are required for rRNA processing*).

The snRNPs involved in splicing, together with many additional proteins, form a large particulate complex, called the **spliceosome**. Isolated from the *in vitro* splicing systems, it comprises a 50-60S ribonucleoprotein particle. The spliceosome may be formed in stages as the snRNPs join, proceeding through several "presplicing complexes." The spliceosome is a large body, greater in mass than the ribosome.

**Figure 24.8** summarizes the components of the spliceosome (3210). The 5 snRNAs account for more than a quarter of the mass; together with their 45 associated proteins, they account for almost half of the mass. Some 70 other proteins found in the spliceosome are described as splicing factors. They include proteins required for assembly of the spliceosome, proteins required for it to bind to the RNA substrate, and proteins involved in the catalytic process. In addition to these proteins, another ~30 proteins associated with the spliceosome have been implicated in acting at other stages of gene expression, suggesting that the spliceosome may serve as a coordinating apparatus.

**Figure 24.8** The spliceosome is ~12 MDa. 5 snRNAs account for almost half of the mass. The remaining proteins include known splicing factors and also proteins that are involved in other stages of gene expression.

The spliceosome forms on the intact precursor RNA and passes through an intermediate state in which it contains the individual 5' exon linear molecule and the right lariat-intron-exon. Little spliced product is found in the complex, which suggests that it is usually released immediately following the cleavage of the 3' site and ligation of the exons.

We may think of the snRNP particles as being involved in building the structure of the spliceosome. Like the ribosome, the spliceosome depends on RNA-RNA interactions as well as protein-RNA and protein-protein interactions. Some of the reactions involving the snRNPs require their RNAs to base pair directly with sequences in the RNA being spliced; other reactions require recognition between snRNPs or between their proteins and other components of the spliceosome.

The importance of snRNA molecules can be tested directly in yeast by making mutations in their genes. Mutations in 5 snRNA genes are lethal and prevent splicing. All of the snRNAs involved in splicing can be recognized in conserved forms in animal, bird, and insect cells. The corresponding RNAs in yeast are often rather larger, but conserved regions include features that are similar to the snRNAs of higher eukaryotes.

The snRNPs involved in splicing are U1, U2, U5, U4, and U6. They are named according to the snRNAs that are present. Each snRNP contains a single snRNA and several (<20) proteins. The U4 and U6 snRNPs are usually found as a single (U4/U6) particle. A common structural core for each snRNP consists of a group of 8 proteins, all of which are recognized by an autoimmune antiserum called **anti-Sm**; conserved sequences in the proteins form the target for the antibodies. The other proteins in each snRNP are unique to it. The Sm proteins bind to the conserved sequence PuAU<sub>3</sub>-Gpu<sub>6</sub>, which is present in all snRNAs except U6. The U6 snRNP contains instead a set of Sm-like (Lsm) proteins. The Sm proteins must be involved in the autoimmune reaction, although their relationship to the phenotype of the autoimmune disease is not clear (for review see 244; 245; 247).

Some of the proteins in the snRNPs may be involved directly in splicing; others may be required in structural roles or just for assembly or interactions between the snRNP particles. About one third of the proteins involved in splicing are components of the snRNPs. Increasing evidence for a direct role of RNA in the splicing reaction suggests that relatively few of the splicing factors play a direct role in catalysis; most are involved in structural or assembly roles.

## RNA SPLICING AND PROCESSING

### 5.24.6 U1 snRNP initiates splicing

---

#### Key Terms

An **SR protein** has a variable length of an Arg-Ser-rich region and is involved in splicing.

#### Key Concepts

- U1 snRNP initiates splicing by binding to the 5' splice site by means of an RNA-RNA pairing reaction.
- The E complex contains U1 snRNP bound at the 5' splice site, the protein U2AF bound to a pyrimidine tract between the branch site and the 3' splice site, and SR proteins connecting U1 snRNP to U2AF.

---

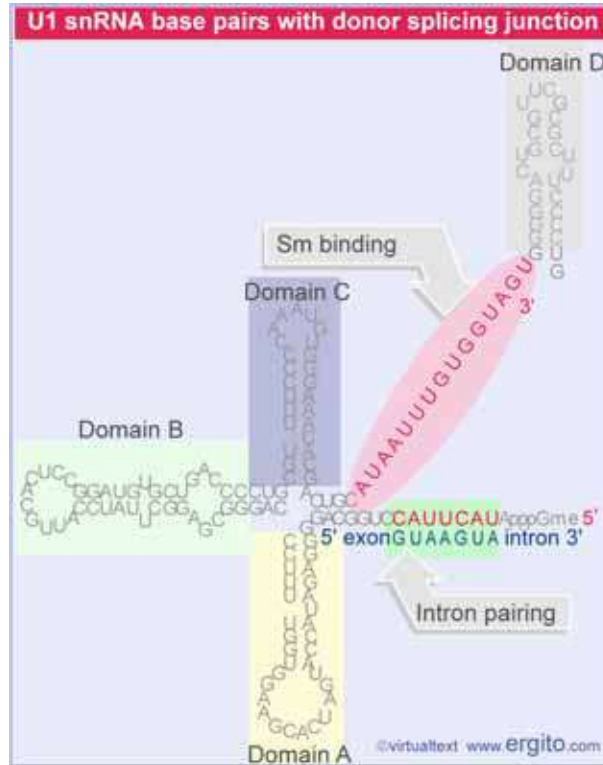

Splicing can be broadly divided into two stages:

- First the consensus sequences at the 5' splice site, branch sequence, and adjacent pyrimidine tract are recognized. A complex assembles that contains all of the splicing components.
- Then the cleavage and ligation reactions change the structure of the substrate RNA. Components of the complex are released or reorganized as it proceeds through the splicing reactions.

*The important point is that all of the splicing components are assembled and have assured that the splice sites are available before any irreversible change is made to the RNA (for review see 3239).*

Recognition of the consensus sequences involves both RNAs and proteins. Certain snRNAs have sequences that are complementary to the consensus sequences or to one another, and base pairing between snRNA and pre-mRNA, or between snRNAs, plays an important role in splicing.

The human U1 snRNP contains 8 proteins as well as the RNA. The secondary structure of the U1 snRNA is drawn in **Figure 24.9**. It contains several domains. The Sm-binding site is required for interaction with the common snRNP proteins. Domains identified by the individual stem-loop structures provide binding sites for proteins that are unique to U1 snRNP.

**Figure 24.9** U1 snRNA has a base paired structure that creates several domains. The 5' end remains single stranded and can base pair with the 5' splicing site.

Binding of U1 snRNP to the 5' splice site is the first step in splicing. The recruitment of U1 snRNP involves an interaction between one of its proteins (U1-70k) and the protein ASF/SF2 (a general splicing factor in the SR class: see below). U1 snRNA base pairs with the 5' site by means of a single-stranded region at its 5' –terminus which usually includes a stretch of 4-6 bases that is complementary with the splice site.

Mutations in the 5' splice site and U1 snRNA can be used to test directly whether pairing between them is necessary. The results of such an experiment are illustrated in **Figure 24.10**. The wild-type sequence of the splice site of the 12S adenovirus pre-mRNA pairs at 5 out of 6 positions with U1 snRNA. A mutant in the 12S RNA that cannot be spliced has two sequence changes; the GG residues at positions 5-6 in the intron are changed to AU. The mutation changes the pattern of base pairing between U1 snRNA and the 5' splice site, although it does not alter the *overall* extent of pairing (because complementarity is lost at one position and gained at the other). The effect on splicing suggests that the base-pairing interaction is important.

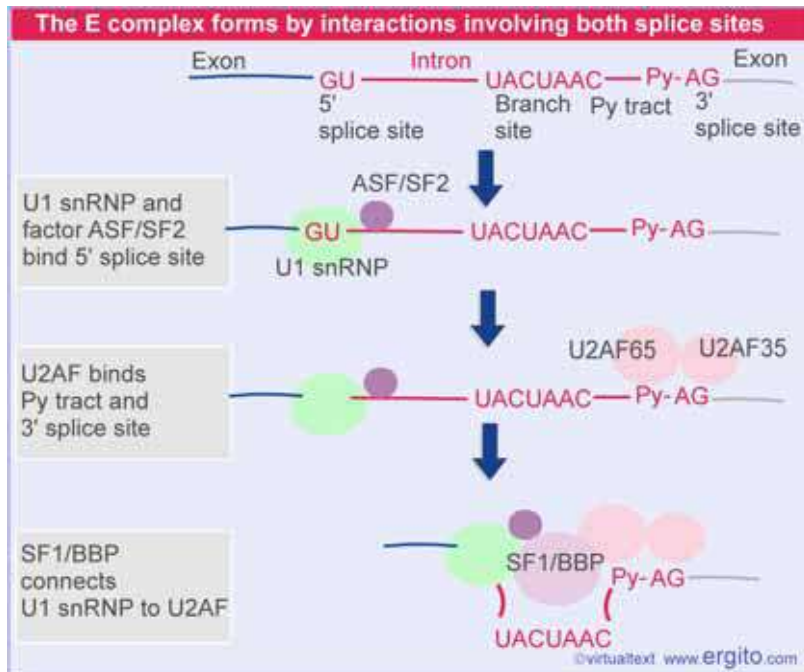

**Figure 24.10** Mutations that abolish function of the 5' splicing site can be suppressed by compensating mutations in U1 snRNA that restore base pairing.

When a mutation is introduced into U1 snRNA that restores pairing at position 5, normal splicing is regained. Other cases in which corresponding mutations are made in U1 snRNA to see whether they can suppress the mutation in the splice site suggests the general rule: complementarity between U1 snRNA and the 5' splice site is necessary for splicing, but the efficiency of splicing is not determined solely by the number of base pairs that can form (714). The pairing reaction is stabilized by the proteins of the U1 snRNP (3246).

**Figure 24.11** shows the early stages of splicing. The first complex formed during splicing is the E (early presplicing) complex, which contains U1 snRNP, the splicing factor U2AF, and members of a family called **SR proteins**, which comprise an important group of splicing factors and regulators. They take their name from the

presence of an Arg-Ser-rich region that is variable in length. SR proteins interact with one another via their Arg-Ser-rich regions. They also bind to RNA. They are an essential component of the spliceosome, forming a framework on the RNA substrate. They connect U2AF to U1 (see **Figure 24.12**). The E complex is sometimes called the commitment complex, because its formation identifies a pre-mRNA as a substrate for formation of the splicing complex.

**Figure 24.11** The commitment (E) complex forms by the successive addition of U1 snRNP to the 5' splice site, U2AF to the pyrimidine tract/3' splice site, and the bridging protein SF1/BBP.

In the E complex, U2AF is bound to the region between the branch site and the 3' splice site. The name of U2AF reflects its original isolation as the U2 auxiliary factor. In most organisms, it has a large subunit (U2AF65) that contacts a pyrimidine tract downstream of the branch site, while a small subunit (U2AF35) directly contacts the dinucleotide AG at the 3' splice site (3247; 3248; 3249). In *S. cerevisiae*, this function is filled by the protein Mud2, which is a counterpart of U2AF65, and binds only to the pyrimidine tract. This marks a difference in the mechanism of splicing between *S. cerevisiae* and other organisms. In the yeast, the 3' splice site is not involved in the early stages of forming the splicing complex, but in all other known cases, it is required.

Another splicing factor, called SF1 in mammals and BBP in yeast, connects U2AF/Mud2 to the U1 snRNP bound at the 5' splice site (3250; 3251). Complex formation is enhanced by the cooperative reactions of the two proteins; SF1 and U2AF (or BBP and Mud2) bind together to the RNA substrate  $\sim 10\times$  more effectively than either alone. This interaction is probably responsible for making the first connection between the two splice sites across the intron.

The E complex is converted to the A complex when U2 snRNP binds to the branch site. Both U1 snRNP and U2AF/Mud2 are needed for U2 binding. The U2 snRNA

includes sequences complementary to the branch site. A sequence near the 5' end of the snRNA base pairs with the branch sequence in the intron. In yeast this typically involves formation of a duplex with the UACUAAC box (see **Figure 24.14**). Several proteins of the U2 snRNP are bound to the substrate RNA just upstream of the branch site. The addition of U2 snRNP to the E complex generates the A presplicing complex. The binding of U2 snRNP requires ATP hydrolysis, and commits a pre-mRNA to the splicing pathway (1560; 718).

## RNA SPLICING AND PROCESSING

### 5.24.7 The E complex can be formed by intron definition or exon definition

---

#### Key Terms

**Intron definition** describes the process when a pair of splicing sites are recognized by interactions involving only the 5' site and the branchpoint/3' site.

**Exon definition** describes the process when a pair of splicing sites are recognized by interactions involving the 5' site of the intron and also the 5' of the next intron downstream.

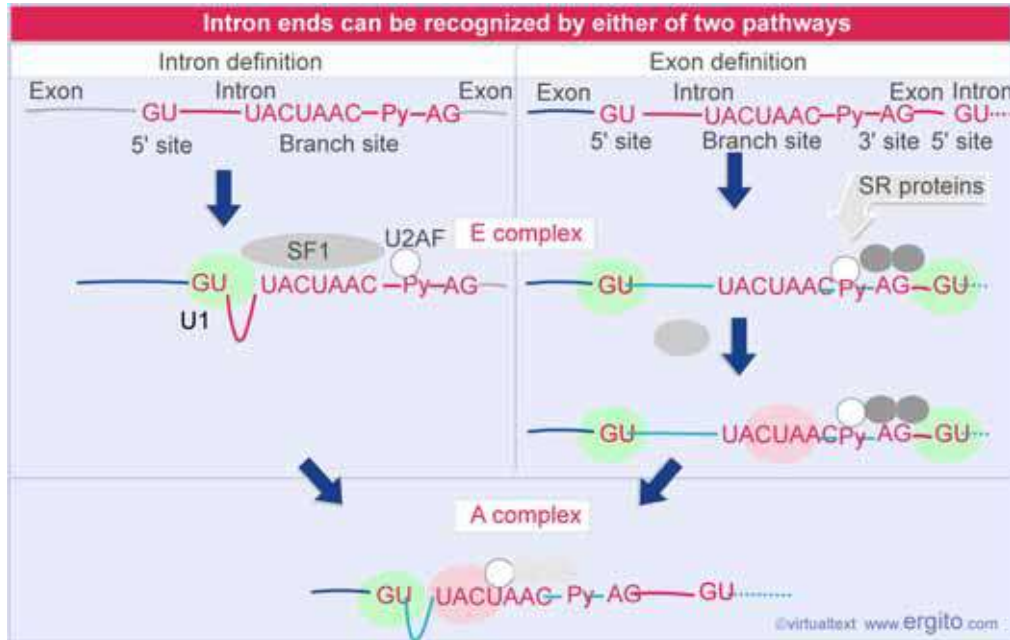

#### Key Concepts

- The direct way of forming an E complex is for U1 snRNP to bind at the 5' splice site and U2AF to bind at a pyrimidine tract between the branch site and the 3' splice site.
- Another possibility is for the complex to form between U2AF at the pyrimidine tract and U1 snRNP at a downstream 5' splice site.
- The E complex is converted to the A complex when U2 snRNP binds at the branch site.
- If an E complex forms using a downstream 5' splice site, this splice site is replaced by the appropriate upstream 5' splice site when the E complex is converted to the A complex.
- Weak 3' splice sites may require a splicing enhancer located in the exon downstream to bind SR proteins directly.

---

There is more than one way to form the E complex. **Figure 24.12** illustrates some possibilities. The most direct reaction is for both splice sites to be recognized across the intron. The presence of U1 snRNP at the 5' splice site is necessary for U2AF to bind at the pyrimidine tract downstream of the branch site, making it possible that the 5' and 3' ends of the intron are brought together in this complex. The E complex is converted to the A complex when U2 snRNP binds at the branch site. *The basic feature of this route for splicing is that the two splice sites are recognized without requiring any sequences outside of the intron.* This process is called **intron definition**.

**Figure 24.12** There may be multiple routes for initial recognition of 5' and 3' splice sites.

In an extreme case, the SR proteins may enable U2AF/U2 snRNP to bind *in vitro* in the absence of U1, raising the possibility that there could be a U1-independent pathway for splicing.

An alternative route to form the spliceosome may be followed when the introns are long and the splice sites are weak. As shown on the right of the figure, the 5' splice site is recognized by U1 snRNA in the usual way. However, the 3' splice site is recognized as part of a complex that forms across the *next exon*, in which the next 5' splice site is also bound by U1 snRNA. This U1 snRNA is connected by SR proteins to the U2AF at the pyrimidine tract. When U2 snRNP joins to generate the A complex, there is a rearrangement, in which the correct (leftmost) 5' splice site displaces the downstream 5' splice site in the complex. The important feature of this route for splicing is that sequences downstream of the intron itself are required. Usually these sequences include the next 5' splice site. This process is called **exon definition**. This mechanism is not universal: neither SR proteins nor exon definition are found in *S. cerevisiae*.

"Weak" 3' splice sites do not bind U2AF and U2 snRNP effectively. Additional sequences are needed to bind the SR proteins, which assist U2AF in binding to the pyrimidine tract. Such sequences are called "splicing enhancers," and they are most commonly found in the exon downstream of the 3' splice site (734).

## RNA SPLICING AND PROCESSING

### 5.24.8 5 snRNPs form the spliceosome

---

#### Key Concepts

- Binding of U5 and U4/U6 snRNPs converts the A complex to the B1 spliceosome, which contains all the components necessary for splicing.
- The spliceosome passes through a series of further complexes as splicing proceeds.
- Release of U1 snRNP allows U6 snRNA to interact with the 5' splice site, and converts the B1 spliceosome to the B2 spliceosome.
- When U4 dissociates from U6 snRNP, U6 snRNA can pair with U2 snRNA to form the catalytic active site.

---

Following formation of the E complex, the other snRNPs and factors involved in splicing associate with the complex in a defined order. **Figure 24.13** shows the components of the complexes that can be identified as the reaction proceeds.

**Figure 24.13** The splicing reaction proceeds through discrete stages in which spliceosome formation involves the interaction of components that recognize the consensus sequences.

The B1 complex is formed when a trimer containing the U5 and U4/U6 snRNPs binds to the A complex containing U1 and U2 snRNPs. This complex is regarded as a spliceosome, since it contains the components needed for the splicing reaction. It is converted to the B2 complex after U1 is released. The dissociation of U1 is necessary to allow other components to come into juxtaposition with the 5' splice site, most notably U6 snRNA. At this point U5 snRNA changes its position; initially it is close to exon sequences at the 5' splice site, but it shifts to the vicinity of the intron sequences (722).

The catalytic reaction is triggered by the release of U4; this requires hydrolysis of

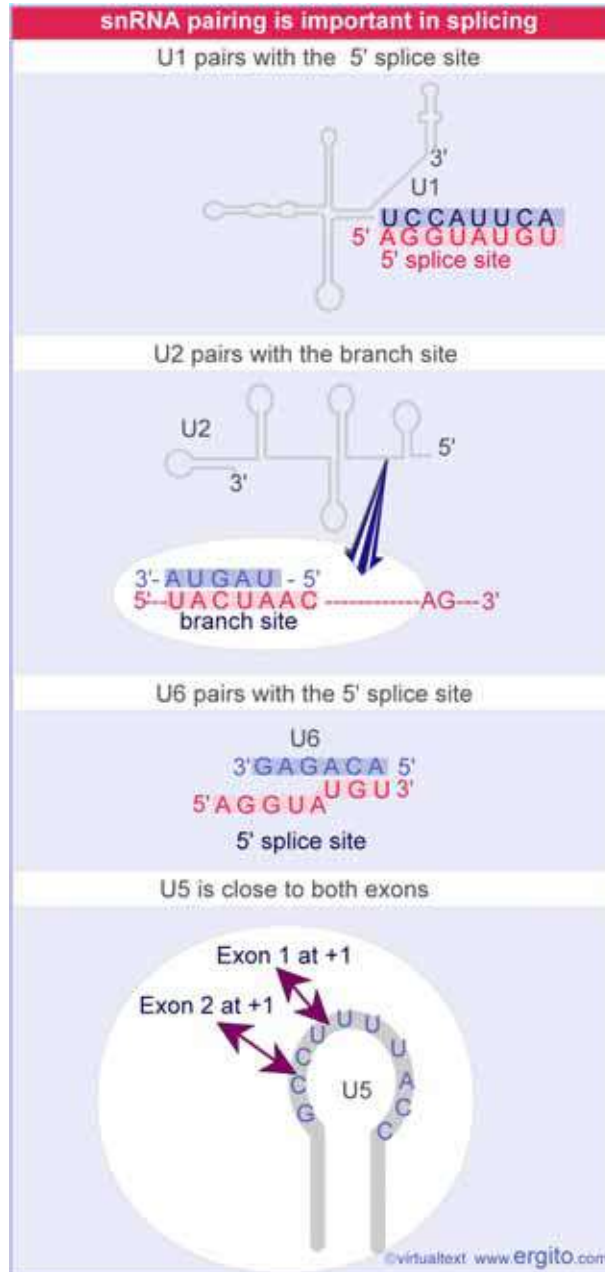

ATP. The role of U4 snRNA may be to sequester U6 snRNA until it is needed. **Figure 24.14** shows the changes that occur in the base pairing interactions between snRNAs during splicing. In the U6/U4 snRNP, a continuous length of 26 bases of U6 is paired with two separated regions of U4. When U4 dissociates, the region in U6 that is released becomes free to take up another structure. The first part of it pairs with U2; the second part forms an intramolecular hairpin. The interaction between U4 and U6 is mutually incompatible with the interaction between U2 and U6, so the release of U4 controls the ability of the spliceosome to proceed (721; for review see 252).

**Figure 24.14** U6-U4 pairing is incompatible with U6-U2 pairing. When U6 joins the spliceosome it is paired with U4. Release of U4 allows a conformational change in U6; one part of the released sequence forms a hairpin (dark grey), and the other part (black) pairs with U2. Because an adjacent region of U2 is already paired with the branch site, this brings U6 into juxtaposition with the branch. Note that the substrate RNA is reversed from the usual orientation and is shown 3'-5'.

Although for clarity the figure shows the RNA substrate in extended form, the 5' splice site is actually close to the U6 sequence immediately on the 5' side of the stretch bound to U2. This sequence in U6 snRNA pairs with sequences in the intron just downstream of the conserved GU at the 5' splice site (mutations that enhance such pairing improve the efficiency of splicing).

So several pairing reactions between snRNAs and the substrate RNA occur in the course of splicing. They are summarized in **Figure 24.15**. The snRNPs have sequences that pair with the substrate and with one another. They also have single-stranded regions in loops that are in close proximity to sequences in the substrate, and which play an important role, as judged by the ability of mutations in the loops to block splicing.

**Figure 24.15** Splicing utilizes a series of base pairing reactions between snRNAs and splice sites.

The base pairing between U2 and the branch point, and between U2 and U6, creates a structure that resembles the active center of group II self-splicing introns (see **Figure 24.20**). This suggests the possibility that the catalytic component could comprise an RNA structure generated by the U2-U6 interaction. U6 is paired with the 5' splice site, and crosslinking experiments show that a loop in U5 snRNA is immediately adjacent to the first base positions in both exons. But although we can define the proximities of the substrate (5' splice site and branch site) and snurps (U2 and U6) at the catalytic center (as shown in **Figure 24.14**), the components that undertake the transesterifications have not been directly identified (723; 724; 725).

The formation of the lariat at the branch site is responsible for determining the use of the 3' splice site, since the 3' consensus sequence nearest to the 3' side of the branch becomes the target for the second transesterification. The second splicing reaction follows rapidly. Binding of U5 snRNP to the 3' splice site is needed for this reaction, but there is no evidence for a base pairing reaction.

The important conclusion suggested by these results is that *the snRNA components of the splicing apparatus interact both among themselves and with the substrate RNA by means of base pairing interactions, and these interactions allow for changes in structure that may bring reacting groups into apposition and may even create catalytic centers.* Furthermore, the conformational changes in the snRNAs are reversible; for example, U6 snRNA is not used up in a splicing reaction, and at completion must be released from U2, so that it can reform the duplex structure with U4 to undertake another cycle of splicing.

We have described individual reactions in which each snRNP participates, but as might be expected from a complex series of reactions, any particular snRNP may play more than one role in splicing. So the ability of U1 snRNP to promote binding of U2 snRNP to the branch site is independent of its ability to bind to the 5' splice site. Similarly, different regions of U2 snRNA can be defined that are needed to bind to the branch site and to interact with other splicing components.

An extensive mutational analysis has been undertaken in yeast to identify both the RNA and protein components of the spliceosome. Mutations in genes needed for splicing are identified by the accumulation of unspliced precursors. A series of loci that identify genes potentially coding for proteins involved in splicing were originally called *RNA*, but are now known as *PRP* mutants (for pre-RNA processing). Several of the products of these genes have motifs that identify them as RNA-binding proteins, and some appear to be related to a family of ATP-dependent RNA helicases. We suppose that, in addition to RNA-RNA interactions, protein-RNA interactions are important in creating or releasing structures in the pre-mRNA or snRNA components of the spliceosomes.

Some of the PRP proteins are components of snRNP particles, but others function as independent factors. One interesting example is PRP16, a helicase that hydrolyzes ATP, and associates transiently with the spliceosome to participate in the second catalytic step. Another example is PRP22, another ATP-dependent helicase, which is required to release the mature mRNA from the spliceosome. The conservation of bonds during the splicing reaction means that input of energy is not required to drive bond formation *per se*, which implies that the ATP hydrolysis is required for other purposes. The use of ATP by PRP16 and PRP22 may be examples of a more general phenomenon: the use of ATP hydrolysis to drive conformational changes that are needed to proceed through splicing (for review see 254).

## RNA SPLICING AND PROCESSING

### 5.24.9 An alternative splicing apparatus uses different snRNPs

#### Key Concepts

- An alternative splicing pathway uses another set of snRNPs that comprise the U12 spliceosome.
- The target introns are defined by longer consensus sequences at the splice junctions, but usually include the same GU-AG junctions.
- Some introns have the splice junctions AU-AC, including some that are U1-dependent and some that are U12-dependent.

GU-AG introns comprise the vast majority (>98% of splicing junctions in the human genome). <1% use the related junctions GC-AG. And then there is a minor class of introns marked by the ends AU-AC (comprising 0.1% of introns). The first of these introns to be discovered required an alternative splicing apparatus, called the U12 spliceosome, consisting of U11 and U12 (related to U1 and U2, respectively), a U5 variant, and the U4<sup>atac</sup> and U6<sup>atac</sup> snRNAs. The splicing reaction is essentially similar to that at GU-AG introns, and the snRNAs play analogous roles. Whether there are differences in the protein components of this apparatus is not known.

It now turns out that the dependence on the type of spliceosome is also influenced by sequences in the intron, so that there are some AU-AC introns spliced by U2-type spliceosomes, and some GU-AG introns spliced by U12-type spliceosomes. A strong consensus sequence at the left end defines the U12-dependent type of intron: 5' <sup>G</sup>UAUCCUUU# ...PyA<sup>G</sup> 3'. In fact, most U12-dependent introns have the GU...<sup>A</sup>AG termini. In addition, they have a highly conserved branch point, UCCUUPuAPy, which pairs with U12. For this reason, the term U12-dependent intron is used rather than AU-AC intron.

The two types of introns coexist in a variety of genomes, and in some cases are found in the same gene. U12-dependent introns tend to be flanked by U2-dependent introns. What is known about the phylogeny of these introns suggests that AU-AC U12-dependent introns may once have been more common, but tend to be converted to GU-AG termini, and to U2-dependence, in the course of evolution (726; 727; 728). The common evolution of the systems is emphasized by the fact that they use analogous sets of base pairing between the snRNAs and with the substrate pre-mRNA.

The involvement of snRNPs in splicing is only one example of their involvement in RNA processing reactions. snRNPs are required for several reactions in the processing of nuclear RNA to mature rRNAs. Especially in view of the demonstration that group I introns are self-splicing, and that the RNA of ribonuclease P has catalytic activity (as discussed in *Molecular Biology 5.26 Catalytic RNA*), it is plausible to think that RNA-RNA reactions are important in many RNA processing

events.

## RNA SPLICING AND PROCESSING

### 5.24.10 Splicing is connected to export of mRNA

---

#### Key Concepts

- The REF proteins bind to splicing junctions by associating with the spliceosome.
  - After splicing, they remain attached to the RNA at the exon-exon junction.
  - They interact with the transport protein TAP/Mex that exports the RNA through the nuclear pore.
- 

After it has been synthesized and processed, mRNA is exported from the nucleus to the cytoplasm in the form of a ribonucleoprotein complex. The proteins that are responsible for transport "shuttle" between the nucleus and cytoplasm, remaining in the compartment only briefly (see *Molecular Biology 2.8.28 Transport receptors carry cargo proteins through the pore*). One important question is how these proteins recognize their RNA substrates, and what ensures that only fully processed mRNAs are exported. Part of the answer may lie in the relative timing of events: spliceosomes may form to remove introns before transcription has been completed. However, there may also be a direct connection between splicing and export.

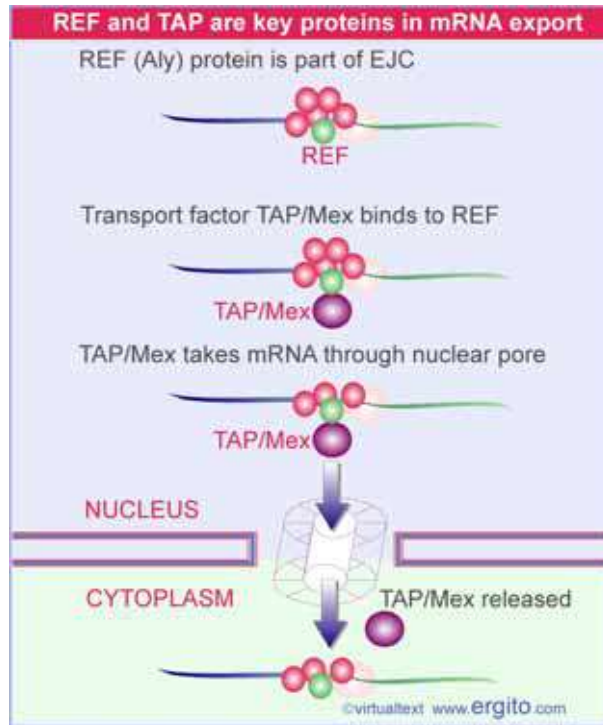

Introns may prevent export of mRNA because they are associated with the splicing apparatus. The spliceosome also may provide the initial point of contact for the export apparatus. **Figure 24.16** shows a model in which a protein complex binds to the RNA via the splicing apparatus. The complex consists of >9 proteins and is called the EJC (exon junction complex).

**Figure 24.16** The EJC (exon junction complex) binds to RNA by recognizing the splicing complex.

The EJC is involved in several functions of spliced mRNAs (for review see 3428). Some of the proteins of the EJC are directly involved in these functions, and others recruit additional proteins for particular functions. The first contact in assembling the EJC is made with one of the splicing factors (2072; 2073; 2074). Then after splicing, the EJC remains attached to the mRNA just upstream of the exon-exon junction (2071; 2075; 3232; 3233). The EJC is not associated with RNAs transcribed from genes that lack introns, so its involvement in the process is unique for spliced products.

If introns are deleted from a gene, its RNA product is exported much more slowly to the cytoplasm (2069). This suggests that the intron may provide a signal for attachment of the export apparatus. We can now account for this phenomenon in terms of a series of protein interactions, as shown in **Figure 24.17**. The EJC includes a group of proteins called the REF family (the best characterized member is called Aly) (2070). The REF proteins in turn interact with a transport protein (variously called TAP and Mex) which has direct responsibility for interaction with the nuclear pore (for review see 2422).

**Figure 24.17** A REF protein binds to a splicing factor and remains with the spliced RNA product. REF binds to an export factor that binds to the nuclear pore.

A similar system may be used to identify a spliced RNA so that nonsense mutations prior to the last exon trigger its degradation in the cytoplasm (see *Molecular Biology 2.5.14 Nonsense mutations trigger a surveillance system*).

## RNA SPLICING AND PROCESSING

### 5.24.11 Group II introns autosplice via lariat formation

---

#### Key Terms

**Autosplicing (Self-splicing)** describes the ability of an intron to excise itself from an RNA by a catalytic action that depends only on the sequence of RNA in the intron.

#### Key Concepts

- Group II introns excise themselves from RNA by an autocatalytic splicing event.
- The splice junctions and mechanism of splicing of group II introns are similar to splicing of nuclear introns.
- A group II intron folds into a secondary structure that generates a catalytic site resembling the structure of U6-U2-nuclear intron.

---

Introns in protein-coding genes (in fact, in all genes except nuclear tRNA-coding genes) can be divided into three general classes. Nuclear pre-mRNA introns are identified only by the possession of the GU...AG dinucleotides at the 5' and 3' ends and the branch site/pyrimidine tract near the 3' end. They do not show any common features of secondary structure. Group I and group II introns are found in organelles and in bacteria. (Group I introns are found also in the nucleus in lower eukaryotes.) Group I and group II introns are classified according to their internal organization. Each can be folded into a typical type of secondary structure.

The group I and group II introns have the remarkable ability to excise themselves from an RNA. This is called **autosplicing**. Group I introns are more common than group II introns. There is little relationship between the two classes, but in each case the RNA can perform the splicing reaction *in vitro* by itself, without requiring enzymatic activities provided by proteins; however, proteins are almost certainly required *in vivo* to assist with folding (see *Molecular Biology 5.26 Catalytic RNA*).

**Figure 24.18** shows that three classes of introns are excised by two successive transesterifications (shown previously for nuclear introns in **Figure 24.6**). In the first reaction, the 5' exon-intron junction is attacked by a free hydroxyl group (provided by an internal 2' -OH position in nuclear and group II introns, and by a free guanine nucleotide in group I introns). In the second reaction, the free 3' -OH at the end of the released exon in turn attacks the 3' intron-exon junction.

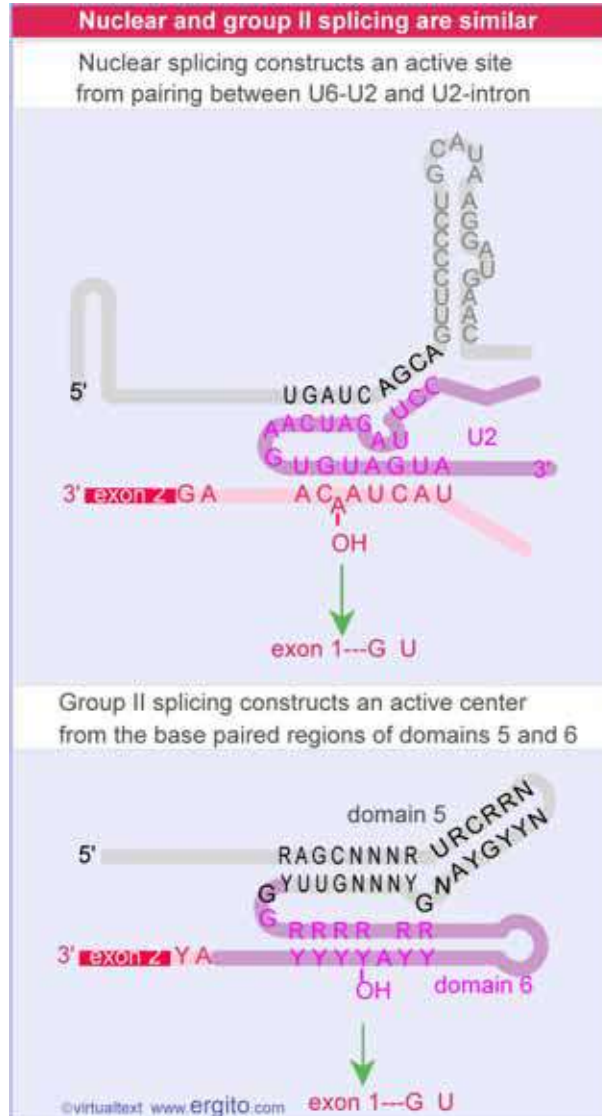

**Figure 24.18** Three classes of splicing reactions proceed by two transesterifications. First, a free OH group attacks the exon 1–intron junction. Second, the OH created at the end of exon 1 attacks the intron–exon 2 junction.

There are parallels between group II introns and pre-mRNA splicing. Group II mitochondrial introns are excised by the same mechanism as nuclear pre-mRNAs, via a lariat that is held together by a 5'–2' bond. An example of a lariat produced by splicing a group II intron is shown in **Figure 24.19**. When an isolated group II RNA is incubated *in vitro* in the absence of additional components, it is able to perform the splicing reaction. This means that the two transesterification reactions shown in **Figure 24.18** can be performed by the group II intron RNA sequence itself. Because the number of phosphodiester bonds is conserved in the reaction, an external supply of energy is not required; this could have been an important feature in the evolution of splicing (for review see 260).

**Figure 24.19** Splicing releases a mitochondrial group II intron in the form of a stable lariat. Photograph kindly provided by Leslie Grivell and Annika Arnberg.

A group II intron forms into a secondary structure that contains several domains formed by base-paired stems and single-stranded loops. Domain 5 is separated by 2 bases from domain 6, which contains an A residue that donates the 2'-OH group for the first transesterification. This constitutes a catalytic domain in the RNA. **Figure 24.20** compares this secondary structure with the structure formed by the combination of U6 with U2 and of U2 with the branch site. The similarity suggests that U6 may have a catalytic role.

**Figure 24.20** Nuclear splicing and group II splicing involve the formation of similar secondary structures. The sequences are more specific in nuclear splicing; group II splicing uses positions that may be occupied by either purine (R) or either pyrimidine (Y).

The features of group II splicing suggest that splicing evolved from an autocatalytic reaction undertaken by an individual RNA molecule, in which it accomplished a controlled deletion of an internal sequence. Probably such a reaction requires the RNA to fold into a specific conformation, or series of conformations, and would occur exclusively in *cis* conformation.

The ability of group II introns to remove themselves by an autocatalytic splicing event stands in great contrast to the requirement of nuclear introns for a complex splicing apparatus. We may regard the snRNAs of the spliceosome as compensating for the lack of sequence information in the intron, and providing the information required to form particular structures in RNA. The functions of the snRNAs may

have evolved from the original autocatalytic system. These snRNAs act in *trans* upon the substrate pre-mRNA; we might imagine that the ability of U1 to pair with the 5' splice site, or of U2 to pair with the branch sequence, replaced a similar reaction that required the relevant sequence to be carried by the intron. So the snRNAs may undergo reactions with the pre-mRNA substrate and with one another that have substituted for the series of conformational changes that occur in RNAs that splice by group II mechanisms. In effect, these changes have relieved the substrate pre-mRNA of the obligation to carry the sequences needed to sponsor the reaction. As the splicing apparatus has become more complex (and as the number of potential substrates has increased), proteins have played a more important role.

## RNA SPLICING AND PROCESSING

### 5.24.12 Alternative splicing involves differential use of splice junctions

---

#### Key Terms

**Alternative splicing** describes the production of different RNA products from a single product by changes in the usage of splicing junctions.

#### Key Concepts

- Specific exons may be excluded or included in the RNA product by using or failing to use a pair of splicing junctions.
- Exons may be extended by changing one of the splice junctions to use an alternative junction.
- Sex determination in *Drosophila* involves a series of alternative splicing events in genes coding for successive products of a pathway.
- P elements of *Drosophila* show germline-specific alternative splicing.

---

When an interrupted gene is transcribed into an RNA that gives rise to a single type of spliced mRNA, there is no ambiguity in assignment of exons and introns. But the RNAs of some genes follow patterns of **alternative splicing**, when a single gene gives rise to more than one mRNA sequence. In some cases, the ultimate pattern of expression is dictated by the primary transcript, because the use of different startpoints or the generation of alternative 3' ends alters the pattern of splicing. In other cases, a single primary transcript is spliced in more than one way, and internal exons are substituted, added, or deleted. In some cases, the multiple products all are made in the same cell, but in others the process is regulated so that particular splicing patterns occur only under particular conditions (for review see 246).

One of the most pressing questions in splicing is to determine what controls the use of such alternative pathways. Proteins that intervene to bias the use of alternative splice sites have been identified in two ways. In some mammalian systems, it has been possible to characterize alternative splicing *in vitro*, and to identify proteins that are required for the process. In *D. melanogaster*, aberrations in alternative splicing may be caused either by mutations in the genes that are alternatively spliced or in the genes whose products are necessary for the reaction.

**Figure 24.21** shows examples of alternative splicing in which one splice site remains constant, but the other varies. The large T/ small t antigens of SV40 and the products of the adenovirus E1A region are generated by connecting a varying 5' site to a constant 3' site. In the case of the T/t antigens, the 5' site used for T antigen removes a termination codon that is present in the t antigen mRNA, so that T antigen is larger than t antigen. In the case of the E1A transcripts, one of the 5' sites connects to the last exon in a different reading frame, again making a significant change in the C-terminal part of the protein. In these examples, all the relevant

splicing events take place in every cell in which the gene is expressed, so all the protein products are made.

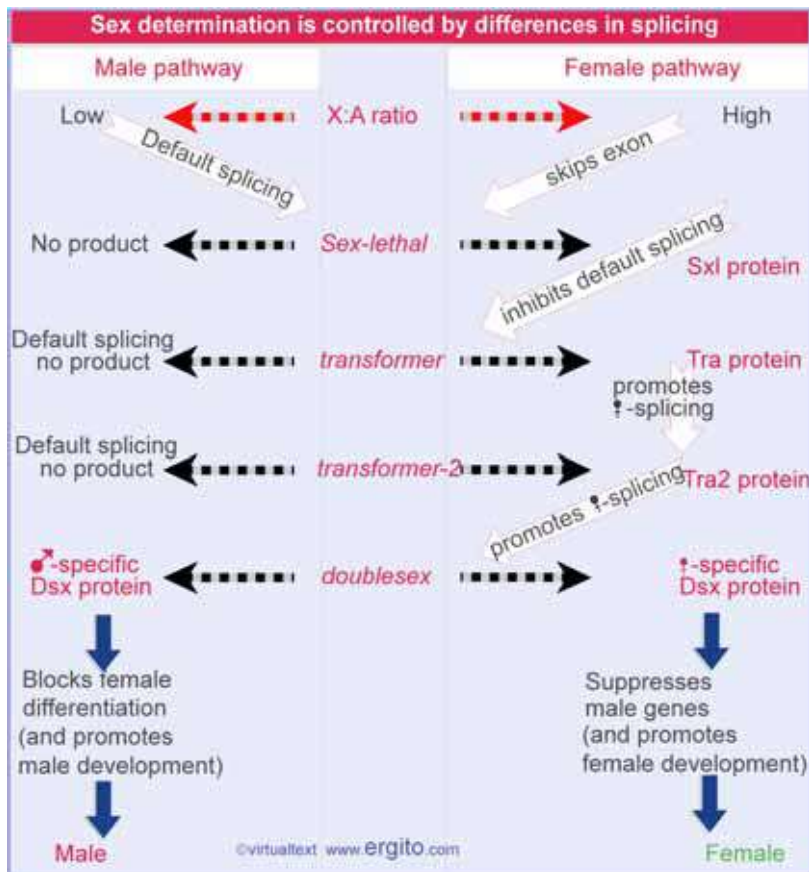

**Figure 24.21** Alternative forms of splicing may generate a variety of protein products from an individual gene. Changing the splice sites may introduce termination codons (shown by asterisks) or change reading frames.

There are differences in the ratios of T/t antigens in different cell types. A protein extracted from cells that produce relatively more small t antigen can cause preferential production of small t RNA in extracts from other cell types. This protein, which was called ASF (alternative splicing factor), turns out to be the same as the splicing factor SF2, which is required for early steps in spliceosome assembly and for the first cleavage-ligation reaction (see **Figure 24.13**). ASF/SF2 is an RNA-binding protein in the SR family. When a pre-mRNA has more than one 5' splice site preceding a single 3' splice site, increased concentrations of ASF/SF2 promote use of the 5' site nearest to the 3' site at the expense of the other site (3316; 3317). This effect of ASF/SF2 can be counteracted by another splicing factor, SF5.

The exact molecular roles of the factors in controlling splice utilization are not yet known, but we see in general terms that alternative splicing involving different 5' sites may be influenced by proteins involved in spliceosome assembly. In the case of T/t antigens, the effect probably rests on increased binding of the SR proteins to the site that is preferentially used. Alternative splicing also may be influenced by repression of one site. Exons 2 and 3 of the mouse troponin T gene are mutually exclusive; exon 2 is used in smooth muscle, but exon 3 is used in other tissues. Smooth muscle contains proteins that bind to repeated elements located on either side of exon 3, and which prevent use of the 3' and 5' sites that are needed to include it.

The pathway of sex determination in *D. melanogaster* involves interactions between a series of genes in which alternative splicing events distinguish male and female. The pathway takes the form illustrated in **Figure 24.22**, in which the ratio of X chromosomes to autosomes determines the expression of *sxl*, and changes in expression are passed sequentially through the other genes to *dsx*, the last in the pathway.

**Figure 24.22** Sex determination in *D. melanogaster* involves a pathway in which different splicing events occur in females. Blocks at any stage of the pathway result in male development.

The pathway starts with sex-specific splicing of *sxl*. Exon 3 of the *sxl* gene contains a termination codon that prevents synthesis of functional protein. This exon is included in the mRNA produced in males, but is skipped in females. (Exon skipping

illustrated for another example in **Figure 24.23**.) As a result, only females produce Sxl protein. The protein has a concentration of basic amino acids that resembles other RNA-binding proteins.

The presence of Sxl protein changes the splicing of the *transformer (tra)* gene. **Figure 24.21** shows that this involves splicing a constant 5' site to alternative 3' sites. One splicing pattern occurs in both males and females, and results in an RNA that has an early termination codon. The presence of Sxl protein inhibits usage of the normal 3' splice site by binding to the polypyrimidine tract at its branch site (3319). When this site is skipped, the next 3' site is used. This generates a female-specific mRNA that codes for a protein.

So *tra* produces a protein only in females; this protein is a splicing regulator. *tra2* has a similar function in females (but is also expressed in the male germline). The Tra and Tra2 proteins are SR splicing factors that act directly upon the target transcripts. Tra and Tra2 cooperate (in females) to affect the splicing of *dsx*.

**Figure 24.23** shows examples of cases in which splice sites are used to add or to substitute exons or introns, again with the consequence that different protein products are generated. In the *doublesex (dsx)* gene, females splice the 5' site of intron 3 to the 3' site of that intron; as a result translation terminates at the end of exon 4. Males splice the 5' site of intron 3 directly to the 3' site of intron 4, thus omitting exon 4 from the mRNA, and allowing translation to continue through exon 6. The result of the alternative splicing is that different proteins are produced in each sex: the male product blocks female sexual differentiation, while the female product represses expression of male-specific genes.

**Figure 24.23** Alternative splicing events that involve both sites may cause exons to be added or substituted.

Alternative splicing of *dsx* RNA is controlled by competition between 3' splice sites. *dsx* RNA has an element downstream of the leftmost 3' splice site that is bound by Tra2; Tra and SR proteins associate with Tra2 at the site, which becomes an enhancer that assists binding of U2AF at the adjacent pyrimidine tract (3320; 3321). This commits the formation of the spliceosome to use this 3' site in females rather than the alternative 3' site. The proteins recognize the enhancer cooperatively, possibly relying on formation of some secondary structure as well as sequence *per se*.

Sex determination therefore has a pleasing symmetry: the pathway starts with a female-specific splicing event that causes omission of an exon that has a termination codon, and ends with a female-specific splicing event that causes inclusion of an exon that has a termination codon. The events have different molecular bases. At the first control point, Sxl inhibits the default splicing pattern. At the last control point, Tra and Tra2 cooperate to promote the female-specific splice.

The Tra and Tra2 proteins are not needed for normal splicing, because in their absence flies develop normally (as males). As specific regulators, they need not necessarily participate in the mechanics of the splicing reaction; in this respect they differ from SF2, which is a factor required for general splicing, but can also

influence choice of alternative splice sites.

P elements of *D. melanogaster* show a tissue-specific splicing pattern. In somatic cells, there are two splicing events, but in germline an additional splicing event removes another intron. Because a termination codon lies in the germline-specific intron, a longer protein (with different properties) is produced in germline. We discuss the consequences for control of transposition in *Molecular Biology 4.16.15 P elements are activated in the germline*, and note for now that the tissue specificity results from differences in the splicing apparatus.

The default splicing pathway of the P element pre-mRNA when the RNA is subjected to a heterologous (human) splicing extract is the germline pattern, in which intron 3 is excised. But extracts of somatic cells of *D. melanogaster* contain a protein that inhibits excision of this intron. The protein binds to sequences in exon 3; if these sequences are deleted, the intron is excised. The function of the protein is therefore probably to repress association of the spliceosome with the 5' site of intron 3.

## RNA SPLICING AND PROCESSING

### 5.24.13 *trans*-splicing reactions use small RNAs

---

#### Key Terms

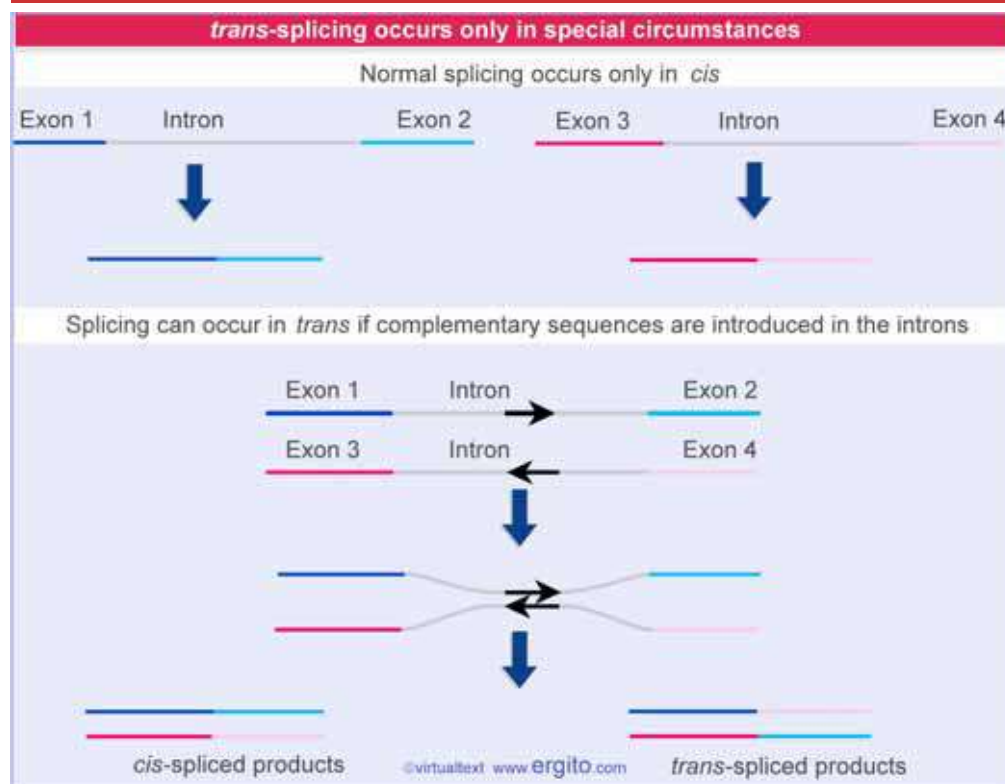

**SL RNA (Spliced leader RNA)** is a small RNA that donates an exon in the *trans*-splicing reaction of trypanosomes and nematodes.

#### Key Concepts

- Splicing reactions usually occur only in *cis* between splice junctions on the same molecule of RNA.
- *trans*-splicing occurs in trypanosomes and worms where a short sequence (SL RNA) is spliced to the 5' ends of many precursor mRNAs.
- SL RNA has a structure resembling the Sm-binding site of U snRNAs and may play an analogous role in the reaction.

---

In both mechanistic and evolutionary terms, splicing has been viewed as an *intramolecular* reaction, amounting essentially to a controlled deletion of the intron sequences at the level of RNA. In genetic terms, splicing occurs only in *cis*. This means that *only sequences on the same molecule of RNA can be spliced together*. The upper part of **Figure 24.24** shows the normal situation. The introns can be removed from each RNA molecule, allowing the exons of that RNA molecule to be spliced together, but there is no *intermolecular* splicing of exons between different RNA molecules. We cannot say that *trans* splicing never occurs between pre-mRNA transcripts of the same gene, but we know that it must be exceedingly rare, because if it were prevalent the exons of a gene would be able to complement one another genetically instead of belonging to a single complementation group.

**Figure 24.24** Splicing usually occurs only in *cis* between exons carried on the same physical RNA molecule, but *trans* splicing can occur when special constructs are made that support base pairing between introns.

Some manipulations can generate *trans*-splicing. In the example illustrated in the lower part of **Figure 24.24**, complementary sequences were introduced into the introns of two RNAs. Base pairing between the complements should create an H-shaped molecule. This molecule could be spliced in *cis*, to connect exons that are covalently connected by an intron, or it could be spliced in *trans*, to connect exons of the juxtaposed RNA molecules. Both reactions occur *in vitro*.

Another situation in which *trans*-splicing is possible *in vitro* occurs when substrate RNAs are provided in the form of one containing a 5' splice site and the other containing a 3' splice site together with appropriate downstream sequences (which may be either the next 5' splice site or a splicing enhancer). In effect, this mimics splicing by exon definition (see the right side of **Figure 24.12**), and shows that *in vitro* it is not necessary for the left and right splice sites to be on the same RNA molecule.

These results show that there is no *mechanistic* impediment to *trans*-splicing. They exclude models for splicing that require processive movement of a spliceosome along the RNA. It must be possible for a spliceosome to recognize the 5' and 3' splice sites of different RNAs when they are in close proximity.

Although *trans*-splicing is rare, it occurs *in vivo* in some special situations. One is revealed by the presence of a common 35 base leader sequence at the end of numerous mRNAs in the trypanosome. But the leader sequence is not coded

upstream of the individual transcription units. Instead it is transcribed into an independent RNA, carrying additional sequences at its 3' end, from a repetitive unit located elsewhere in the genome. **Figure 24.25** shows that this RNA carries the 35 base leader sequence followed by a 5' splice site sequence. The sequences coding for the mRNAs carry a 3' splice site just preceding the sequence found in the mature mRNA (730).

**Figure 24.25** The SL RNA provides an exon that is connected to the first exon of an mRNA by *trans*-splicing. The reaction involves the same interactions as nuclear *cis*-splicing, but generates a Y-shaped RNA instead of a lariat.

When the leader and the mRNA are connected by a *trans*-splicing reaction, the 3' region of the leader RNA and the 5' region of the mRNA in effect comprise the 5' and 3' halves of an intron. When splicing occurs, a 5'–2' link forms by the usual reaction between the GU of the 5' intron and the branch sequence near the AG of the 3' intron. Because the two parts of the intron are not covalently linked, this generates a Y-shaped molecule instead of a lariat (729).

A similar situation is presented by the expression of actin genes in *C. elegans*. Three actin mRNAs (and some other RNAs) share the same 22 base leader sequence at the 5' terminus. The leader sequence is not coded in the actin gene, but is transcribed independently as part of a 100 base RNA coded by a gene elsewhere. *trans*-splicing also occurs in chloroplasts (731).

The RNA that donates the 5' exon for *trans* splicing is called the **SL RNA** (spliced leader RNA). The SL RNAs found in several species of trypanosomes and also in the nematode (*C. elegans*) have some common features. They fold into a common secondary structure that has three stem-loops and a single-stranded region that

resembles the Sm-binding site. The SL RNAs therefore exist as snRNPs that count as members of the Sm snRNP class. Trypanosomes possess the U2, U4, and U6 snRNAs, but do not have U1 or U5 snRNAs. The absence of U1 snRNA can be explained by the properties of the SL RNA, which can carry out the functions that U1 snRNA usually performs at the 5' splice site; thus SL RNA in effect consists of an snRNA sequence possessing U1 function, linked to the exon-intron site that it recognizes.

There are two types of SL RNA in *C. elegans*. SL1 RNA (the first to be discovered) is used for splicing to coding sequences that are preceded only by 5' nontranslated regions (the most common situation). SL2 RNA is used in cases in which a pre-mRNA contains two coding sequences; it is spliced to the second sequence, thus releasing it from the first, and allowing it to be used as an independent mRNA (732; 733; for review see 250). About 15% of all genes in *C. elegans* are organized in transcription units that include more than one gene (most often 2-3 genes) (2862). The significance of this form of organization for control of gene expression is not clear. These transcription units do not generally resemble operons where the genes function coordinately in a pathway.

The *trans*-splicing reaction of the SL RNA may represent a step towards the evolution of the pre-mRNA splicing apparatus. The SL RNA provides in *cis* the ability to recognize the 5' splice site, and this probably depends upon the specific conformation of the RNA. The remaining functions required for splicing are provided by independent snRNPs. The SL RNA can function without participation of proteins like those in U1 snRNP, which suggests that the recognition of the 5' splice site depends directly on RNA.

## RNA SPLICING AND PROCESSING

### 5.24.14 Yeast tRNA splicing involves cutting and rejoining

---

#### Key Terms

An **RNA ligase** is an enzyme that functions in tRNA splicing to make a phosphodiester bond between the two exon sequences that are generated by cleavage of the intron.

#### Key Concepts

- tRNA splicing occurs by successive cleavage and ligation reactions.

---

Most splicing reactions depend on short consensus sequences and occur by transesterification reactions in which breaking and making of bonds is coordinated. The splicing of tRNA genes is achieved by a different mechanism that relies upon separate cleavage and ligation reactions.

Some 59 of the 272 nuclear tRNA genes in the yeast *S. cerevisiae* are interrupted. Each has a single intron, located just one nucleotide beyond the 3' side of the anticodon. The introns vary in length from 14-60 bp. Those in related tRNA genes are related in sequence, but the introns in tRNA genes representing different amino acids are unrelated. *There is no consensus sequence that could be recognized by the splicing enzymes.* This is also true of interrupted nuclear tRNA genes of plants, amphibians, and mammals.

All the introns include a sequence that is complementary to the anticodon of the tRNA. This creates an alternative conformation for the anticodon arm in which the anticodon is base paired to form an extension of the usual arm. An example is drawn in **Figure 24.26**. Only the anticodon arm is affected – the rest of the molecule retains its usual structure.

**Figure 24.26** The intron in yeast tRNA<sup>Phe</sup> base pairs with the anticodon to change the structure of the anticodon arm. Pairing between an excluded base in the stem and the intron loop in the precursor may be required for splicing.

The exact sequence and size of the intron is not important. Most mutations in the intron do not prevent splicing. *Splicing of tRNA depends principally on recognition of a common secondary structure in tRNA rather than a common sequence of the intron.* Regions in various parts of the molecule are important, including the stretch between the acceptor arm and D arm, in the T $\psi$ C arm, and especially the anticodon arm. This is reminiscent of the structural demands placed on tRNA for protein synthesis (see *Molecular Biology 2.6 Protein synthesis*).

The intron is not entirely irrelevant, however. Pairing between a base in the intron loop and an unpaired base in the stem is required for splicing. Mutations at other positions that influence this pairing (for example, to generate alternative patterns for pairing) influence splicing. The rules that govern availability of tRNA precursors for splicing resemble the rules that govern recognition by aminoacyl-tRNA synthetases (see *Molecular Biology 2.7.9 tRNAs are charged with amino acids by synthetases*).

In a temperature-sensitive mutant of yeast that fails to remove the introns, the interrupted precursors accumulate in the nucleus. The precursors can be used as substrates for a cell-free system extracted from wild-type cells. The splicing of the precursor can be followed by virtue of the resulting size reduction. This is seen by the change in position of the band on gel electrophoresis, as illustrated in **Figure 24.27**. The reduction in size can be accounted for by the appearance of a band representing the intron.

**Figure 24.27** Splicing of yeast tRNA *in vitro* can be followed by assaying the RNA precursor and products by gel electrophoresis.

The cell-free extract can be fractionated by assaying the ability to splice the tRNA. The *in vitro* reaction requires ATP. Characterizing the reactions that occur with and without ATP shows that the *two separate stages of the reaction are catalyzed by different enzymes*.

- The first step does not require ATP. It involves phosphodiester bond cleavage by an atypical nuclease reaction. It is catalyzed by an endonuclease.
- The second step requires ATP and involves bond formation; it is a ligation reaction, and the responsible enzyme activity is described as an **RNA ligase**.

## RNA SPLICING AND PROCESSING

## 5.24.15 The splicing endonuclease recognizes tRNA

## Key Concepts

- An endonuclease cleaves the tRNA precursors at both ends of the intron.
- The yeast endonuclease is a heterotetramer, with two (related) catalytic subunits.
- It uses a measuring mechanism to determine the sites of cleavage by their positions relative to a point in the tRNA structure.
- The archaeal nuclease has a simpler structure and recognizes a bulge-helix-bulge structural motif in the substrate.

The endonuclease is responsible for the specificity of intron recognition. It cleaves the precursor at both ends of the intron. The yeast endonuclease is a heterotetrameric protein. Its activities are illustrated in **Figure 24.28**. The related subunits Sen34 and Sen2 cleave the 3' and 5' splice sites, respectively. Subunit Sen54 may determine the sites of cleavage by "measuring" distance from a point in the tRNA structure. This point is in the elbow of the (mature) L-shaped structure (2878). The role of subunit Sen15 is not known, but its gene is essential in yeast. The base pair that forms between the first base in the anticodon loop and the base preceding the 3' splice site is required for 3' splice site cleavage (735; 736; 737; 2880).

**Figure 24.28** The 3' and 5' cleavages in *S. cerevisiae* pre-tRNA are catalyzed by different subunits of the endonuclease. Another subunit may determine location of the cleavage sites by measuring distance from the mature structure. The AI base pair is also important.

An interesting insight into the evolution of tRNA splicing is provided by the endonucleases of archaea. These are homodimers or homotetramers, in which each subunit has an active site (although only two of the sites function in the tetramer) that

cleaves one of the splice sites (2879). The subunit has sequences related to the sequences of the active sites in the Sen34 and Sen2 subunits of the yeast enzyme. However, the archaeal enzymes recognize their substrates in a different way. Instead of measuring distance from particular sequences, they recognize a structural feature, called the bulge-helix-bulge. **Figure 24.29** shows that cleavage occurs in the two bulges (2877; 2876).

**Figure 24.29** Archaeal tRNA splicing endonuclease cleaves each strand at a bulge in a bulge-helix-bulge motif.

So the origin of splicing of tRNA precedes the separation of the archaea and the eukaryotes. If it originated by insertion of the intron into tRNAs, this must have been a very ancient event.

## RNA SPLICING AND PROCESSING

### 5.24.16 tRNA cleavage and ligation are separate reactions

---

#### Key Concepts

- Release of the intron generates two half-tRNAs that pair to form the mature structure.
  - The halves have the unusual ends 5' hydroxyl and 2'-3' cyclic phosphate.
  - The 5'-OH end is phosphorylated by a polynucleotide kinase, the cyclic phosphate group is opened by phosphodiesterase to generate a 2'-phosphate terminus and 3'-OH group, exon ends are joined by an RNA ligase, and the 2'-phosphate is removed by a phosphatase.
- 

The overall tRNA splicing reaction is summarized in **Figure 24.30**. The products of cleavage are a linear intron and two half-tRNA molecules. These intermediates have unique ends. Each 5' terminus ends in a hydroxyl group; each 3' terminus ends in a 2',3'-cyclic phosphate group. (All other known RNA splicing enzymes cleave on the other side of the phosphate bond.)

**Figure 24.30** Splicing of tRNA requires separate nuclease and ligase activities. The exon-intron boundaries are cleaved by the nuclease to generate 2' -3' cyclic phosphate and 5' OH termini. The cyclic phosphate is opened to generate 3' -OH and 2' phosphate groups. The 5' -OH is phosphorylated. After releasing the intron, the tRNA half molecules fold into a tRNA-like structure that now has a 3' -OH, 5' -P break. This is sealed by a ligase.

The two half-tRNAs base pair to form a tRNA-like structure. When ATP is added, the second reaction occurs. Both of the unusual ends generated by the endonuclease must be altered.

The cyclic phosphate group is opened to generate a 2' -phosphate terminus. This reaction requires cyclic phosphodiesterase activity. The product has a 2' -phosphate group and a 3' -OH group.

The 5' -OH group generated by the nuclease must be phosphorylated to give a 5' -phosphate. This generates a site in which the 3' -OH is next to the 5' -phosphate. Covalent integrity of the polynucleotide chain is then restored by ligase activity.

All three activities – phosphodiesterase, polynucleotide kinase, and adenylate synthetase (which provides the ligase function) – are arranged in different functional domains on a single protein. They act sequentially to join the two tRNA halves.

The spliced molecule is now uninterrupted, with a 5' -3' phosphate linkage at the site of splicing, but it also has a 2' -phosphate group marking the event. The surplus group must be removed by a phosphatase.

Generation of a 2' ,3' -cyclic phosphate also occurs during the tRNA-splicing reaction in plants and mammals. The reaction in plants seems to be the same as in

yeast, but the detailed chemical reactions are different in mammals.

The yeast tRNA precursors also can be spliced in an extract obtained from the germinal vesicle (nucleus) of *Xenopus* oocytes. This shows that the reaction is not species-specific. *Xenopus* must have enzymes able to recognize the introns in the yeast tRNAs.

The ability to splice the products of tRNA genes is therefore well conserved, but is likely to have a different origin from the other splicing reactions (such as that of nuclear pre-mRNA). The tRNA-splicing reaction uses cleavage and synthesis of bonds and is determined by sequences that are external to the intron. Other splicing reactions use transesterification, in which bonds are transferred directly, and the sequences required for the reaction lie within the intron.

## RNA SPLICING AND PROCESSING

### 5.24.17 The unfolded protein response is related to tRNA splicing

---

#### Key Concepts

- Ire1p is an inner nuclear membrane protein with its N-terminal domain in the ER lumen, and its C-terminal domain in the nucleus.
- Binding of an unfolded protein to the N-terminal domain activates the C-terminal nuclease by autophosphorylation.
- The activated nuclease cleaves Hac1 mRNA to release an intron and generate exons that are ligated by a tRNA ligase.
- The spliced Hac1 mRNA codes for a transcription factor that activates genes coding for chaperones that help to fold unfolded proteins.

---

An unusual splicing system that is related to tRNA splicing mediates the response to unfolded proteins in yeast. The accumulation of unfolded proteins in the lumen of the ER triggers a response pathway that leads to increased transcription of genes coding for chaperones that assist protein folding in the ER. A signal must therefore be transmitted from the lumen of the ER to the nucleus.

The sensor that activates the pathway is the protein Ire1p. It is an integral membrane protein (Ser/Thr) kinase that has domains on each side of the ER membrane. The N-terminal domain in the lumen of the ER detects the presence of unfolded proteins, presumably by binding to exposed motifs. This causes aggregation of monomers and activates the C-terminal domain on the other side of the membrane by autophosphorylation.

Genes that are activated by this pathway have a common promoter element, the UPRE (unfolded protein response element). The transcription factor Hac1p binds to the UPRE, and is produced in response to accumulation of unfolded proteins. The trigger for production of Hac1p is the action of Ire1p on Hac1 mRNA.

The operation of the pathway is summarized in **Figure 24.31**. Under normal conditions, when the pathway is not activated, Hac1 mRNA is translated into a protein that is rapidly degraded. The activation of Ire1p results in the splicing of the Hac1 mRNA to change the sequence of the protein to a more stable form. This form provides the functional transcription factor that activates genes with the UPRE.

**Figure 24.31** The unfolded protein response occurs by activating special splicing of HAC1 mRNA to produce a transcription factor that recognizes the UPRE.

Unusual splicing components are involved in this reaction. Ire1P has an endonuclease activity that acts directly on Hac1 mRNA to cleave the two splicing junctions (739). The two junctions are ligated by the tRNA ligase that acts in the tRNA splicing pathway (738). The endonuclease reaction resembles the cleavage of tRNA during splicing (3322).

Where does the modification of Hac1 mRNA occur? Ire1p is probably located in the inner nuclear membrane, with the N-terminal sensor domain in the ER lumen, and the C-terminal kinase/nuclease domain in the nucleus. This would enable it to act directly on Hac1 mRNA before it is exported to the cytoplasm. It also would allow easy access by the tRNA ligase. There is no apparent relationship between the Ire1p nuclease activity and the tRNA splicing endonuclease, so it is not obvious how this specialized system would have evolved.

---

**RNA SPLICING AND PROCESSING****5.24.18 The 3' ends of polI and polIII transcripts are generated by termination****Key Concepts**

- RNA polymerase I terminates transcription at an 18 base terminator sequence.
- RNA polymerase III terminates transcription in poly(U)<sub>4</sub> sequence embedded in a G-C-rich sequence.

3' ends of RNAs can be generated in two ways. Some RNA polymerases terminate transcription at a defined (terminator) sequence in DNA, as shown in **Figure 24.32**. Other RNA polymerases do not show discrete termination, but continue past the site corresponding to the 3' end, which is generated by cleavage of the RNA by an endonuclease, as shown in **Figure 24.33**.

**Figure 24.32** When a 3' end is generated by termination, RNA polymerase and RNA are released at a discrete (terminator) sequence in DNA.

**Figure 24.33** When a 3' end is generated by cleavage, RNA polymerase continues transcription while an endonuclease cleaves at a defined sequence in the RNA.

Information about the termination reaction for eukaryotic RNA polymerases is less detailed than our knowledge of initiation. RNA polymerases I and III have discrete termination events (like bacterial RNA polymerase), but it is not clear whether RNA polymerase II usually terminates in this way.

For RNA polymerase I, the sole product of transcription is a large precursor that contains the sequences of the major rRNA. The precursor is subjected to extensive processing. Termination occurs at a discrete site >1000 bp downstream of the mature 3' end, which is generated by cleavage. Termination involves recognition of an 18 base terminator sequence by an ancillary factor.

With RNA polymerase III, transcription *in vitro* generates molecules with the same 5' and 3' ends as those synthesized *in vivo*. The termination reaction resembles intrinsic termination by bacterial RNA polymerase (see *Molecular Biology 3.9.21 There are two types of terminators in E. coli*). Termination usually occurs at the second U within a run of 4 U bases, but there is heterogeneity, with some molecules ending in 3 or even 4 U bases. The same heterogeneity is seen in molecules synthesized *in vivo*, so it seems to be a *bona fide* feature of the termination reaction.

Just like the prokaryotic terminators, the U run is embedded in a G-C-rich region. Although sequences of dyad symmetry are present, they are not needed for termination, since mutations that abolish the symmetry do not prevent the normal completion of RNA synthesis. Nor are any sequences beyond the U run necessary, since all distal sequences can be replaced without any effect on termination.

The U run itself is not sufficient for termination, because regions of 4 successive U residues exist within transcription units read by RNA polymerase III. (However, there are no internal  $U_5$  runs, which fits with the greater efficiency of termination when the terminator is a  $U_5$  rather than  $U_4$  sequence.) The critical feature in termination must therefore be the recognition of a  $U_4$  sequence in a context that is

rich in G-C base pairs.

How does the termination reaction occur? It cannot rely on the weakness of the rU-dA RNA-DNA hybrid region that lies at the end of the transcript, because often only the first two U residues are transcribed. Perhaps the G-C-rich region plays a role in slowing down the enzyme, but there does not seem to be a counterpart to the hairpin involved in prokaryotic termination. We remain puzzled how the enzyme can respond so specifically to such a short signal. And in contrast with the initiation reaction, which RNA polymerase III cannot accomplish alone, termination seems to be a function of the enzyme itself.

*This content is available online at <http://www.ergito.com/main.jsp?bcs=MBIO.5.24.18>*

---

## RNA SPLICING AND PROCESSING

### 5.24.19 The 3' ends of mRNAs are generated by cleavage and polyadenylation

---

#### Key Terms

**Cordycepin** is 3' deoxyadenosine, an inhibitor of polyadenylation of RNA.

**Endonucleases** cleave bonds within a nucleic acid chain; they may be specific for RNA or for single-stranded or double-stranded DNA.

**Poly(A) polymerase** is the enzyme that adds the stretch of polyadenylic acid to the 3' of eukaryotic mRNA. It does not use a template.

#### Key Concepts

- The sequence AAUAAA is a signal for cleavage to generate a 3' end of mRNA that is polyadenylated.
- The reaction requires a protein complex that contains a specificity factor, an endonuclease, and poly(A) polymerase.
- The specificity factor and endonuclease cleave RNA downstream of AAUAAA.
- The specificity factor and poly(A) polymerase add ~200 A residues processively to the 3' end.
- A-U-rich sequences in the 3' tail control cytoplasmic polyadenylation or deadenylation during *Xenopus* embryonic development.

---

It is not clear whether RNA polymerase II actually engages in a termination event at a specific site. It is possible that its termination is only loosely specified. In some transcription units, termination occurs >1000 bp downstream of the site corresponding to the mature 3' end of the mRNA (which is generated by cleavage at a specific sequence). Instead of using specific terminator sequences, the enzyme ceases RNA synthesis within multiple sites located in rather long "terminator regions." The nature of the individual termination sites is not known.

The 3' ends of mRNAs are generated by cleavage followed by polyadenylation. Addition of poly(A) to nuclear RNA can be prevented by the analog 3' -deoxyadenosine, also known as **cordycepin**. Although cordycepin does not stop the transcription of nuclear RNA, its addition prevents the appearance of mRNA in the cytoplasm. This shows that polyadenylation is *necessary* for the maturation of mRNA from nuclear RNA.

Generation of the 3' end is illustrated in **Figure 24.34**. RNA polymerase transcribes past the site corresponding to the 3' end, and sequences in the RNA are recognized as targets for an endonucleolytic cut followed by polyadenylation. A single processing complex undertakes both the cutting and polyadenylation. The polyadenylation stabilizes the mRNA against degradation from the 3' end. Its 5' end

is already stabilized by the cap. RNA polymerase continues transcription after the cleavage, but the 5' end that is generated by the cleavage is unprotected. As a result, the rest of the transcript is rapidly degraded. This makes it difficult to determine what is happening beyond the point of cleavage.

**Figure 24.34** The sequence AAUAAA is necessary for cleavage to generate a 3' end for polyadenylation.

A common feature of mRNAs in higher eukaryotes (but not in yeast) is the presence of the highly conserved sequence AAUAAA in the region from 11-30 nucleotides upstream of the site of poly(A) addition. Deletion or mutation of the AAUAAA hexamer prevents generation of the polyadenylated 3' end. The signal is needed for both cleavage and polyadenylation (744; 745; for review see 248).

The development of a system in which polyadenylation occurs *in vitro* opened the route to analyzing the reactions. The formation and functions of the complex that undertakes 3' processing are illustrated in **Figure 24.35**. Generation of the proper 3' terminal structure requires an **endonuclease** (consisting of the components CFI and CFII) to cleave the RNA, a **poly(A) polymerase** (PAP) to synthesize the poly(A) tail, and a *specificity component* (CPSF) that recognizes the AAUAAA sequence and directs the other activities. A stimulatory factor, CstF, binds to a G-U-rich sequence that is downstream from the cleavage site itself (746).

**Figure 24.35** The 3' processing complex consists of several activities. CPSF and CstF each consist of several subunits; the other components are monomeric. The total mass is >900 kD.

The specificity factor contains 4 subunits, which together bind specifically to RNA containing the sequence AAUAAA. The individual subunits are proteins that have common RNA-binding motifs, but which by themselves bind nonspecifically to RNA. Protein-protein interactions between the subunits may be needed to generate the specific AAUAAA-binding site. CPSF binds strongly to AAUAAA only when CstF is also present to bind to the G-U-rich site.

The specificity factor is needed for both the cleavage and polyadenylation reactions. It exists in a complex with the endonuclease and poly(A) polymerase, and this complex usually undertakes cleavage followed by polyadenylation in a tightly coupled manner.

The two components CFI and CFII (cleavage factors I and II), together with specificity factor, are necessary and sufficient for the endonucleolytic cleavage.

The poly(A) polymerase has a nonspecific catalytic activity. When it is combined with the other components, the synthetic reaction becomes specific for RNA containing the sequence AAUAAA. The polyadenylation reaction passes through two stages. First, a rather short oligo(A) sequence (~10 residues) is added to the 3' end. This reaction is absolutely dependent on the AAUAAA sequence, and poly(A) polymerase performs it under the direction of the specificity factor. In the second phase, the oligo(A) tail is extended to the full ~200 residue length. This reaction requires another stimulatory factor that recognizes the oligo(A) tail and directs poly(A) polymerase specifically to extend the 3' end of a poly(A) sequence.

The poly(A) polymerase by itself adds A residues individually to the 3' position. Its intrinsic mode of action is distributive; it dissociates after each nucleotide has been added. However, in the presence of CPSF and PABP (poly(A)-binding protein), it functions processively to extend an individual poly(A) chain. The PABP is a 33 kD protein that binds stoichiometrically to the poly(A) stretch. The length of poly(A) is controlled by the PABP, which in some way limits the action of poly(A) polymerase to ~200 additions of A residues. The limit may represent the accumulation of a critical mass of PABP on the poly(A) chain. PABP binds to the translation initiation factor eIF4G, thus generating a closed loop in which a protein complex contains both the 5' and 3' ends of the mRNA (see **Figure 6.20** in *Molecular Biology 2.6.9 Eukaryotes use a complex of many initiation factors*).

Polyadenylation is an important determinant of mRNA function. It may affect both stability and initiation of translation (see *Molecular Biology 2.5.10 The 3' terminus is polyadenylated*). In embryonic development in some organisms, the presence of poly(A) is used to control translation, and pre-existing mRNAs may either be polyadenylated (to stimulate translation) or deadenylated (to terminate translation). During *Xenopus* embryonic development, polyadenylation of mRNA in the cytoplasm in *Xenopus* depends on a specific *cis*-acting element (the CPE) in the 3' tail. This is another AU-rich sequence, UUUUUAU (2313; 2314).

In *Xenopus* embryos at least two type of *cis*-acting sequences found in the 3' tail can trigger deadenylation. EDEN (embryonic deadenylation element) is a 17 nucleotide sequence (2310). ARE elements are AU-rich, usually containing tandem repeats of AUUUA (2311). There is a poly(A)-specific RNAase (PARN) that could be involved in the degradation (2312). Of course, deadenylation is not always triggered by specific elements; in some situations (including the normal degradation of mRNA as it ages), poly(A) is degraded unless it is specifically stabilized.

## RNA SPLICING AND PROCESSING

### 5.24.20 Cleavage of the 3' end of histone mRNA may require a small RNA

---

#### Key Concepts

- Histone mRNAs are not polyadenylated; their 3' ends are generated by a cleavage reaction that depends on the structure of the mRNA.
  - The cleavage reaction requires the SLBP to bind to a stem-loop structure, and the U7 snRNA to pair with an adjacent single-stranded region.
- 

Some mRNAs are not polyadenylated. The formation of their 3' ends is therefore different from the coordinated cleavage/polyadenylation reaction. The most prominent members of this mRNA class are the mRNAs coding for histones that are synthesized during DNA replication. Formation of their 3' ends depends upon secondary structure. The structure at the 3' terminus is a highly conserved stem-loop structure, with a stem of 6 bp and a loop of 4 nucleotides. Cleavage occurs 4-5 bases downstream of the stem-loop. Two factors are required for the cleavage reaction: the stem-loop binding protein (SLBP) recognizes the structure (3324); and the U7 snRNA pairs with a purine-rich sequence (the histone downstream element, or HDE) located ~10 nucleotides downstream of the cleavage site (743; 3325).

Mutations that prevent formation of the duplex stem of the stem-loop prevent formation of the end of the RNA. Secondary mutations that restore duplex structure (though not necessarily the original sequence) behave as revertants. This suggests that *formation of the secondary structure is more important than the exact sequence*. The SLBP binds to the stem-loop and then interacts with U7 snRNP to enhance its interaction with the downstream binding site for U7 snRNA (3326). U7 snRNP is a minor snRNP consisting of the 63 nucleotide U7 snRNA and a set of several proteins (including Sm proteins; see *Molecular Biology 5.24.5 snRNAs are required for splicing*).

The reaction between histone H3 mRNA and U7 snRNA is drawn in **Figure 24.36**. The upstream hairpin and the HDE that pairs with U7 snRNA are conserved in histone H3 mRNAs of several species. The U7 snRNA has sequences towards its 5' end that pair with the histone mRNA consensus sequences. 3' processing is inhibited by mutations in the HDE that reduce ability to pair with U7 snRNA. Compensatory mutations in U7 snRNA that restore complementarity also restore 3' processing (3327). This suggests that U7 snRNA functions by base pairing with the histone mRNA. The sequence of the HDE varies among the various histone mRNAs, with the result that binding of snRNA is not by itself necessarily stable, but requires also the interaction with SLBP

**Figure 24.36** Generation of the 3' end of histone H3 mRNA depends on a conserved hairpin and a sequence that base pairs with U7 snRNA.

Cleavage to generate a 3' terminus occurs a fixed distance from the site recognized by U7 snRNA, which suggests that the snRNA is involved in defining the cleavage site (for review see 241). However, the factor(s) actually responsible for cleavage have not yet been identified.

## RNA SPLICING AND PROCESSING

### 5.24.21 Production of rRNA requires cleavage events

---

#### Key Terms

**45S RNA** is a precursor that contains the sequences of both major ribosomal RNAs (28S and 18S rRNAs).

#### Key Concepts

- The large and small rRNAs are released by cleavage from a common precursor RNA.
- 

The major rRNAs are synthesized as part of a single primary transcript that is processed to generate the mature products. The precursor contains the sequences of the 18S, 5.8S, and 28S rRNAs. In higher eukaryotes, the precursor is named for its sedimentation rate as **45S RNA**. In lower eukaryotes, it is smaller (35S in yeast).

The mature rRNAs are released from the precursor by a combination of cleavage events and trimming reactions (for review see 980). **Figure 24.37** shows the general pathway in yeast. There can be variations in the order of events, but basically similar reactions are involved in all eukaryotes. Most of the 5' ends are generated directly by a cleavage event. Most of the 3' ends are generated by cleavage followed by a 3'–5' trimming reaction.

**Figure 24.37** Mature eukaryotic rRNAs are generated by cleavage and trimming events from a primary transcript.

Many ribonucleases have been implicated in processing rRNA, including the exosome, an assembly of several exonucleases that also participates in mRNA degradation (see *Molecular Biology 2.5.13 mRNA degradation involves multiple activities*). Mutations in individual enzymes usually do not prevent processing, suggesting that their activities are redundant and that different combinations of cleavages can be used to generate the mature molecules.

There are always multiple copies of the transcription unit for the rRNAs. The copies are organized as tandem repeats (see *Molecular Biology 1.4.9 The repeated genes for rRNA maintain constant sequence*).

5S RNA is transcribed from separate genes by RNA polymerase III. Usually the 5S genes are clustered, but are separate from the genes for the major rRNAs. (In the case of yeast, a 5S gene is associated with each major transcription unit, but is transcribed independently.)

There is a difference in the organization of the precursor in bacteria. The sequence corresponding to 5.8S rRNA forms the 5' end of the large (23S) rRNA, that is, there is no processing between these sequences. **Figure 24.38** shows that the precursor also contains the 5S rRNA and one or two tRNAs. In *E. coli*, the 7 *rrn* operons are

dispersed around the genome; four *rrn* loci contain one tRNA gene between the 16S and 23S rRNA sequences, and the other *rrn* loci contain two tRNA genes in this region. Additional tRNA genes may or may not be present between the 5S sequence and the 3' end. So the processing reactions required to release the products depend on the content of the particular *rrn* locus.

**Figure 24.38** The *rrn* operons in *E. coli* contain genes for both rRNA and tRNA. The exact lengths of the transcripts depend on which promoters (P) and terminators (t) are used. Each RNA product must be released from the transcript by cuts on either side.

In both prokaryotic and eukaryotic rRNA processing, ribosomal proteins (and possibly also other proteins) bind to the precursor, so that the substrate for processing is not the free RNA but is a ribonucleoprotein complex.

## RNA SPLICING AND PROCESSING

### 5.24.22 Small RNAs are required for rRNA processing

---

#### Key Terms

A **snoRNA** is a small nuclear RNA that is localized in the nucleolus.

#### Key Concepts

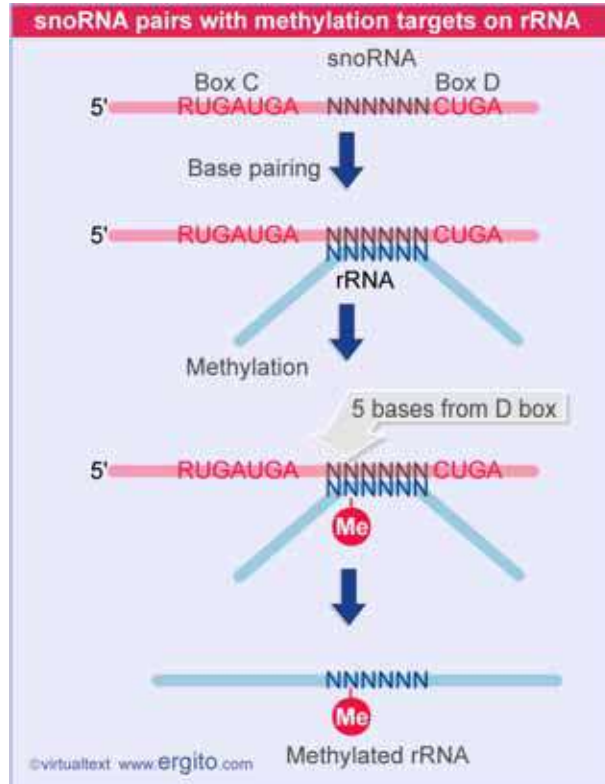

- The C/D group of snoRNAs is required for modifying the 2' position of ribose with a methyl group.
  - The H/ACA group of snoRNAs is required for converting uridine to pseudouridine.
  - In each case the snoRNA base pairs with a sequence of rRNA that contains the target base to generate a typical structure that is the substrate for modification.
- 

Processing and modification of rRNA requires a class of small RNAs called **snoRNAs** (small nucleolar RNAs). There are 71 snoRNAs in the yeast (*S. cerevisiae*) genome. They are associated with the protein fibrillarin, which is an abundant component of the nucleolus (the region of the nucleus where the rRNA genes are transcribed). Some snoRNAs are required for cleavage of the precursor to rRNA; one example is U3 snoRNA, which is required for the first cleavage event in both yeast and *Xenopus* (740). We do not know what role the snoRNA plays in cleavage. It could be required to pair with the rRNA sequence to form a secondary structure that is recognized by an endonuclease.

Two groups of snoRNAs are required for the modifications that are made to bases in the rRNA (see *Great Experiments 4.6 Small nucleolar RNAs guide rRNA modification*). The members of each group are identified by very short conserved sequences and common features of secondary structure (1216; 1217).

The C/D group of snoRNAs is required for adding a methyl group to the 2' position of ribose. There are >100 2' -O-methyl groups at conserved locations in vertebrate rRNAs. This group takes its name from two short conserved sequence motifs called boxes C and D. Each snoRNA contains a sequence near the D box that is complementary to a region of the 18S or 28S rRNA that is methylated. Loss of a particular snoRNA prevents methylation in the rRNA region to which it is complementary.

**Figure 24.39** suggests that the snoRNA base pairs with the rRNA to create the duplex region that is recognized as a substrate for methylation. Methylation occurs within the region of complementarity, at a position that is fixed 5 bases on the 5' side of the D box (741; 1220). Probably each methylation event is specified by a different snoRNA; ~40 snoRNAs have been characterized so far. The methylase(s) have not been characterized; one possibility is that the snoRNA itself provides part of the methylase activity.

**Figure 24.39** A snoRNA base pairs with a region of rRNA that is to be methylated.

Another group of snoRNAs is involved in the synthesis of pseudouridine. There are 43  $\psi$  residues in yeast rRNAs and ~100 in vertebrate rRNAs. The synthesis of pseudouridine involves the reaction shown in **Figure 24.40** in which the N1 bond from uridylic acid to ribose is broken, the base is rotated, and C5 is rejoined to the sugar.

**Figure 24.40** Uridine is converted to pseudouridine by replacing the N1-sugar bond with a C5-sugar bond and rotating the base relative to the sugar.

Pseudouridine formation in rRNA requires the H/ACA group of ~20 snoRNAs. They are named for the presence of an ACA triplet 3 nucleotides from the 3' end and a partially conserved sequence (the H box) that lies between two stem-loop hairpin structures. Each of these snoRNAs has a sequence complementary to rRNA within the stem of each hairpin. **Figure 24.41** shows the structure that would be produced by

pairing with the rRNA. Within each pairing region, there are two unpaired bases, one of which is a uridine that is converted to pseudouridine (742; 1218).

**Figure 24.41** H/ACA snoRNAs have two short conserved sequences and two hairpin structures, each of which has regions in the stem that are complementary to rRNA. Pseudouridine is formed by converting an unpaired uridine within the complementary region of the rRNA.

The H/ACA snoRNAs are associated with a nucleolar protein called Gar1p, which is required for pseudouridine formation, but its function is unknown (1219). The known pseudouridine synthases are proteins that function without an RNA cofactor. Synthases that could be involved in snoRNA-mediated pseudouridine synthesis have not been identified.

The involvement of the U7 snRNA in 3' end generation, and the role of snoRNAs in rRNA processing and modification, is consistent with the view we develop in *Molecular Biology 5.26 Catalytic RNA* that many – perhaps all – RNA processing events depend on RNA-RNA interactions. As with splicing reactions, the snRNA probably functions in the form of a ribonucleoprotein particle containing proteins as well as the RNA. It is common (although not the only mechanism of action) for the RNA of the particle to base pair with a short sequence in the substrate RNA.

## RNA SPLICING AND PROCESSING

### 5.24.23 Summary

---

Splicing accomplishes the removal of introns and the joining of exons into the mature sequence of RNA. There are at least four types of reaction, as distinguished by their requirements *in vitro* and the intermediates that they generate. The systems include eukaryotic nuclear introns, group I and group II introns, and tRNA introns. Each reaction involves a change of organization within an individual RNA molecule, and is therefore a *cis*-acting event.

pre-mRNA splicing follows preferred but not obligatory pathways. Only very short consensus sequences are necessary; the rest of the intron appears irrelevant. All 5' splice sites are probably equivalent, as are all 3' splice sites. The required sequences are given by the GU-AG rule, which describes the ends of the intron. The UACUAAAC branch site of yeast, or a less well conserved consensus in mammalian introns, is also required. The reaction with the 5' splice site involves formation of a lariat that joins the GU end of the intron via a 5'-2' linkage to the A at position 6 of the branch site. Then the 3'-OH end of the exon attacks the 3' splice site, so that the exons are ligated and the intron is released as a lariat. Both reactions are transesterifications in which bonds are conserved. Several stages of the reaction require hydrolysis of ATP, probably to drive conformational changes in the RNA and/or protein components. Lariat formation is responsible for choice of the 3' splice site. Alternative splicing patterns are caused by protein factors that either stimulate use of a new site or that block use of the default site.

pre-mRNA splicing requires formation of a spliceosome, a large particle that assembles the consensus sequences into a reactive conformation. The spliceosome most often forms by the process of intron definition, involving recognition of the 5' splice site, branch site, and 3' splice site. An alternative pathway involves exon definition, which involves initial recognition of the 5' splice sites of both the substrate intron and the next intron. Its formation passes through a series of stages from the E (commitment) complex that contains U1 snRNP and splicing factors, through the A and B complexes as additional components are added.

The spliceosome contains the U1, U2, U4/U6, and U5 snRNPs and some additional splicing factors. The U1, U2, and U5 snRNPs each contain a single snRNA and several proteins; the U4/U6 snRNP contains 2 snRNAs and several proteins. Some proteins are common to all snRNP particles. The snRNPs recognize consensus sequences. U1 snRNA base pairs with the 5' splice site, U2 snRNA base pairs with the branch sequence, U5 snRNP acts at the 5' splice site. When U4 releases U6, the U6 snRNA base pairs with U2, and this may create the catalytic center for splicing. An alternative set of snRNPs provides analogous functions for splicing the U12-dependent subclass of introns. The snRNA molecules may have catalytic-like roles in splicing and other processing reactions.

In the nucleolus, two groups of snoRNAs are responsible for pairing with rRNAs at sites that are modified; group C/D snoRNAs indicate target sites for methylation, and group ACA snoRNAs identify sites where uridine is converted to pseudouridine.

Splicing is usually intramolecular, but *trans*-(intermolecular) splicing occurs in trypanosomes and nematodes. It involves a reaction between a small SL RNA and the pre-mRNA. The SL RNA resembles U1 snRNA and may combine the role of providing the exon and the functions of U1. In worms there are two types of SL RNA, one used for splicing to the 5' end of an mRNA, the other for splicing to an internal site.

Group II introns share with nuclear introns the use of a lariat as intermediate, but are able to perform the reaction as a self-catalyzed property of the RNA. These introns follow the GT-AG rule, but form a characteristic secondary structure that holds the reacting splice sites in the appropriate apposition.

Yeast tRNA splicing involves separate endonuclease and ligase reactions. The endonuclease recognizes the secondary (or tertiary) structure of the precursor and cleaves both ends of the intron. The two half-tRNAs released by loss of the intron can be ligated in the presence of ATP.

The termination capacity of RNA polymerase II has not been characterized, and 3' ends of its transcripts are generated by cleavage. The sequence AAUAAA, located 11-30 bases upstream of the cleavage site, provides the signal for both cleavage and polyadenylation. An endonuclease and the poly(A) polymerase are associated in a complex with other factors that confer specificity for the AAUAAA signal.

## IMMUNE DIVERSITY

### 5.25.1 Introduction

---

#### Key Terms

An **immune response** is an organism's reaction, mediated by components of the immune system, to an antigen.

An **antigen** is any foreign substance whose entry into an organism provokes an immune response by stimulating the synthesis of an antibody (an immunoglobulin protein that can bind to the antigen).

A **B cell** is a lymphocyte that produces antibodies. B cells development occurs primarily in bone marrow.

**T cells** are lymphocytes of the T (thymic) lineage; may be subdivided into several functional types. They carry TcR (T-cell receptor) and are involved in the cell-mediated immune response.

The **humoral response** is an immune response that is mediated primarily by antibodies. It is defined as immunity that can be transferred from one organism to another by serum antibody.

An **immunoglobulin (Antibody)** is a class of protein that is produced by B cells in response to antigen.

An **antibody** is a protein (immunoglobulin) produced by B lymphocyte cells that recognizes a particular 'foreign antigen', and thus triggers the immune response.

A **helper T cell** is a T lymphocyte that activates macrophages and stimulates B cell proliferation and antibody production. Helper T cells usually express cell surface CD4 but not CD8.

Two mutants are said to **complement** each other when a diploid that is heterozygous for each mutation produces the wild type phenotype.

The **cell-mediated response** is the immune response that is mediated primarily by T lymphocytes. It is defined based on immunity that cannot be transferred from one organism to another by serum antibody.

A **cytotoxic T cell** is a T lymphocyte (usually CD8<sup>+</sup>) that can be stimulated to kill cells containing intracellular pathogens, such as viruses.

The **T cell receptor (TCR)** is the antigen receptor on T lymphocytes. It is clonally expressed and binds to a complex of MHC class I or class II protein and antigen-derived peptide.

The **major histocompatibility complex (MHC)** is a chromosomal region containing genes that are involved in the immune response. The genes encode proteins for antigen presentation, cytokines, and complement proteins. The MHC is highly polymorphic.

**Tolerance** is the lack of an immune response to an antigen (either self antigen or foreign antigen) due to clonal deletion.

An **autoimmune disease** is a pathological condition in which the immune response is directed to self antigen.

---

**Clonal deletion** describes the elimination of a clonal population of lymphocytes. At certain stages of lymphocyte development, clonal deletion can be induced when lymphocyte antigen receptors bind to their cognate antigen.

A **superfamily** is a set of genes all related by presumed descent from a common ancestor, but now showing considerable variation.

---

It is an axiom of genetics that the genetic constitution created in the zygote by the combination of sperm and egg is inherited by all somatic cells of the organism. We look to differential control of gene expression, rather than to changes in DNA content, to explain the different phenotypes of particular somatic cells.

Yet there are exceptional situations in which the reorganization of certain DNA sequences is used to regulate gene expression or to create new genes. The immune system provides a striking and extensive case in which the content of the genome changes, when recombination creates active genes in lymphocytes. Other cases are represented by the substitution of one sequence for another to change the mating type of yeast or to generate new surface antigens by trypanosomes (see *Molecular Biology 4.18 Rearrangement of DNA*).

The **immune response** of vertebrates provides a protective system that distinguishes foreign proteins from the proteins of the organism itself. Foreign material (or part of the foreign material) is recognized as comprising an **antigen**. Usually the antigen is a protein (or protein-attached moiety) that has entered the bloodstream of the animal – for example, the coat protein of an infecting virus. Exposure to an antigen initiates production of an immune response that *specifically recognizes the antigen and destroys it*.

Immune reactions are the responsibility of white blood cells – the B and T lymphocytes, and macrophages. The lymphocytes are named after the tissues that produce them. In mammals, **B cells** mature in the bone marrow, while **T cells** mature in the thymus. *Each class of lymphocyte uses the rearrangement of DNA as a mechanism for producing the proteins that enable it to participate in the immune response.*

The immune system has many ways to destroy an antigenic invader, but it is useful to consider them in two general classes. Which type of response the immune system mounts when it encounters a foreign structure depends partly on the nature of the antigen. The response is defined according to whether it is executed principally by B cells or T cells.

The **humoral response** depends on B cells. It is mediated by the secretion of antibodies, which are **immunoglobulin** proteins. *Production of an antibody specific for a foreign molecule is the primary event responsible for recognition of an antigen.* Recognition requires the antibody to bind to a small region or structure on the antigen.

The function of antibodies is represented in **Figure 25.1**. Foreign material circulating in the bloodstream, for example, a toxin or pathogenic bacterium, has a surface that presents antigens. The antigen(s) are recognized by the antibodies, which form an

antigen-antibody complex. This complex then attracts the attention of other components of the immune system.

**Figure 25.1** Humoral immunity is conferred by the binding of free antibodies to antigens to form antigen-antibody complexes that are removed from the bloodstream by macrophages or that are attacked directly by the complement proteins.

The humoral response depends on these other components in two ways. First, B cells need signals provided by T cells to enable them to secrete antibodies. These T cells are called **helper T cells**, because they assist the B cells. Second, antigen-antibody formation is a trigger for the antigen to be destroyed. The major pathway is provided by the action of **complement**, a component whose name reflects its ability to "complement" the action of the antibody itself. Complement consists of a set of ~20 proteins that function through a cascade of proteolytic actions. If the target antigen is part of a cell, for example, an infecting bacterium, the action of complement culminates in lysing the target cell. The action of complement also provides a means of attracting macrophages, which scavenge the target cells or their products. Alternatively, the antigen-antibody complex may be taken up directly by macrophages (scavenger cells) and destroyed.

The **cell-mediated response** is executed by a class of T lymphocytes called **cytotoxic T cells** (also called killer T cells). The basic function of the T cell in recognizing a target antigen is indicated in **Figure 25.2**. A cell-mediated response typically is elicited by an intracellular parasite, such as a virus that infects the body's own cells. As a result of the viral infection, fragments of foreign (viral) antigens are displayed on the surface of the cell. These fragments are recognized by the **T cell receptor (TCR)**, which is the T cells' equivalent of the antibody produced by a B

cell.

**Figure 25.2** In cell-mediated immunity, killer T cells use the T-cell receptor to recognize a fragment of the foreign antigen which is presented on the surface of the target cell by the MHC protein.

A crucial feature of this recognition reaction is that *the antigen must be presented by a cellular protein that is a member of the MHC (major histocompatibility complex)*. The MHC protein has a groove on its surface that binds a peptide fragment derived from the foreign antigen. The combination of peptide fragment and MHC protein is recognized by the T cell receptor. Every individual has a characteristic set of MHC proteins. They are important in graft reactions; a graft of tissue from one individual to another is rejected because of the difference in MHC proteins between the donor and recipient, an issue of major medical importance. The demand that the T lymphocytes recognize both foreign antigen and MHC protein ensures that the cell-mediated response acts only on host cells that have been infected with a foreign antigen. (We discuss the division of MHC proteins into the general types of class I and class II later in *Molecular Biology 5.25.20 The major histocompatibility locus codes for many genes of the immune system.*)

The purpose of each type of immune response is to attack a foreign target. Target recognition is the prerogative of B-cell immunoglobulins and T cell receptors. A crucial aspect of their function lies in the ability to distinguish "self" from "nonself." Proteins and cells of the body itself must *never* be attacked. Foreign targets must be *destroyed entirely*. The property of failing to attack "self" is called **tolerance**. Loss of

this ability results in an **autoimmune disease**, in which the immune system attacks its own body, often with disastrous consequences.

What prevents the lymphocyte pool from responding to "self" proteins? Tolerance probably arises early in lymphocyte cell development when B and T cells that recognize "self" antigens are destroyed. This is called **clonal deletion**. In addition to this negative selection, there is also positive selection for T cells carrying certain sets of T cell receptors.

A corollary of tolerance is that it can be difficult to obtain antibodies against proteins that are closely related to those of the organism itself. As a practical matter, therefore, it may be difficult to use (for example) mice or rabbits to obtain antibodies against human proteins that have been highly conserved in mammalian evolution. The tolerance of the mouse or rabbit for its own protein may extend to the human protein in such cases.

Each of the three groups of proteins required for the immune response – immunoglobulins, T cell receptors, MHC proteins – is diverse. Examining a large number of individuals, we find many variants of each protein. Each protein is coded by a large family of genes; and in the case of antibodies and the T cell receptors, the diversity of the population is increased by DNA rearrangements that occur in the relevant lymphocytes.

Immunoglobulins and T cell receptors are direct counterparts, each produced by its own type of lymphocyte. The proteins are related in structure, and their genes are related in organization. The sources of variability are similar. The MHC proteins also share some common features with the antibodies, as do other lymphocyte-specific proteins. In dealing with the genetic organization of the immune system, we are therefore concerned with a series of related gene families, indeed a **superfamily** that may have evolved from some common ancestor representing a primitive immune response.

## IMMUNE DIVERSITY

### 5.25.2 Clonal selection amplifies lymphocytes that respond to individual antigens

---

#### Key Terms

The **clonal selection** theory proposed that each lymphocyte expresses a single antigen receptor specificity and that only those lymphocytes that bind to a given antigen are stimulated to proliferate and to function in eliminating that antigen. Thus, the antigen "selects" the lymphocytes to be activated. Clonal selection is now an established principle in immunology.

The **primary immune response** is an organism's immune response upon first exposure to a given antigen. It is characterized by a relatively shorter duration and lower affinity antibodies than in the secondary immune response.

A **memory cell** is a lymphocyte that has been stimulated during the primary immune response to antigen and that is rapidly activated upon subsequent exposure to that antigen. Memory cells respond more rapidly to antigen than naive cells.

The **secondary immune response** is an organism's immune response upon a second exposure to a given antigen. This second exposure is also referred to as a "booster". The secondary immune response is characterized by a more rapid induction, greater magnitude, and higher affinity antibodies than the primary immune response.

A **hapten** is a small molecule that acts as an antigen when conjugated to a protein.

An **antigenic determinant** is the portion of an antigen that is recognized by the antigen receptor on lymphocytes. It is also called an epitope.

An **epitope** is the portion of an antigen that is recognized by the antigen receptor on lymphocytes. It is also called an antigenic determinant.

#### Key Concepts

- Each B lymphocyte expresses a single immunoglobulin and each T lymphocyte expresses a single T cell receptor.
  - There is a very large variety of immunoglobulins and T cell receptors.
  - Antigen binding to an immunoglobulin or T cell receptor triggers clonal multiplication of the cell.
- 

The name of the immune response describes one of its central features. After an organism has been exposed to an antigen, it becomes *immune* to the effects of a new infection. Before exposure to a particular antigen, the organism lacks adequate capacity to deal with any toxic effects. This ability is acquired during the immune response. After the infection has been defeated, the organism retains the ability to respond rapidly in the event of a re-infection.

These features are accommodated by the **clonal selection** theory illustrated in **Figure**

**25.3.** The pool of lymphocytes contains B cells and T cells carrying a large variety of immunoglobulins or T cell receptors. *But any individual B lymphocyte produces one immunoglobulin, which is capable of recognizing only a single antigen; similarly any individual T lymphocyte produces only one particular T cell receptor.*

**Figure 25.3** The pool of immature lymphocytes contains B cells and T cells making antibodies and receptors with a variety of specificities. Reaction with an antigen leads to clonal expansion of the lymphocyte with the antibody (B cell) or receptor (T cell) that can recognize the antigen.

In the pool of immature lymphocytes, the unstimulated B cells and T cells are morphologically indistinguishable. But on exposure to antigen, a B cell whose antibody is able to bind the antigen, or a T cell whose receptor can recognize it, is stimulated to divide, probably by some feedback from the surface of the cell, where the antibody/receptor-antigen reaction occurs. The stimulated cells then develop into mature B or T lymphocytes, which includes morphological changes involving (for example) an increase in cell size (especially pronounced for B cells).

The initial expansion of a specific B- or T cell population upon first exposure to an antigen is called the **primary immune response**. Large numbers of B or T lymphocytes with specificity for the target antigen are produced. Each population represents a clone of the original responding cell. Antibody is secreted from the B cells in large quantities, and it may even come to dominate the antibody population.

After a successful primary immune response has been mounted, the organism retains B cells and T cells carrying the corresponding antibody or receptor. These **memory cells** represent an intermediate state between the immature cell and the mature cell. They have not acquired all of the features of the mature cell, but they are long-lived, and can rapidly be converted to mature cells. Their presence allows a **secondary immune response** to be mounted rapidly if the animal is exposed to the same antigen again.

The pool of immature lymphocytes in a mammal contains  $\sim 10^{12}$  cells. This pool contains some lymphocytes that have unique specificities (because a corresponding antigen has never been encountered), while others are represented by up to  $10^6$  cells (because clonal selection has expanded the pool to respond to an antigen).

What features are recognized in an antigen? Antigens are usually macromolecular. Although small molecules may have antigenic determinants and can be recognized by antibodies, usually they are not effective in provoking an immune response (because of their small size). But they do provoke a response when conjugated with a larger carrier molecule (usually a protein). A small molecule that is used to provoke a response by such means is called a **hapten**.

Only a small part of the surface of a macromolecular antigen is actually recognized by any one antibody. The binding site consists of only 5-6 amino acids. Of course, any particular protein may have more than one such binding site, in which case it provokes antibodies with specificities for different regions. The region provoking a response is called an **antigenic determinant** or **epitope**. When an antigen contains several epitopes, some may be more effective than others in provoking the immune response; in fact, they may be so effective that they entirely dominate the response.

How do lymphocytes find target antigens and where does their maturation take place? Lymphocytes are peripatetic cells. They develop from immature stem cells that are located in the adult bone marrow. They migrate to the peripheral lymphoid tissues (spleen, lymph nodes) either directly via the bloodstream (if they are B cells) or via the thymus (where they become T cells). The lymphocytes recirculate between blood and lymph; the process of dispersion ensures that an antigen will be exposed to lymphocytes of all possible specificities. When a lymphocyte encounters an antigen that binds its antibody or receptor, clonal expansion begins the immune response.

## IMMUNE DIVERSITY

### 5.25.3 Immunoglobulin genes are assembled from their parts in lymphocytes

---

#### Key Terms

The immunoglobulin **light chain** is one of two types of subunits in an antibody tetramer. Each antibody contains two light chains. The N-terminus of the light chain forms part of the antigen recognition site.

The immunoglobulin **heavy chain** is one of two types of subunits in an antibody tetramer. Each antibody contains two heavy chains. The N-terminus of the heavy chain forms part of the antigen recognition site, whereas the C-terminus determines the subclass (isotype).

The **variable region (V region)** of an immunoglobulin chain is coded by the V gene and varies extensively when different chains are compared, as the result of multiple (different) genomic copies and changes introduced during construction of an active immunoglobulin.

**Constant regions (C region)** of immunoglobulins are coded by C genes and are the parts of the chain that vary least. Those of heavy chains identify the type of immunoglobulin.

A **V gene** is sequence coding for the major part of the variable (N-terminal) region of an immunoglobulin chain.

**C genes** code for the constant regions of immunoglobulin protein chains.

**Somatic recombination** describes the process of joining a V gene to a C gene in a lymphocyte to generate an immunoglobulin or T cell receptor.

#### Key Concepts

- An immunoglobulin is a tetramer of two light chains and two heavy chains.
- Light chains fall into the lambda and kappa families; heavy chains form a single family.
- Each chain has an N-terminal variable region (V) and a C-terminal constant region (C).
- The V domain recognizes antigen and the C domain provides the effector response.
- V domains and C domains are separately coded by V gene segments and C gene segments.
- A gene coding for an intact immunoglobulin chain is generated by somatic recombination to join a V gene segment with a C gene segment.

---

A remarkable feature of the immune response is an animal's ability to produce an appropriate antibody whenever it is exposed to a new antigen. How can the organism be prepared to produce antibody proteins each designed specifically to recognize an

antigen whose structure cannot be anticipated?

For practical purposes, we usually reckon that a mammal has the ability to produce  $10^6$ - $10^8$  different antibodies. Each antibody is an immunoglobulin tetramer consisting of two identical **light chains** (L) and two identical **heavy chains** (H). If any light chain can associate with any heavy chain, to produce  $10^6$ - $10^8$  potential antibodies requires  $10^3$ - $10^4$  different light chains and  $10^3$ - $10^4$  different heavy chains.

There are 2 types of light chain and ~10 types of heavy chain. Different classes of immunoglobulins have different effector functions. The class is determined by the heavy chain constant region, which exercises the effector function (see **Figure 25.17**).

The structure of the immunoglobulin tetramer is illustrated in **Figure 25.4**. Light chains and heavy chains share the same general type of organization in which each protein chain consists of two principal regions: the N-terminal **variable region (V region)**; and the C-terminal **constant region (C region)**. They were defined originally by comparing the amino acid sequences of different immunoglobulin chains. As the names suggest, the variable regions show considerable changes in sequence from one protein to the next, while the constant regions show substantial homology.

**Figure 25.4** Heavy and light chains combine to generate an immunoglobulin with several discrete domains.

Corresponding regions of the light and heavy chains associate to generate distinct domains in the immunoglobulin protein.

The variable (V) domain is generated by association between the variable regions of the light chain and heavy chain. *The V domain is responsible for recognizing the antigen.* An immunoglobulin has a Y-shaped structure in which the arms of the Y are identical, and each arm has a copy of the V domain. Production of V domains of different specificities creates the ability to respond to diverse antigens. The total

number of variable regions for either light- or heavy-chain proteins is measured in hundreds. *So the protein displays the maximum versatility in the region responsible for binding the antigen.*

The number of constant regions is vastly smaller than the number of variable regions – typically there are only 1-10 C regions for any particular type of chain. The constant regions in the subunits of the immunoglobulin tetramer associate to generate several individual C domains. The first domain results from association of the single constant region of the light chain ( $C_L$ ) with the  $C_{H1}$  part of the heavy-chain constant region. The two copies of this domain complete the arms of the Y-shaped molecule. Association between the C regions of the heavy chains generates the remaining C domains, which vary in number depending on the type of heavy chain.

Comparing the characteristics of the variable and constant regions, we see the central dilemma in immunoglobulin gene structure. How does the genome code for a set of proteins in which any individual polypeptide chain must have one of <10 possible C regions, but can have any one of several hundred possible V regions? It turns out that the number of coding sequences for each type of region reflects its variability. There are many genes coding for V regions, but only a few genes coding for C regions.

In this context, "*gene*" means a sequence of DNA coding for a discrete part of the final immunoglobulin polypeptide (heavy or light chain). So **V genes** code for variable regions and **C genes** code for constant regions, although *neither type of gene is expressed as an independent unit*. To construct a unit that can be expressed in the form of an authentic light or heavy chain, a V gene must be joined physically to a C gene. In this system, two "genes" code for one polypeptide. To avoid confusion, we will refer to these units as "gene segments" rather than "genes."

The sequences coding for light chains and heavy chains are assembled in the same way: *any one of many V gene segments may be joined to any one of a few C gene segments*. This **somatic recombination** occurs in the B lymphocyte in which the antibody is expressed. The large number of available V gene segments is responsible for a major part of the diversity of immunoglobulins. However, not all diversity is coded in the genome; some is generated by changes that occur during the process of constructing a functional gene (for review see 261; 263).

Essentially the same description applies to the formation of functional genes coding for the protein chains of the T cell receptor. Two types of receptor are found on T cells, one consisting of two types of chain called  $\alpha$  and  $\beta$ , the other consisting of  $\gamma$  and  $\delta$  chains. Like the genes coding for immunoglobulins, the genes coding for the individual chains in T cell receptors consist of separate parts, including V and C regions, that are brought together in an active T cell (see *Molecular Biology 5.25.18 T cell receptors are related to immunoglobulins*; for review see 770).

The crucial fact about the synthesis of immunoglobulins, therefore, is that *the arrangement of V gene segments and C gene segments is different in the cells producing the immunoglobulins (or T cell receptors) from all other somatic cells or germ cells* (768).

The construction of a functional immunoglobulin or T cell receptor gene might seem

to be a Lamarckian process, representing a change in the genome that responds to a particular feature of the phenotype (the antigen). At birth, the organism does not possess the functional gene for producing a particular antibody or T cell receptor. It possesses a large number of V gene segments and a smaller number of C gene segments. The subsequent construction of an active gene from these parts allows the antibody/receptor to be synthesized so that it is available to react with the antigen. The clonal selection theory requires that this rearrangement of DNA occurs *before the exposure to antigen*, which then results in *selection* for those cells carrying a protein able to bind the antigen. The entire process occurs in somatic cells and does not affect the germline; so the response to an antigen is not inherited by progeny of the organism.

There are two families of immunoglobulin light chains,  $\kappa$  and  $\lambda$ , and one family containing all the types of heavy chain (H). Each family resides on a different chromosome, and consists of its own set of both V gene segments and C gene segments. This is called the *germline pattern*, and is found in the germline and in somatic cells of all lineages other than the immune system.

But in a cell expressing an antibody, each of its chains – one light type (either  $\kappa$  or  $\lambda$ ) and one heavy type – is coded by a single intact gene. The recombination event that brings a V gene segment to partner a C gene segment creates an active gene consisting of exons that correspond precisely with the functional domains of the protein. The introns are removed in the usual way by RNA splicing.

Recombination between V and C gene segments to give functional loci occurs in a population of immature lymphocytes. A B lymphocyte usually has only one productive rearrangement of light-chain gene segments (either  $\kappa$  or  $\lambda$ ) and one of heavy-chain gene segments. Similarly, a T lymphocyte productively rearranges an  $\alpha$  gene and a  $\beta$  gene, or one  $\delta$  gene and one  $\gamma$  gene. The antibody or T cell receptor produced by any one cell is determined by the particular configuration of V gene segments and C gene segments that has been joined.

The principles by which functional genes are assembled are the same in each family, but there are differences in the details of the organization of the V and C gene segments, and correspondingly of the recombination reaction between them. In addition to the V and C gene segments, other short DNA sequences (including J segments and D segments) are included in the functional somatic loci (for review see 267; 264).

---

**IMMUNE DIVERSITY****5.25.4 Light chains are assembled by a single recombination**

---

**Key Terms**

**J segments (joining segments)** are coding sequences in the immunoglobulin and T cell receptor loci. The J segments are between the variable (V) and constant (C) gene segments.

**Key Concepts**

- A lambda light chain is assembled by a single recombination between a V gene and a J-C gene segment.
- The V gene segment has a leader exon, intron, and variable-coding region.
- The J-C gene segment has a short J-coding exon, intron, and C-coding region.
- A kappa light chain is assembled by a single recombination between a V gene segment and one of five J segments preceding the C gene.

---

A  $\lambda$  light chain is assembled from two parts, as illustrated in **Figure 25.5**. The V gene segment consists of the leader exon (L) separated by a single intron from the variable (V) segment. The C gene segment consists of the J segment separated by a single intron from the constant (C) exon.

**Figure 25.5** The lambda C gene segment is preceded by a J segment, so that V-J recombination generates a functional lambda light-chain gene.

The name of the **J segment** is an abbreviation for joining, since it identifies the region to which the V segment becomes connected. So the joining reaction does not directly involve V and C gene segments, but occurs via the J segment; when we discuss the joining of "V and C gene segments" for light chains, we really mean V-JC joining.

The J segment is short and codes for the last few (13) amino acids of the variable region, as defined by amino acid sequences. In the intact gene generated by recombination, the V-J segment constitutes a single exon coding for the entire variable region.

The consequences of the  $\kappa$  joining reaction are illustrated in **Figure 25.6**. A  $\kappa$  light chain also is assembled from two parts, but there is a difference in the organization of the C gene segment. A group of five J segments is spread over a region of 500-700 bp, separated by an intron of 2-3 kb from the C  $\kappa$  exon. In the mouse, the central J segment is nonfunctional ( $\psi J3$ ). A V  $\kappa$  segment may be joined to any one of the J segments (769).

**Figure 25.6** The kappa C gene segment is preceded by multiple J segments in the germ line. V-J joining may recognize any one of the J segments, which is then spliced to the C gene segment during RNA processing.

Whichever J segment is used becomes the terminal part of the intact variable exon. Any J segments on the left of the recombining J segment are lost (J1 has been lost in the figure). Any J segment on the right of the recombining J segment is treated as part of the intron between the variable and constant exons (J3 is included in the intron that is spliced out in the figure).

All functional J segments possess a signal at the left boundary that makes it possible to recombine with the V segment; and they possess a signal at the right boundary that can be used for splicing to the C exon. Whichever J segment is recognized in DNA joining uses its splicing signal in RNA processing.

---

**IMMUNE DIVERSITY****5.25.5 Heavy chains are assembled by two recombinations**

---

**Key Terms**

The **D segment** is an additional sequence that is found between the V and J regions of an immunoglobulin heavy chain.

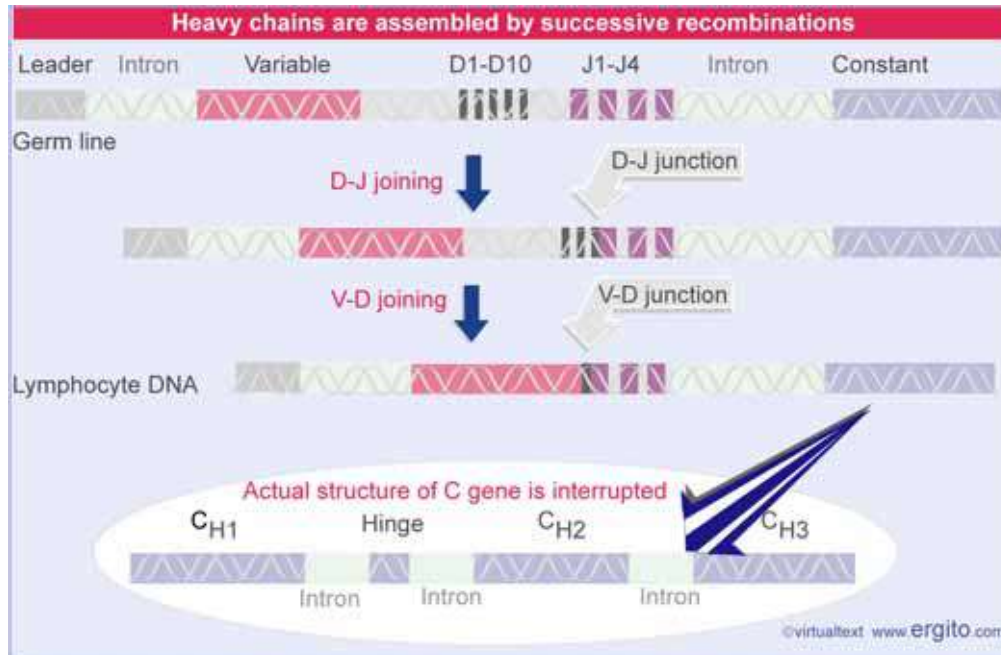

**Key Concepts**

- The units for heavy chain recombination are a V gene, D segment, and J-C gene segment.
- The first recombination joins D to J-C.
- The second recombination joins V to D-J-C.
- The C segment consists of several exons.

---

Heavy chain construction involves an additional segment. The **D segment** (for diversity) was discovered by the presence in the protein of an extra 2-13 amino acids between the sequences coded by the V segment and the J segment. An array of >10 D segments lies on the chromosome between the  $V_H$  segments and the 4  $J_H$  segments.

V-D-J joining takes place in two stages, as illustrated in **Figure 25.7**. First one of the D segments recombines with a  $J_H$  segment; then a  $V_H$  segment recombines with the  $DJ_H$  combined segment. The reconstruction leads to expression of the adjacent  $C_H$  segment (which consists of several exons). (We discuss the use of different  $C_H$  gene segments in *Molecular Biology 5.25.12 Class switching is caused by DNA recombination*; now we will just consider the reaction in terms of the connection to one of several J segments that precede a  $C_H$  gene segment.)

**Figure 25.7** Heavy genes are assembled by sequential joining reactions. First a D segment is joined to a J segment; then a V gene segment is joined to the D segment.

The D segments are organized in a tandem array. The mouse heavy-chain locus contains 12 D segments of variable length; the human locus has ~30 D segments (not all necessarily active). Some unknown mechanism must ensure that the *same* D segment is involved in the D-J joining and V-D joining reactions. (When we discuss joining of V and C gene segments for heavy chains, we assume the process has been completed by V-D and D-J joining reactions.)

The V gene segments of all three immunoglobulin families are similar in organization. The first exon codes for the signal sequence (involved in membrane attachment), and the second exon codes for the major part of the variable region itself (<100 codons long). The remainder of the variable region is provided by the D segment (in the H family only) and by a J segment (in all three families).

The structure of the constant region depends on the type of chain. For both  $\kappa$  and  $\lambda$  light chains, the constant region is coded by a single exon (which becomes the third exon of the reconstructed, active gene). For H chains, the constant region is coded by several exons; corresponding with the protein chain shown in **Figure 25.4**, separate exons code for the regions C<sub>H1</sub>, hinge, C<sub>H2</sub>, and C<sub>H3</sub>. Each C<sub>H</sub> exon is ~100 codons long; the hinge is shorter. The introns usually are relatively small (~300 bp).

This content is available online at <http://www.ergito.com/main.jsp?bcs=MBIO.5.25.5>

## IMMUNE DIVERSITY

### 5.25.6 Recombination generates extensive diversity

#### Key Concepts

- A light chain locus can produce >1000 chains by combining 300 V genes with 4-5 C genes.
- An H locus can produce >4000 chains by combining 300 V genes, 20 D segments, and 4 J segments.

Now we must examine the different types of V and C gene segments to see how much diversity can be accommodated by the variety of the coding regions carried in the germline. In each light Ig gene family, many V gene segments are linked to a much smaller number of C gene segments.

**Figure 25.8** shows that the  $\lambda$  locus has ~6 C gene segments, each preceded by its own J segment. The  $\lambda$  locus in mouse is much less diverse than the human locus. The main difference is that in mouse there are only two  $V_\lambda$  gene segments; each is linked to two J-C regions. Of the 4  $C_\lambda$  gene segments, one is inactive. At some time in the past, the mouse suffered a catastrophic deletion of most of its germline  $V_\lambda$  gene segments.

**Figure 25.8** The lambda family consists of V gene segments linked to a small number of J-C gene segments.

**Figure 25.9** shows that the  $\kappa$  locus has only one C gene segment, although it is preceded by 5 J segments (one of them inactive). The  $V_\kappa$  gene segments occupy a large cluster on the chromosome, upstream of the constant region. The human cluster has two regions. Just preceding the  $C_\kappa$  gene segment, a region of 600 kb contains the 5  $J_\kappa$  segments and 40  $V_\kappa$  gene segments. A gap of 800 kb separates this region from another group of 36  $V_\kappa$  gene segments.

**Figure 25.9** The human and mouse kappa families consist of V gene segments linked to 5 J segments connected to a single C gene segment.

The V $\kappa$  gene segments can be subdivided into families, defined by the criterion that members of a family have >80% amino acid identity. The mouse family is unusually large, ~1000 genes, and there are ~18 V $\kappa$  families, varying in size from 2-100 members. Like other families of related genes, therefore, related V gene segments form subclusters, generated by duplication and divergence of individual ancestral members. However, many of the V segments are inactive pseudogenes, and <50 of the ~300 total are likely to be used to generate immunoglobulins.

A given lymphocyte generates *either* a  $\kappa$  or a  $\lambda$  light chain to associate with the heavy chain. In man, ~60% of the light chains are  $\kappa$  and ~40% are  $\lambda$ . In mouse, 95% of B cells express the  $\kappa$  type of light chain, presumably because of the reduced number of  $\lambda$  gene segments.

The single locus for heavy chain production in Man consists of several discrete sections, as summarized in **Figure 25.10**. It is similar in the mouse, where there are more V $_H$  gene segments, fewer D and J segments, and a slight difference in the number and organization of C gene segments. The 3' member of the V $_H$  cluster is separated by only 20 kb from the first D segment. The D segments are spread over ~50 kb, and then comes the cluster of J segments. Over the next 220 kb lie all the C $_H$  gene segments. There are 9 functional C $_H$  gene segments and 2 pseudogenes. The organization suggests that a  $\gamma$  gene segment must have been duplicated to give the subcluster of  $\gamma$ - $\gamma$ - $\epsilon$ - $\alpha$ , after which the entire group was then duplicated.

**Figure 25.10** A single gene cluster in man contains all the information for heavy-chain gene assembly.

How far is the diversity of germline information responsible for V region diversity in immunoglobulin proteins? By combining any one of ~50 V gene segments with any one of 4-5 J segments, a typical light chain locus has the potential to produce some 250 chains. There is even greater diversity in the H chain locus; by combining any one of ~50 V $_H$  gene segments, 20 D segments, and 4 J segments, the genome potentially can produce 4000 variable regions to accompany any C $_H$  gene segment. In mammals, this is the starting point for diversity, but additional mechanisms introduce further changes. *When closely related variants of immunoglobulins are examined, there often are more proteins than can be accounted for by the number of*

*corresponding V gene segments.* The new members are created by somatic changes in individual genes during or after the recombination process (see *Molecular Biology 5.25.14 Somatic mutation generates additional diversity in mouse and man*).

## IMMUNE DIVERSITY

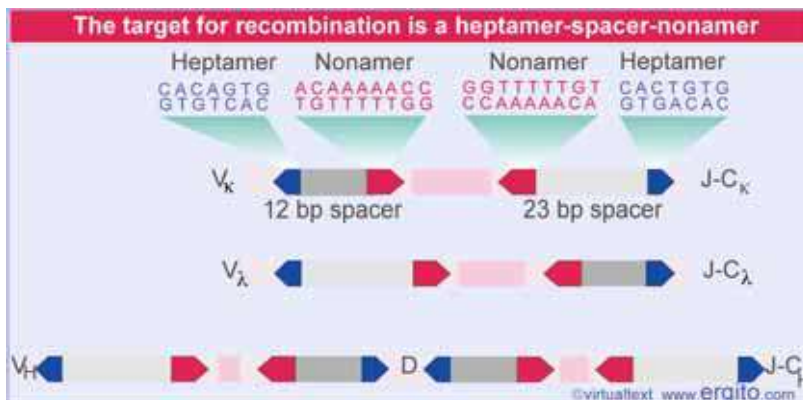

### 5.25.7 Immune recombination uses two types of consensus sequence

#### Key Concepts

- The consensus sequence used for recombination is a heptamer separated by either 12 or 23 base pairs from a nonamer.
- Recombination occurs between two consensus sequences that have different spacings.

Assembly of light- and heavy-chain genes involves the same mechanism (although the number of parts is different). The same consensus sequences are found at the boundaries of all germline segments that participate in joining reactions. Each consensus sequence consists of a heptamer separated by either 12 or 23 bp from a nonamer.

**Figure 25.11** illustrates the relationship between the consensus sequences at the mouse Ig loci. At the  $\kappa$  locus, each  $V_{\kappa}$  gene segment is followed by a consensus sequence with a 12 bp spacing. Each  $J_{\kappa}$  segment is preceded by a consensus sequence with a 23 bp spacing. The V and J consensus sequences are inverted in orientation. At the  $\lambda$  locus, each  $V_{\lambda}$  gene segment is followed by a consensus sequence with 23 bp spacing, while each  $J_{\lambda}$  gene segment is preceded by a consensus of the 12 bp spacer type (771).

**Figure 25.11** Consensus sequences are present in inverted orientation at each pair of recombining sites. One member of each pair has a spacing of 12 bp between its components; the other has 23 bp spacing.

The rule that governs the joining reaction is that *a consensus sequence with one type of spacing can be joined only to a consensus sequence with the other type of spacing*. Since the consensus sequences at V and J segments can lie in either order, the different spacings do not impart any directional information, but serve to prevent one V gene segment from recombining with another, or one J segment from recombining

with another.

This concept is borne out by the structure of the components of the heavy gene segments. Each  $V_H$  gene segment is followed by a consensus sequence of the 23 bp spacer type. The  $D_H$  segments are flanked on either side by consensus sequences of the 12 bp spacer type. The  $J_H$  segments are preceded by consensus sequences of the 23 bp spacer type. So the  $V_H$  gene segment must be joined to a  $D$  segment; and the  $D$  segment must be joined to a  $J$  segment. A  $V$  gene segment cannot be joined directly to a  $J$  segment, because both possess the same type of consensus sequence.

The spacing between the components of the consensus sequences corresponds almost to one or two turns of the double helix. This may reflect a geometric relationship in the recombination reaction. For example, the recombination protein(s) may approach the DNA from one side, in the same way that RNA polymerase and repressors approach recognition elements such as promoters and operators.

**IMMUNE DIVERSITY****5.25.8 Recombination generates deletions or inversions**

---

**Key Terms**

A **signal end** is produced during recombination of immunoglobulin and T cell receptor genes. The signal ends are at the termini of the cleaved fragment containing the recombination signal sequences. The subsequent joining of the signal ends yields a signal joint.

A **coding end** is produced during recombination of immunoglobulin and T cell receptor genes. Coding ends are at the termini of the cleaved V and (D)J coding regions. The subsequent joining of the coding ends yields a coding joint.

**Key Concepts**

- Recombination occurs by double-strand breaks at the heptamers of two consensus sequences.
- The signal ends of the fragment between the breaks usually join to generate an excised circular fragment.
- The coding ends are covalently linked to join V to J-C (L chain) or D to J-C and V to D-J-C (H chain).
- If the recombining genes are in inverted instead of direct orientation, there is an inversion instead of deletion of an excised circle.

---

Recombination of the components of immunoglobulin genes is accomplished by a physical rearrangement of sequences, involving breakage and reunion, but the mechanism is different from homologous recombination. The general nature of the reaction is illustrated in **Figure 25.12** for the example of a  $\kappa$  light chain. (The reaction is similar at a heavy chain locus, except that there are two recombination events: first D-J, then V-DJ.)

**Figure 25.12** Breakage and reunion at consensus sequences generates immunoglobulin genes.

Breakage and reunion occur as separate reactions. A double-strand break is made at the heptamers that lie at the ends of the coding units. This releases the entire fragment between the V gene segment and J-C gene segment; the cleaved termini of this fragment are called **signal ends**. The cleaved termini of the V and J-C loci are called **coding ends**. The two coding ends are covalently linked to form a coding joint; this is the connection that links the V and J segments. If the two signal ends are also connected, the excised fragment would form a circular molecule.

We have shown the V and J-C loci as organized in the same orientation. As a result, the cleavage at each consensus sequence releases the region between them as a linear fragment. If the signal ends are joined, it is converted into a circular molecule, as indicated in **Figure 25.12**. Deletion to release an excised circle is the predominant mode of recombination at the immunoglobulin and TCR loci.

In some exceptional cases the V gene segment is inverted in orientation on the chromosome relative to the J-C loci. In such a case, breakage and reunion inverts the intervening material instead of deleting it. The outcomes of deletion versus inversion are the same as shown previously for homologous recombination between direct or inverted repeats in **Figure 16.9** and **Figure 16.10**. There is one further proviso, however; recombination with an inverted V gene segment makes it *necessary* for the signal ends to be joined, because otherwise there is a break in the locus. Inversion occurs in TCR recombination, and also sometimes in the  $\kappa$  light chain locus.

**IMMUNE DIVERSITY****5.25.9 The RAG proteins catalyze breakage and reunion**

---

**Key Terms**

A **P nucleotide** sequence is a short palindromic (inverted repeat) sequence that is generated during rearrangement of immunoglobulin and T cell receptor V, (D), J gene segments. P nucleotides are generated at coding joints when RAG proteins cleave the hairpin ends generated during rearrangement.

An **N nucleotide** sequence is a short non-templated sequence that is added randomly by the enzyme at coding joints during rearrangement of immunoglobulin and T cell receptor genes. N nucleotides augment the diversity of antigen receptors.

**Key Concepts**

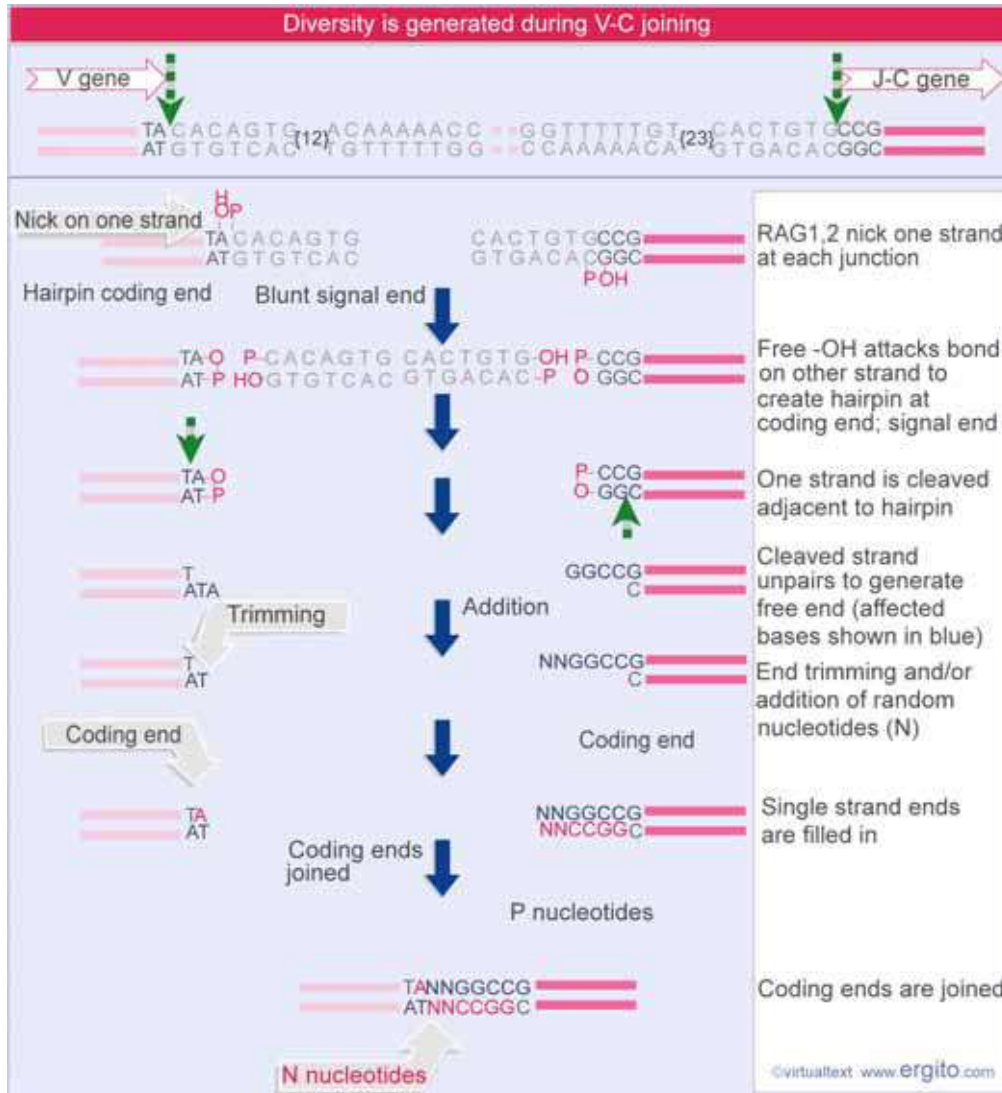

- The RAG proteins are necessary and sufficient for the cleavage reaction.
- RAG1 recognizes the nonamer consensus sequences for recombination. RAG2 binds to RAG1 and cleaves at the heptamer.
- The reaction resembles the topoisomerase-like resolution reaction that occurs in transposition.
- It proceeds through a hairpin intermediate at the coding end; opening of the hairpin is responsible for insertion of extra bases (P nucleotides) in the recombined gene.
- Deoxynucleoside transferase inserts additional N nucleotides at the coding end.
- The codon at the site of the V-(D)J joining reaction has an extremely variable sequence and codes for amino acid 96 in the antigen-binding site.
- The double-strand breaks at the coding joints are repaired by the same system involved in nonhomologous end-joining of damaged DNA.
- An enhancer in the C gene activates the promoter of the V gene after recombination has generated the intact immunoglobulin gene.

---

The proteins RAG1 and RAG2 are necessary and sufficient to cleave DNA for V(D)J recombination. They are coded by two genes, separated by <10 kb on the chromosome, whose transfection into fibroblasts causes a suitable substrate DNA to undergo the V(D)J joining reaction (1260; 1261) (see *Great Experiments 12.5 Identification of the V(D)J recombination activating genes, RAG1 and RAG2*). Mice that lack either *RAG1* or *RAG2* are unable to recombine their immunoglobulins or T cell receptors, and as a result have immature B and T lymphocytes. The RAG proteins together undertake the catalytic reactions of cleaving and rejoining DNA, and also provide a structural framework within which the reactions occur (3022; 3023; 3025).

RAG1 recognizes the heptamer/nonamer signals with the appropriate 12/23 spacing and recruits RAG2 to the complex. The nonamer provides the site for initial recognition, and the heptamer directs the site of cleavage.

The reactions involved in recombination are shown in **Figure 25.13**. The complex nicks one strand at each junction. The nick has 3' -OH and 5' -P ends. The free 3' -OH end then attacks the phosphate bond at the corresponding position *in the other strand of the duplex*. This creates a hairpin at the coding end, in which the 3' end of one strand is covalently linked to the 5' end of the other strand; it leaves a blunt double-strand break at the signal end.

**Figure 25.13** Processing of coding ends introduces variability at the junction.

This second cleavage is a transesterification reaction in which bond energies are conserved. It resembles the topoisomerase-like reactions catalyzed by the resolvase proteins of bacterial transposons (see *Molecular Biology 4.16.9 TnA transposition requires transposase and resolvase*). The parallel with these reactions is supported

further by a homology between RAG1 and bacterial invertase proteins (which invert specific segments of DNA by similar recombination reactions). In fact, the RAG proteins can insert a donor DNA whose free ends consist of the appropriate signal sequences (heptamer–12/23–spacer nonamer) into an unrelated target DNA in an *in vitro* transposition reaction (1196; 1197; 1198). This suggests that somatic recombination of immune genes evolved from an ancestral transposon. It also suggests that the RAG proteins are responsible for chromosomal translocations in which Ig or TCR loci are connected to other loci (see *Molecular Biology* 6.30.12 *Proto-oncogenes can be activated by translocation*).

The hairpins at the coding ends provide the substrate for the next stage of reaction. If a single-strand break is introduced into one strand close to the hairpin, an unpairing reaction at the end generates a single-stranded protrusion. Synthesis of a complement to the exposed single strand then converts the coding end to an extended duplex. This reaction explains the introduction of **P nucleotides** at coding ends; they consist of a few extra base pairs, related to, but reversed in orientation from, the original coding end.

Some extra bases also may be inserted, apparently with random sequences, between the coding ends. They are called **N nucleotides**. Their insertion occurs via the activity of the enzyme deoxynucleoside transferase (known to be an active component of lymphocytes) at a free 3' coding end generated during the joining process.

Changes in sequence during recombination are therefore a consequence of the enzymatic mechanisms involved in breaking and rejoining the DNA. In heavy chain recombination, base pairs are lost or inserted at the V<sub>H</sub>-D or D-J or both junctions. Deletion also occurs in V<sub>λ</sub>-J<sub>λ</sub> joining, but insertion at these joints is unusual (773; for review see 274; 275). The changes in sequence affect the amino acid coded at V-D and D-J junctions in heavy chains or at the V-J junction in light chains.

*These various mechanisms together ensure that a coding joint may have a sequence that is different from what would be predicted by a direct joining of the coding ends of the V, D, and J regions.*

Changes in the sequence at the junction make it possible for a great variety of amino acids to be coded at this site. It is interesting that the amino acid at position 96 is created by the V-J joining reaction. It forms part of the antigen-binding site and also is involved in making contacts between the light and heavy chains. So the maximum diversity is generated at the site that contacts the target antigen.

Changes in the number of base pairs at the coding joint affect the reading frame. The joining process appears to be random with regard to reading frame, so that probably only one third of the joined sequences retain the proper frame of reading through the junctions. If the V-J region is joined so that the J segment is out of phase, translation is terminated prematurely by a nonsense codon in the incorrect frame. We may think of the formation of aberrant genes as comprising the price the cell must pay for the increased diversity that it gains by being able to adjust the sequence at the joining site.

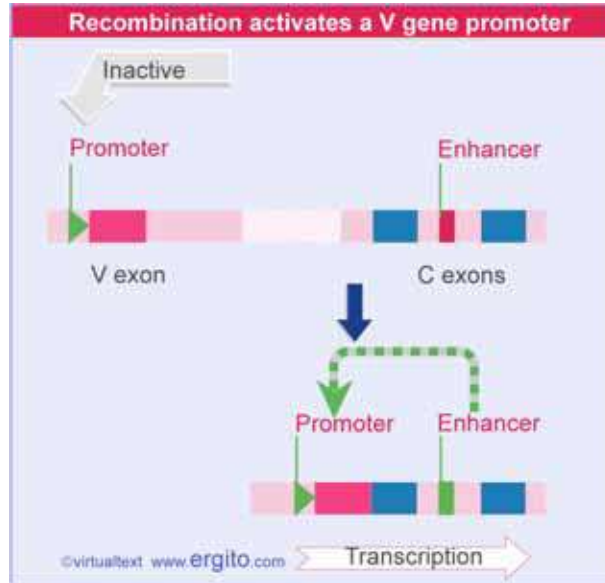

Similar although even greater diversity is generated in the joining reactions that

involve the D segment of the heavy chain. The same result is seen with regard to reading frame; nonproductive genes are generated by joining events that place J and C out of phase with the preceding V gene segment.

The joining reaction that works on the coding end uses the same pathway of nonhomologous end-joining (NHEJ) that repairs double-strand breaks in cells (for review see 2514) (See *Molecular Biology 4.15.28 Eukaryotic cells have conserved repair systems*). The initial stages of the reaction were identified by isolating intermediates from lymphocytes of mice with the *SCID* mutation, which results in a much reduced activity in immunoglobulin and TCR recombination. *SCID* mice accumulate broken molecules that terminate in double-strand breaks at the coding ends, and are thus deficient in completing some aspect of the joining reaction. The *SCID* mutation inactivates a DNA-dependent protein kinase (DNA-PK). The kinase is recruited to DNA by the Ku70 and Ku80 proteins, which bind to the DNA ends. DNA-PK phosphorylates and thereby activates the protein Artemis, which nicks the hairpin ends (2397) (it also has exonuclease and endonuclease activities that function in the NHEJ pathway). The actual ligation is undertaken by DNA ligase IV and also requires the protein XRCC4. As a result, mutations in the Ku proteins or in XRCC4 or DNA ligase IV are found among human patients who have diseases caused by deficiencies in DNA repair that result in increased sensitivity to radiation.

What is the connection between joining of V and C gene segments and their activation? Unrearranged V gene segments are not actively represented in RNA. But when a V gene segment is joined productively to a C $\kappa$  gene segment, the resulting unit is transcribed. However, since the sequence upstream of a V gene segment is not altered by the joining reaction, *the promoter must be the same in unrearranged, nonproductively rearranged, and productively rearranged genes.*

A promoter lies upstream of every V gene segment, but is inactive. It is activated by its relocation to the C region. The effect must depend on sequences downstream. What role might they play? An enhancer located within or downstream of the C gene segment activates the promoter at the V gene segment. The enhancer is tissue specific; it is active only in B cells. Its existence suggests the model illustrated in **Figure 25.14**, in which the V gene segment promoter is activated when it is brought within the range of the enhancer.

**Figure 25.14** A V gene promoter is inactive until recombination brings it into the proximity of an enhancer in the C gene segment. The enhancer is active only in B lymphocytes.

## IMMUNE DIVERSITY

### 5.25.10 Allelic exclusion is triggered by productive rearrangement

---

#### Key Terms

**Allelic exclusion** describes the expression in any particular lymphocyte of only one allele coding for the expressed immunoglobulin. This is caused by feedback from the first immunoglobulin allele to be expressed that prevents activation of a copy on the other chromosome.

The recombination of V, (D), J gene segments results in a **productive rearrangement** if all the rearranged gene segments are in the correct reading frame.

The recombination of V, (D), J gene segments results in a **nonproductive rearrangement** if the rearranged gene segments are not in the correct reading frame. A nonproductive rearrangement occurs when nucleotide addition or subtraction disrupts the reading frame or when .

#### Key Concepts

- Recombination to generate an intact immunoglobulin gene is productive if it leads to expression of an active protein.
- A productive rearrangement prevents any further rearrangement from occurring, but a nonproductive rearrangement does not.
- Allelic exclusion applies separately to light chains (only one kappa *or* lambda may be productively rearranged) and to heavy chains (one heavy chain is productively rearranged).

---

Each B cell expresses a single type of light chain and a single type of heavy chain, because only a single productive rearrangement of each type occurs in a given lymphocyte, to produce one light and one heavy chain gene. Because each event involves the genes of only *one* of the homologous chromosomes, *the alleles on the other chromosome are not expressed in the same cell*. This phenomenon is called **allelic exclusion**.

The occurrence of allelic exclusion complicates the analysis of somatic recombination. A probe reacting with a region that has rearranged on one homologue will also detect the allelic sequences on the other homologue. We are therefore compelled to analyze the different fates of the two chromosomes together.

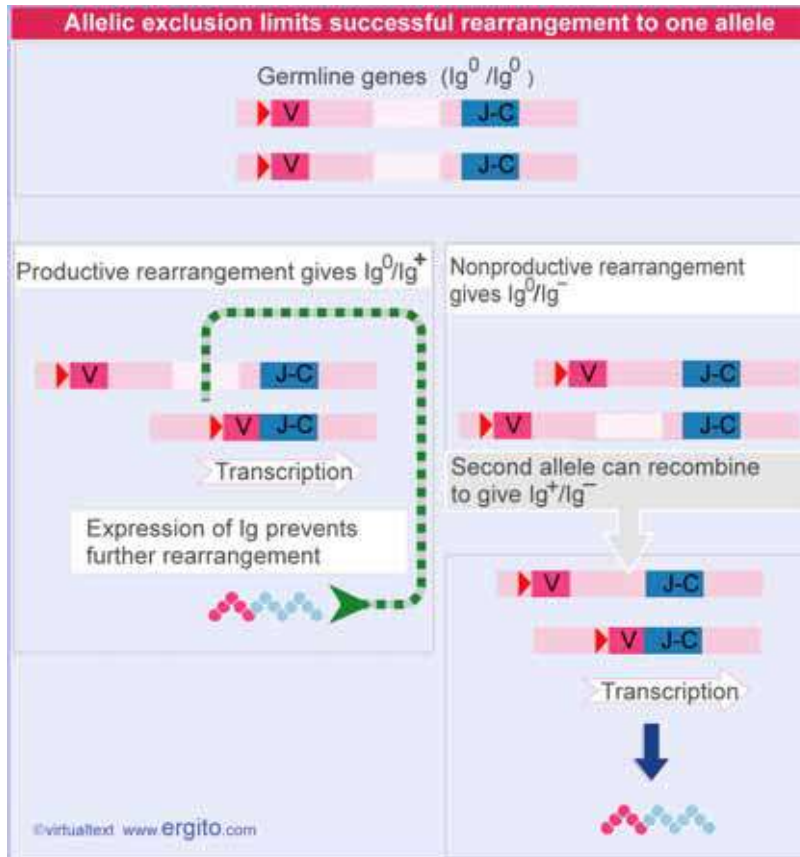

The usual pattern displayed by a rearranged active gene can be interpreted in terms of a deletion of the material between the recombining V and C loci.

Two types of gene organization are seen in active cells:

- Probes to the active gene may reveal one rearranged copy and one germline copy. We assume then that joining has occurred on one chromosome, while the other chromosome has remained unaltered.
- Two different rearranged patterns may be found, indicating that the chromosomes have suffered independent rearrangements. In some of these instances, material between the recombining V and C gene segments is entirely absent from the cell line. This is most easily explained by the occurrence of independent deletions (resulting from recombination) on each chromosome.

When two chromosomes both lack the germline pattern, usually only one of them has passed through a **productive rearrangement** to generate a functional gene. The other has suffered a **nonproductive rearrangement**; this may take several forms, but in each case the gene sequence cannot be expressed as an immunoglobulin chain. (It may be incomplete, for example because D-J joining has occurred but V-D joining has not followed; or it may be aberrant, with the process completed, but failing to generate a gene that codes for a functional protein.)

The coexistence of productive and nonproductive rearrangements suggests the existence of a feedback loop to control the recombination process. A model is outlined in **Figure 25.15**. Suppose that each cell starts with two loci in the unrearranged germline configuration  $Ig^0$ . Either of these loci may be rearranged to generate a productive gene  $Ig^+$  or a nonproductive gene  $Ig^-$ .

**Figure 25.15** A successful rearrangement to produce an active light or heavy chain suppresses further rearrangements of the same type, and results in allelic exclusion.

If the rearrangement is productive, the synthesis of an active chain provides a trigger to prevent rearrangement of the other allele. The active cell has the configuration  $Ig^0/Ig^+$ .

If the rearrangement is nonproductive, it creates a cell with the configuration  $Ig^0/Ig^-$ . There is no impediment to rearrangement of the remaining germline allele. If this rearrangement is productive, the expressing cell has the configuration  $Ig^+/Ig^-$ . Again, the presence of an active chain suppresses the possibility of further rearrangements.

Two successive nonproductive rearrangements produce the cell  $Ig^-/Ig^-$ . In some cases an  $Ig^-/Ig^-$  cell can try yet again. Sometimes the observed patterns of DNA can only have been generated by successive rearrangements.

The crux of the model is that the cell keeps trying to recombine V and C gene segments until a productive rearrangement is achieved. Allelic exclusion is caused by the suppression of further rearrangement as soon as an active chain is produced. The use of this mechanism *in vivo* is demonstrated by the creation of transgenic mice whose germline has a rearranged immunoglobulin gene. Expression of the transgene in B cells suppresses the rearrangement of endogenous genes (for review see 269).

Allelic exclusion is independent for the heavy- and light-chain loci. Heavy chain

genes usually rearrange first. Allelic exclusion for light chains must apply equally to both families (cells may have *either* active  $\kappa$  or  $\lambda$  light chains). It is likely that the cell rearranges its  $\kappa$  genes first, and tries to rearrange  $\lambda$  only if both  $\kappa$  attempts are unsuccessful.

There is an interesting paradox in this series of events. The same consensus sequences and the same V(D)J recombinase are involved in the recombination reactions at H,  $\kappa$ , and  $\lambda$  loci. Yet the three loci rearrange in a set order. What ensures that heavy rearrangement precedes light rearrangement, and that  $\kappa$  precedes  $\lambda$ ? The loci may become accessible to the enzyme at different times, possibly as the result of transcription. Transcription occurs even before rearrangement, although of course the products have no coding function. The transcriptional event may change the structure of chromatin, making the consensus sequences for recombination available to the enzyme.

**IMMUNE DIVERSITY****5.25.11 Early heavy chain expression can be changed by RNA processing**

---

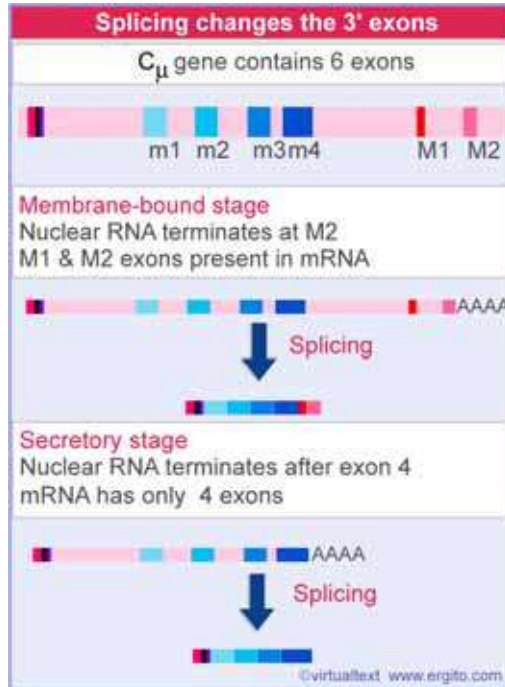

**Key Concepts**

- All lymphocytes start by synthesizing the membrane-bound form of IgM.
  - A change in RNA splicing causes this to be replaced by the secreted form when the B cell differentiates.
- 

The period of IgM synthesis that begins lymphocyte development falls into two parts, during which different versions of the  $\mu$  constant region are synthesized:

- As a stem cell differentiates to a pre-B lymphocyte, an accompanying light chain is synthesized, and the IgM molecule ( $L_2\mu_m$ ) appears at the surface of the cell. This form of IgM contains the  $\mu_m$  version of the constant region ( $m$  indicates that IgM is located in the membrane). The membrane location may be related to the need to initiate cell proliferation in response to the initial recognition of an antigen.
- When the B lymphocyte differentiates further into a plasma cell, the  $\mu_s$  version of the constant region is expressed. The IgM actually is secreted as a pentamer  $IgM_5J$ , in which  $J$  is a joining polypeptide (no connection with the  $J$  region) that forms disulfide linkages with  $\mu$  chains. Secretion of the protein is followed by the humoral response depicted in **Figure 25.1**.

The  $\mu_m$  and  $\mu_s$  versions of the  $\mu$  heavy chain differ only at the C-terminal end. The  $\mu_m$  chain ends in a hydrophobic sequence that probably secures it in the membrane. This sequence is replaced by a shorter hydrophilic sequence in  $\mu_s$ ; the substitution allows the  $\mu$  heavy chain to pass through the membrane. The change of C-terminus is accomplished by an alternative splicing event, which is controlled by the 3' end of the nuclear RNA, as illustrated in **Figure 25.16**.

**Figure 25.16** The 3' end controls the use of splicing junctions so that alternative forms of the heavy gene are expressed.

At the membrane-bound stage, the RNA terminates after exon M2, and the constant region is produced by splicing together six exons. The first four exons code for the four domains of the constant region. The last two exons, M1 and M2, code for the 41-residue hydrophobic C-terminal region and its nontranslated trailer. The 5' splice junction within exon 4 is connected to the 3' splice junction at the beginning of M1.

At the secreted stage, the nuclear RNA terminates after exon 4. The 5' splice junction within this exon that had been linked to M1 in the membrane form is ignored. This allows the exon to extend for an additional 20 codons.

A similar transition from membrane to secreted forms is found with other constant regions. The conservation of exon structures suggests that the mechanism is the same.

## IMMUNE DIVERSITY

### 5.25.12 Class switching is caused by DNA recombination

#### Key Terms

**Class switching** describes a change in Ig gene organization in which the C region of the heavy chain is changed but the V region remains the same.

An **S region** is an intron sequence involved in immunoglobulin class switching. S regions consist of repetitive sequences at the 5' ends of gene segments encoding the heavy chain constant regions.

#### Key Concepts

- Immunoglobulins are divided into five classes according to the type of constant region in the heavy chain.
- Class switching to change the C<sub>H</sub> region occurs by a recombination between S regions that deletes the region between the old C<sub>H</sub> region and the new C<sub>H</sub> region.
- Multiple successive switch recombinations can occur.

The *class* of immunoglobulin is defined by the type of C<sub>H</sub> region. **Figure 25.17** summarizes the five Ig classes. IgM (the first immunoglobulin to be produced by any B cell) and IgG (the most common immunoglobulin) possess the central ability to activate complement, which leads to destruction of invading cells. IgA is found in secretions (such as saliva), and IgE is associated with the allergic response and defense against parasites.

There are five types of heavy chain					
Type	IgM	IgD	IgG	IgA	IgE
Heavy chain	μ	δ	γ	α	ε
Structure	(μ <sub>2</sub> L <sub>2</sub> ) <sub>5</sub> J	δ <sub>2</sub> L <sub>2</sub>	γ <sub>2</sub> L <sub>2</sub>	(α <sub>2</sub> L <sub>2</sub> ) <sub>2</sub> J	ε <sub>2</sub> L <sub>2</sub>
Proportion	5%	1%	80%	14%	<1%
Effector function	Activates complement	Development of tolerance (?)	Activates complement	Found in secretions	Allergic response

**Figure 25.17** Immunoglobulin type and function is determined by the heavy chain. J is a joining protein in IgM; all other Ig types exist as tetramers.

All lymphocytes start productive life as immature cells engaged in synthesis of IgM. Cells expressing IgM have the germline arrangement of the C<sub>H</sub> gene segment cluster shown in **Figure 25.10**. The V-D-J joining reaction triggers expression of the C<sub>H</sub> gene segment. A lymphocyte generally produces only a single class of immunoglobulin at any one time, but the class may change during the cell lineage. A change in expression is called **class switching**. It is accomplished by a substitution in the type of C<sub>H</sub> region that is expressed. Switching can be stimulated by

---

environmental effects; for example, the growth factor TGF  $\beta$  causes switching from  $C_{\mu}$  to  $C_{\alpha}$ .

*Switching involves only the  $C_H$  gene segment; the same  $V_H$  gene segment continues to be expressed. So a given  $V_H$  gene segment may be expressed successively in combination with more than one  $C_H$  gene segment. The same light chain continues to be expressed throughout the lineage of the cell. Class switching therefore allows the type of effector response (mediated by the  $C_H$  region) to change, while maintaining the same capacity to recognize antigen (mediated by the V regions).*

Changes in the expression of  $C_H$  gene segments are made in two ways. The majority occur via further DNA recombination events, involving a system different from that concerned with V-D-J joining (and able to operate only later during B cell development). Another type of change occurs at the level of RNA processing, but generally this is involved with changing the C-terminal sequence of the  $C_H$  region rather than its class (see *Molecular Biology 5.25.11 Early heavy chain expression can be changed by RNA processing*).

Cells expressing downstream  $C_H$  gene segments have deletions of  $C_{\mu}$  and the other gene segments preceding the expressed  $C_H$  gene segment. Class $^{\mu}$  switching is accomplished by a recombination to bring a new  $C_H$  gene segment into juxtaposition with the expressed V-D-J unit. The sequences of switched V-D-J- $C_H$  units show that the sites of switching lie upstream of the  $C_H$  gene segments themselves. The switching sites are called **S regions**. **Figure 25.18** depicts two successive switches.

**Figure 25.18** Class switching of heavy genes may occur by recombination between switch regions (S), deleting the material between the recombining S sites. Successive switches may occur.

In the first switch, expression of  $C_\mu$  is succeeded by expression of  $C_{\gamma_1}$ . The  $C_{\gamma_1}$  gene segment is brought into the expressed position by recombination between the sites  $S_\mu$  and  $S_{\gamma_1}$ . The  $S_\mu$  site lies between V-D-J and the  $C_\mu$  gene segment. The  $S_{\gamma_1}$  site lies upstream of the  $C_{\gamma_1}$  gene segment. The DNA sequence between the two switch sites is excised as a circular molecule.

The linear deletion model imposes a restriction on the heavy-gene locus: *once a class switch has been made, it becomes impossible to express any  $C_H$  gene segment that used to reside between  $C$  and the new  $C_H$  gene segment.* In the example of **Figure 25.18**, cells expressing  $C_{\gamma_1}^\mu$  should be unable to give rise to cells expressing  $C_{\gamma_3}$ , which has been deleted.

However, it should be possible to undertake another switch to any  $C_H$  gene segment *downstream* of the expressed gene. **Figure 25.18** shows a second  $C_\alpha$  switch to  $C_\alpha$  expression, accomplished by recombination between  $S_{\alpha_1}$  and the switch region  $S_{\mu, \gamma_1}$  that was generated by the original switch.

We assume that all of the  $C_H$  gene segments have S regions upstream of the coding sequences. We do not know whether there are any restrictions on the use of S regions. Sequential switches do occur, but we do not know whether they are optional or an obligatory means to proceed to later  $C_H$  gene segments. We should like to know whether IgM can switch directly to *any* other class. Because the S regions lie within

the introns that precede the C<sub>H</sub> coding regions, switching does not alter the translational reading frame.

**IMMUNE DIVERSITY****5.25.13 Switching occurs by a novel recombination reaction**

---

**Key Concepts**

- Switching occurs by a double-strand break followed by the non-homologous end joining reaction.
  - The important feature of a switch region is the presence of inverted repeats.
  - Switching requires activation of promoters that are upstream of the switch sites.
- 

We know that switch sites are not uniquely defined, because different cells expressing the same  $C_H$  gene segment prove to have recombined at different points. Switch regions vary in length (as defined by the limits of the sites involved in recombination) from 1-10 kb. They contain groups of short inverted repeats, with repeating units that vary from 20-80 nucleotides in length. The primary sequence of the switch region does not seem to be important; what matters is the presence of the inverted repeats (2433).

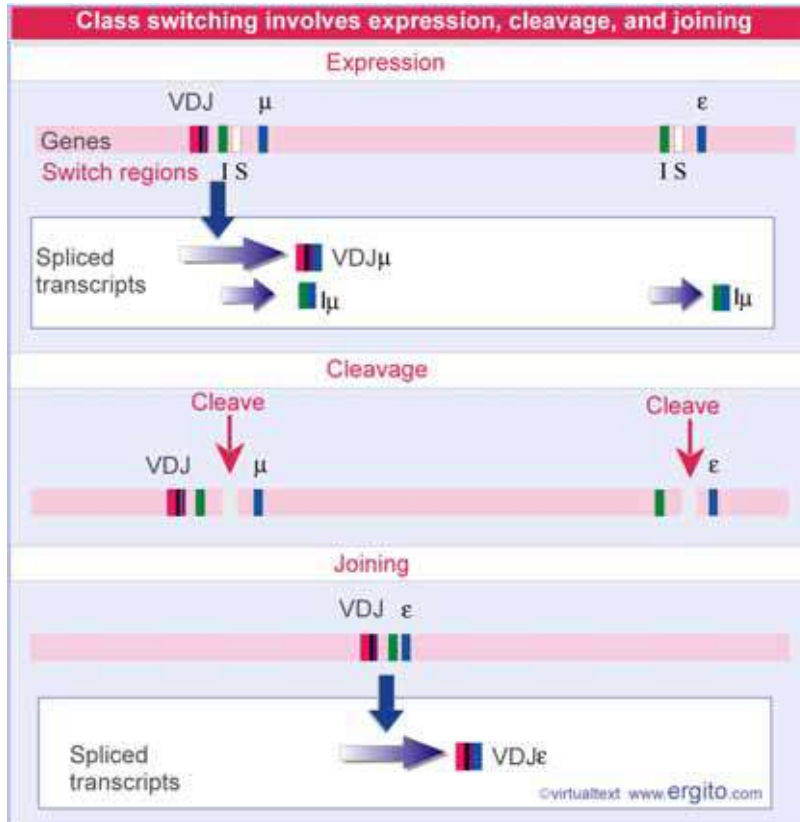

An S region typically is located ~2 kb upstream of a  $C_H$  gene segment. The switching reaction releases the excised material between the switch sites as a circular DNA molecule (1208; 1209; 1210). Two of the proteins required for the joining phase of VDJ recombination (and also for the general nonhomologous end-joining pathway, NHEJ), Ku and DNA-PKcs, are required, suggesting that the joining reaction may use the NHEJ pathway (1213; 1214). Basically this implies that the reaction occurs by a double-strand break followed by rejoining of the cleaved ends.

We can put together the features of the reaction to propose a model for the generation of the double-strand break (for review see 2434). The critical points are:

- transcription through the S region is required;
- the inverted repeats are crucial;
- and the break can occur at many different places within the S region.

**Figure 25.19** shows the stages of the class switching reaction. A promoter (I) lies immediately upstream of each switch region. Switching requires transcription from this promoter (1211; 1212). The promoter may respond to activators that respond to environmental conditions, such as stimulation by cytokines, thus creating a mechanism to regulate switching. The first stage in switching is therefore to activate the I promoters that are upstream of each of the switch regions that will be involved. When these promoters are activated, they generate sterile transcripts that are spliced to join the I region with the corresponding heavy constant region.

**Figure 25.19** Class switching passes through discrete stages. The I promoters initiate transcription of sterile transcripts. The switch regions are cleaved. Joining occurs at the cleaved regions.

The key insight into the mechanism of switching was the discovery of the requirement for the enzyme AID (activation-induced cytidine deaminase) (for review see 4845). In the absence of AID, class switching is blocked before the nicking stage (1206, 1207). Somatic mutation is also blocked, showing an interesting connection between two important processes in immune diversification (see *Molecular Biology 5.25.15 Somatic mutation is induced by cytidine deaminase and uracil glycosylase*).

AID is expressed only at a specific stage during the differentiation of B lymphocytes, restricting the processes of class switching and somatic mutation to this stage. AID is a member of a class of enzymes that act on RNA to change a cytidine to a uridine (see *Molecular Biology 5.26.10 RNA editing occurs at individual bases*). However, AID has a different specificity, and acts on single-stranded DNA (4846).

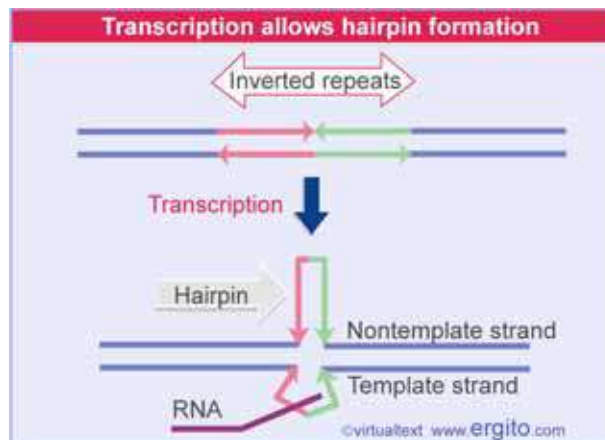

Another enzyme is also required for both class switching and somatic mutation. This is UNG, a uracil DNA glycosylase, which removes the uracil that AID generates by deaminating cytidine. Mice that are deficient in UNG have a 10-fold reduction in class switching. This suggests a model in which the successive actions of AID and UNG create sites from which a base has been removed in DNA. Different consequences follow in the class switching and somatic mutation systems.

The source of the single-stranded DNA target for AID is generated by the process of

sterile transcription, most probably by exposing the nontemplate strand of DNA that is displaced when the other strand is used as template for RNA synthesis. This is supported by the observation that AID preferentially targets cytidines in the nontemplate strand (4847).

To cause class switching, these sites are converted into breaks in the nucleotide chain that provide the cleavage events shown in **Figure 25.19**. The broken ends are joined by the NHEJ pathway, which is a repair system that acts on double-strand breaks in DNA (see *Molecular Biology 4.15.29 A common system repairs double-strand breaks*). We do not know yet how the abasic sites are converted into double-strand breaks. The MSH system that is involved in repairing mismatches in DNA may be required, because mutations in the gene *MSH2* reduce class switching.

One unexplained feature is the involvement of inverted repeats. One possibility is that hairpins are formed by an interaction between the inverted repeats on the displaced nontemplate strand, as shown in **Figure 25.20**. In conjunction with the generation of abasic sites on this strand, this might lead to breakage.

**Figure 25.20** When transcription separates the strands of DNA, one strand may form an inverted repeat if the sequence is palindromic.

Another critical question that remains to be answered is how the system is targeted to the appropriate regions in the heavy chain locus, and what controls the use of switching sites.

**IMMUNE DIVERSITY****5.25.14 Somatic mutation generates additional diversity in mouse and man**

---

**Key Terms**

A **somatic mutation** is a mutation occurring in a somatic cell, and therefore affecting only its daughter cells; it is not inherited by descendants of the organism.

**Hypermutation** describes the introduction of somatic mutations in a rearranged immunoglobulin gene. The mutations can change the sequence of the corresponding antibody, especially in its antigen-binding site.

**Hybridoma** is a cell line produced by fusing a myeloma with a lymphocyte; it continues indefinitely to express the immunoglobulins of both parents.

**Key Concepts**

- Active immunoglobulin genes have V regions with sequences that are changed from the germline because of somatic mutation.
- The mutations occur as substitutions of individual bases.
- The sites of mutation are concentrated in the antigen-binding site.
- The process depends on the enhancer that activates transcription at the Ig locus.

---

Comparisons between the sequences of expressed immunoglobulin genes and the corresponding V gene segments of the germline show that new sequences appear in the expressed population. Some of this additional diversity results from sequence changes at the V-J or V-D-J junctions that occur during the recombination process. However, other changes occur upstream at locations within the variable domain.

Two types of mechanism can generate changes in V gene sequences after rearrangement has generated a functional immunoglobulin gene. In mouse and Man, the mechanism is the induction of **somatic mutations** at individual locations within the gene specifically in the active lymphocyte. The process is sometimes called **hypermutation**. In chicken, rabbit, and pig, a different mechanism uses gene conversion to change a segment of the expressed V gene into the corresponding sequence from a different V gene (see *Molecular Biology 5.25.16 Avian immunoglobulins are assembled from pseudogenes*).

A probe representing an expressed V gene segment can be used to identify all the corresponding fragments in the germline. Their sequences should identify the complete repertoire available to the organism. Any expressed gene whose sequence is different must have been generated by somatic changes.

One difficulty is to ensure that every potential contributor in the germline V gene segments actually has been identified. This problem is overcome by the simplicity of

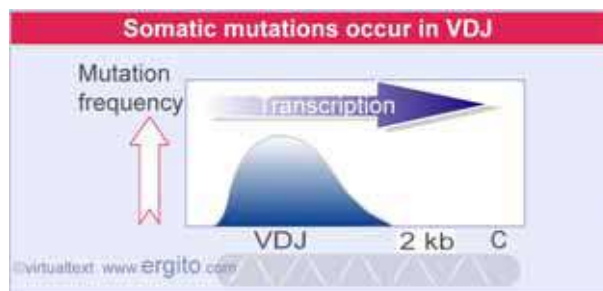

the mouse  $\lambda$  chain system. A survey of several myelomas producing  $\lambda_1$  chains showed that many have the sequence of the single germline gene segment. *But others have new sequences that must have been generated by mutation of the germline gene segment.*

To determine the frequency of somatic mutation in other cases, we need to examine a large number of cells in which the same V gene segment is expressed. A practical procedure for identifying such a group is to characterize the immunoglobulins of a series of cells, all of which express an immune response to a particular antigen.

(Epitopes used for this purpose are small molecules – haptens – whose discrete structure is likely to provoke a consistent response, unlike a large protein, different parts of which provoke different antibodies. A hapten is conjugated with a nonreactive protein to form the antigen. The cells are obtained by immunizing mice with the antigen, obtaining the reactive lymphocytes, and sometimes fusing these lymphocytes with a myeloma [immortal tumor] cell to generate a **hybridoma** that continues to express the desired antibody indefinitely.)

In one example, 10 out of 19 different cell lines producing antibodies directed against the hapten phosphorylcholine had the same  $V_H$  sequence. This sequence was the germline V gene segment T15, one of four related  $V_H$  genes. The other 9 expressed gene segments differed from each other and from all 4 germline members of the family. They were more closely related to the T15 germline sequence than to any of the others, and their flanking sequences were the same as those around T15. This suggested that they arose from the T15 member by somatic mutation (1022).

**Figure 25.21** shows that sequence changes are localized around the V gene segment, extending in a region from ~150 bp downstream of the V gene promoter for ~1.5 kb. They take the form of substitutions of individual nucleotide pairs. Usually there are ~3-15 substitutions, corresponding to <10 amino acid changes in the protein. They are concentrated in the antigen-binding site (thus generating the maximum diversity for recognizing new antigens). Only some of the mutations affect the amino acid sequence, since others lie in third-base coding positions as well as in nontranslated regions (for review see 270; 271).

**Figure 25.21** Somatic mutation occurs in the region surrounding the V segment and extends over the joined VDJ segments.

The large proportion of ineffectual mutations suggests that somatic mutation occurs more or less at random in a region including the V gene segment and extending beyond it. There is a tendency for some mutations to recur on multiple occasions.

These may represent hotspots as a result of some intrinsic preference in the system.

Somatic mutation occurs during clonal proliferation, apparently at a rate  $\sim 10^{-3}$  per bp per cell generation. Approximately half of the progeny cells gain a mutation; as a result, cells expressing mutated antibodies become a high fraction of the clone.

In many cases, a single family of V gene segments is used consistently to respond to a particular antigen. Upon exposure to an antigen, presumably the V region with highest intrinsic affinity provides a starting point. Then somatic mutation increases the repertoire. Random mutations have unpredictable effects on protein function; some inactivate the protein, others confer high specificity for a particular antigen. The proportion and effectiveness of the lymphocytes that respond is increased by selection among the lymphocyte population for those cells bearing antibodies in which mutation has increased the affinity for the antigen.

**IMMUNE DIVERSITY****5.25.15 Somatic mutation is induced by cytidine deaminase and uracil glycosylase**

---

**Key Concepts**

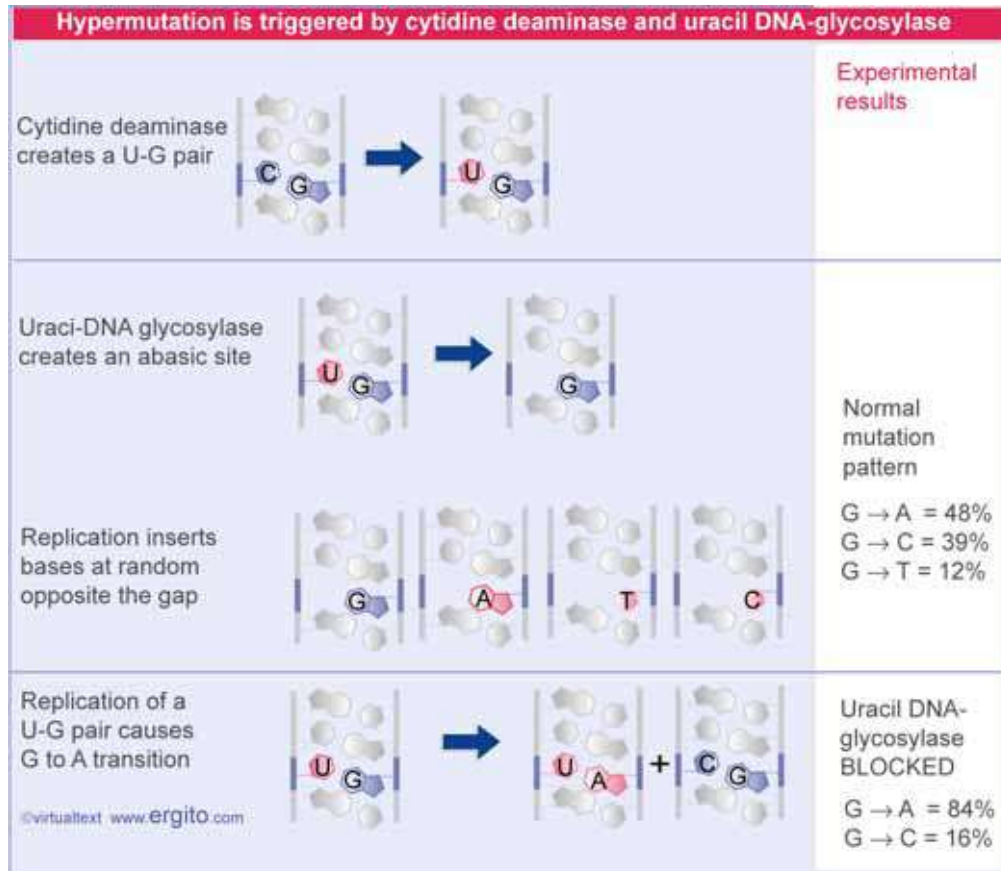

- A cytidine deaminase is required for somatic mutation as well as for class switching.
  - Uracil-DNA glycosylase activity influences the pattern of somatic mutations.
  - Hypermutation may be initiated by the sequential action of these enzymes.
- 

Somatic mutation has many of the same requirements as class switching (see *Molecular Biology 5.25.13 Switching occurs by a novel recombination reaction* (1206; 1207; 3433; for review see 4845):

- transcription must occur in the target region (as shown in this case by the demand for the enhancer that activates transcription at each Ig locus (1215);
- it requires the enzymes AID (activation induced cytidine deaminase) and UNG (uracil-DNA-glycosylase);
- the MSH mismatch-repair system is involved.

The way in which the removal of the deaminated base leads to somatic mutation is suggested by the experiment summarized in **Figure 25.22**. When AID deaminates cytosine, it generates uracil, which then is removed from the DNA by UNG. Normally all possible substitutions occur at the abasic site. But if the action of uracil-DNA glycosylase is blocked, we see a different result. If uracil is not removed from DNA, it should pair with adenine during replication. The ultimate result is to replace the original C-G pair with a T-A pair. Uracil-DNA glycosylase can be blocked by introducing into cells the gene coding for a protein that inhibits the enzyme. (The gene is a component of the bacteriophage PSB-2, whose genome is unusual in containing uracil, so that the enzyme needs to be blocked during a phage infection.) When the gene is introduced into a lymphocyte cell line, there is a dramatic change in the pattern of mutations, with almost all comprising the predicted transition from C-G to A-T (2936).

**Figure 25.22** When the action of cytidine deaminase (top) is followed by that of uracil DNA-glycosylase, an abasic site is created. Replication past this site should insert all four bases at random into the daughter strand (center). If the uracil is not removed from the DNA, its replication causes a C-G to T-A transition.

The key event in generating a random spectrum of mutations is therefore to create the abasic site. Then the MSH repair system is recruited to excise and replace the stretch of DNA containing the damage. The simplest possibility is that the replacement is performed by an error-prone DNA polymerase, mutations may be introduced. Another possibility is that so many abasic sites are created that the repair systems are overwhelmed. When replication occurs, this could lead to the random insertion of bases opposite the abasic sites. We don't know yet what restricts the action of this system to the target region for hypermutation.

The difference in the systems is at the end of the process, when double-strand breaks are introduced in class switching, but individual point mutations are created during somatic mutation. We do not yet know exactly where the systems diverge. One possibility is that breaks are introduced at abasic sites in class switching, but the sites are erratically repaired in somatic mutation. Another possibility is that breaks are introduced in both cases, but are repaired in an error-prone manner in somatic mutation (for review see 2434).

**IMMUNE DIVERSITY****5.25.16 Avian immunoglobulins are assembled from pseudogenes****Key Concepts**

- An immunoglobulin gene in chicken is generated by copying a sequence from one of 25 pseudogenes into the V gene at a single active locus.

The chick immune system is the paradigm for rabbits, cows, and pigs, which rely upon using the diversity that is coded in the genome. A similar mechanism is used by both the single light chain locus (of the  $\lambda$  type) and the H chain locus. The organization of the  $\lambda$  locus is drawn in **Figure 25.23**. It has only one functional V gene segment, J segment, and C gene segment. Upstream of the functional  $V_{\lambda 1}$  gene segment lie 25  $V_{\lambda}$  pseudogenes, organized in either orientation. They are classified as pseudogenes because either the coding segment is deleted at one or both ends, or proper signals for recombination are missing (or both). This assignment is confirmed by the fact that only the  $V_{\lambda 1}$  gene segment recombines with the J-C  $\lambda$  gene segment (772).

**Figure 25.23** The chicken lambda light locus has 25 V pseudogenes upstream of the single functional V-J-C region. But sequences derived from the pseudogenes are found in active rearranged V-J-C genes.

But sequences of active rearranged  $V_{\lambda}$ -J- $C_{\lambda}$  gene segments show considerable diversity! A rearranged gene has one or more positions at which a cluster of changes

has occurred in the sequence. A sequence identical to the new sequence can almost always be found in one of the pseudogenes (which themselves remain unchanged). The exceptional sequences that are not found in a pseudogene always represent changes at the junction between the original sequence and the altered sequence.

So a novel mechanism is employed to generate diversity. Sequences from the pseudogenes, between 10 and 120 bp in length, are substituted into the active  $V\lambda_1$  region by gene conversion. The unmodified  $V\lambda_1$  sequence is not expressed, even at early times during the immune response. A successful conversion event probably occurs every 10-20 cell divisions to every rearranged  $V\lambda_1$  sequence. At the end of the immune maturation period, a rearranged  $V\lambda_1$  sequence has 4-6 converted segments spanning its entire length, derived from 1 different donor pseudogenes. If all pseudogenes participate, this allows  $2.5 \times 10^8$  possible combinations!

The enzymatic basis for copying pseudogene sequences into the expressed locus depends on enzymes involved in recombination and is related to the mechanism for somatic hypermutation that introduces diversity in mouse and man (2154). Some of the genes involved in recombination are required for the gene conversion process; for example, it is prevented by deletion of *RAD54*. Deletion of other recombination genes (*XRCC2*, *XRCC3*, and *RAD51B*) has another, very interesting effect: somatic mutation occurs at the V gene in the expressed locus. The frequency of the somatic mutation is  $\sim 10\times$  greater than the usual rate of gene conversion.

These results show that the absence of somatic mutation in chick is not due to a deficiency in the enzymatic systems that are responsible in mouse and man. The most likely explanation for a connection between (lack of) recombination and somatic mutation is that unrepaired breaks at the locus trigger the induction of mutations. The reason why somatic mutation occurs in mouse and man but not in chick may therefore lie with the details of the operation of the repair system that operates on breaks at the locus. It is more efficient in chick, so that the gene is repaired by gene conversion before mutations can be induced.

**IMMUNE DIVERSITY****5.25.17 B cell memory allows a rapid secondary response**

---

**Key Terms**

The **primary immune response** is an organism's immune response upon first exposure to a given antigen. It is characterized by a relatively shorter duration and lower affinity antibodies than in the secondary immune response.

The **secondary immune response** is an organism's immune response upon a second exposure to a given antigen. This second exposure is also referred to as a "booster". The secondary immune response is characterized by a more rapid induction, greater magnitude, and higher affinity antibodies than the primary immune response.

**B cell memory** is responsible for rapid antibody production during a secondary immune response and subsequent responses. Memory B cells produce antibodies of higher affinity than naive B cells.

The **B cell receptor (BCR)** is the antigen receptor complex on the cell surface of B lymphocytes. It consists of membrane-bound immunoglobulin bound noncovalently to Ig  $\alpha$  and Ig  $\beta$  chains.

**Key Concepts**

- The primary response to an antigen is mounted by B cells that do not survive beyond the response period.
- Memory B cells are produced that have specificity for the same antigen but that are inactive.
- A reexposure to antigen triggers the secondary response in which the memory cells are rapidly activated.

---

We are now in a position to summarize the relationship between the generation of high-affinity antibodies and the differentiation of the B cell. **Figure 25.24** shows that B cells are derived from a self-renewing population of stem cells in the bone marrow. Maturation to give B cells depends upon Ig gene rearrangement, which requires the functions of the *SCID* and *RAG1,2* (and other) genes. If gene rearrangement is blocked, mature B cells are not produced. The antibodies carried by the B cells have specificities determined by the particular combinations of V(D)J regions, and any additional nucleotides incorporated during the joining process.

**Figure 25.24** B cell differentiation is responsible for acquired immunity. Pre-B cells are converted to B cells by Ig gene rearrangement. Initial exposure to antigen provokes both the primary response and storage of memory cells. Subsequent exposure to antigen provokes the secondary response of the memory cells.

Exposure to antigen triggers two aspects of the immune response. The **primary immune response** occurs by clonal expansion of B cells responding to the antigen. This generates a large number of plasma cells that are specific for the antigen; isotype switching occurs to generate the appropriate type of effector response. The population of cells concerned with the primary response is a dead end; these cells do not live beyond the primary response itself.

Provision for a **secondary immune response** is made through the phenomenon of **B cell memory**. Somatic mutation generates B cells that have increased affinity for the antigen. These cells do not trigger an immune response at this time, although they may undergo isotype switching to select other forms of  $C_H$  region. They are stored as

memory cells, with appropriate specificity and effector response type, but are inactive. They are activated if there is a new exposure to the same antigen. Because they are pre-selected for the antigen, they enable a secondary response to be mounted very rapidly, simply by clonal expansion; no further somatic mutation or isotype switching occurs during the secondary response (for review see 276).

The pathways summarized in **Figure 25.24** show the development of acquired immunity, that is, the response to an antigen. In addition to these cells, there is a separate set of B cells, named the Ly-1 cells. These cells have gone through the process of V gene rearrangement, and apparently are selected for expression of a particular repertoire of antibody specificities. They do not undergo somatic mutation or the memory response. They may be involved in natural immunity, that is, an intrinsic ability to respond to certain antigens.

A more detailed view of B cell development is shown in **Figure 25.25**. The first step is recombination between the D and J segments of the  $\mu$  heavy chain. This is succeeded by V-D recombination, generating a  $\mu$  heavy chain. Several recombination events, involving a succession of nonproductive and productive rearrangements, may occur, as shown previously in **Figure 25.15**. These cells express a protein resembling a  $\lambda$  chain, called the surrogate light (SL) chain, which is expressed on the surface and associates with the  $\mu$  heavy chain to form the pre-B-receptor. It resembles an immunoglobulin complex, but does not function as one.

**Figure 25.25** B cell development proceeds through sequential stages.

The production of  $\mu$  chain represses synthesis of SL chain, and the cells divide to become small pre-B cells. Then light chain is expressed and functional immunoglobulin appears on the surface of the immature B cells. Further cell divisions occur, and the expression of  $\delta$  heavy chain is added to that of  $\mu$  chain, as the cells mature into B cells.

Immunoglobulins function both by secretion from B cells and by surface expression. **Figure 25.26** shows that the active complex on the cell surface is called the **B cell receptor (BCR)**, and consists of an immunoglobulin associated with transmembrane proteins called Ig  $\alpha$  and Ig  $\beta$ . They provide the signaling components that trigger intracellular pathways in response to antigen-antibody binding. The activation of the BCR is also influenced by interactions with other receptors, for example, to mediate the interaction of antigen-activated B cells with helper T cells.

**Figure 25.26** The B cell antigen receptor consists of an immunoglobulin tetramer ( $H_2L_2$ ) linked to two copies of the signal-transducing heterodimer (Ig  $\alpha$   $\beta$  ).

## IMMUNE DIVERSITY

### 5.25.18 T cell receptors are related to immunoglobulins

#### Key Concepts

- T cells use a similar mechanism of V(D)J-C joining to B cells to produce either of two types of T cell receptor.
- TCR  $\alpha \beta$  is found on >95% of T lymphocytes, and TCR  $\gamma \delta$  is found on <5%.

The lymphocyte lineage presents an example of evolutionary opportunism: a similar procedure is used in both B cells and T cells to generate proteins that have a variable region able to provide significant diversity, while constant regions are more limited and account for a small range of effector functions. T cells produce either of two types of T cell receptor. The different T cell receptors are synthesized at different times during T cell development, as summarized in **Figure 25.27** (for review see 266; 268).

**Figure 25.27** The  $\gamma \delta$  receptor is synthesized early in T-cell development. TCR  $\alpha \beta$  is synthesized later and is responsible for "classical" cell-mediated immunity, in which target antigen and host histocompatibility antigen are recognized together.

The  $\gamma \delta$  receptor is found on <5% of T lymphocytes. It is synthesized only at an early

stage of T cell development. In mice, it is the only receptor detectable at <15 days of gestation, but has virtually been lost by birth at day 20.

TCR  $\alpha \beta$  is found on >95% of lymphocytes. It is synthesized later in T cell development than  $\gamma \delta$ . In mice, it first becomes apparent at 15–17 days after gestation. By birth it is the predominant receptor. It is synthesized by a separate lineage of cells from those involved in TCR  $\gamma \delta$  synthesis, and involves independent rearrangement events.

Like immunoglobulins, a TCR must recognize a foreign antigen of unpredictable structure. The problem of antigen recognition by B cells and T cells is resolved in the same way, and the organization of the T cell receptor genes resembles the immunoglobulin genes in the use of variable and constant regions. *Each locus is organized in the same way as the immunoglobulin genes, with separate segments that are brought together by a recombination reaction specific to the lymphocyte.* The components are the same as those found in the three Ig families.

The organization of the TCR proteins resembles that of the immunoglobulins. The V sequences have the same general internal organization in both Ig and TCR proteins. The TCR C region is related to the constant Ig regions and has a single constant domain followed by transmembrane and cytoplasmic portions. Exon-intron structure is related to protein function.

The resemblance of the organization of TCR genes with the Ig genes is striking. As summarized in **Figure 25.28**, the organization of TCR  $\alpha$  resembles that of Ig  $\kappa$ , with V gene segments separated from a cluster of J segments that precedes a single C gene segment. The organization of the locus is similar in both Man and mouse, with some differences only in the number of  $V_\alpha$  gene segments and  $J_\alpha$  segments. (In addition to the  $\alpha$  segments, this locus also contains  $\delta$  segments, which we discuss shortly (for review see 273).

**Figure 25.28** The human TCR  $\alpha$  locus has interspersed  $\alpha$  and  $\delta$  segments. A  $V_\delta$  segment is located within the  $V_\alpha$  cluster. The D-J- $C_\delta$  segments lie between the V gene segments and the J- $C_\alpha$  segments. The mouse locus is similar, but has more  $V_\delta$  segments.

The components of TCR  $\beta$  resemble those of IgH. **Figure 25.29** shows that the organization is different, with V gene segments separated from two clusters each containing a D segment, several J segments, and a C gene segment. Again the only differences between Man and mouse are in the numbers of the  $V_\beta$  and  $J_\beta$  units.

**Figure 25.29** The TCR  $\beta$  locus contains many V gene segments spread over ~500 kb, and lying ~280 kb upstream of the two D-J-C clusters.

Diversity is generated by the same mechanisms as in immunoglobulins. Intrinsic diversity results from the combination of a variety of V, D, J, and C segments; some additional diversity results from the introduction of new sequences at the junctions between these components (in the form of P and N nucleotides; see **Figure 25.13**). Some TCR  $\beta$  chains incorporate two D segments, generated by D-D joins (directed by an appropriate organization of the nonamer and heptamer sequences). A difference between TCR and Ig is that somatic mutation does not occur at the TCR loci. Measurements of the extent of diversity show that the  $10^{12}$  T cells in Man contain  $2.5 \times 10^7$  different  $\alpha$  chains associated with  $10^6$  different  $\beta$  chains.

The same mechanisms are likely to be involved in the reactions that recombine Ig genes in B cells and TCR genes in T cells. The recombining TCR segments are surrounded by nonamer and heptamer consensus sequences identical to those used by the Ig genes. This argues strongly that the same enzymes are involved. Most rearrangements probably occur by the deletion model (see **Figure 25.12**). We do not know how the process is controlled so that Ig loci are rearranged in B cells, while T cell receptors are rearranged in T cells.

The organization of the  $\gamma$  locus resembles that of Ig  $\lambda$ , with V gene segments separated from a series of J-C segments. **Figure 25.30** shows that this locus has relatively little diversity, with ~8 functional V segments. The organization is different in Man and mouse. Mouse has 3 functional J-C loci, but some segments are inverted in orientation. Man has multiple J segments for each C gene segment.

**Figure 25.30** The TCR  $\gamma$  locus contains a small number of functional V gene segments (and also some pseudogenes; not shown), lying upstream of the J-C loci.

The  $\delta$  subunit is coded by segments that lie at the TCR  $\alpha$  locus, as illustrated previously in **Figure 25.28**. The segments D $\delta$ -D $\delta$ -J $\delta$ -C $\delta$  lie between the V gene segments and the J $\alpha$ -C $\alpha$  segments. Both of the D segments may be incorporated into the  $\delta$  chain to give the structure VDDJ. The nature of the V gene segments used in the  $\delta$  rearrangement is an interesting question. Very few V sequences are found in active TCR  $\delta$  chains. In man, only one V gene segment is in general use for  $\delta$  rearrangement. In mouse, several V $\delta$  segments are found; some are unique for  $\delta$  rearrangement, but some are also found in  $\alpha$  rearrangements. The basis for specificity in choosing V segments in  $\alpha$  and  $\delta$  rearrangement is not known. One possibility is that many of the V $\alpha$  gene segments can be joined to the DDJ $\delta$  segment, but that only some (therefore defined as V $\delta$ ) can give active proteins (for review see 272).

While for the present we have labeled the V segments that are found in  $\delta$  chains as V $\delta$  gene segments, we must reserve judgment on whether they are really unique to  $\delta$  rearrangement. The interspersed arrangement of genes implies that synthesis of the TCR  $\alpha$   $\beta$  receptor and the  $\gamma$   $\delta$  receptor is mutually exclusive at any one allele, because the  $\delta$  locus is lost entirely when the V $\alpha$ -J $\alpha$  rearrangement occurs.

Rearrangements at the TCR loci, like those of immunoglobulin genes, may be productive or nonproductive. The  $\beta$  locus shows allelic exclusion in much the same way as immunoglobulin loci; rearrangement is suppressed once a productive allele has been generated. The  $\alpha$  locus may be different; several cases of continued rearrangement suggest the possibility that substitution of V $\alpha$  sequences may continue after a productive allele has been generated.

---

**IMMUNE DIVERSITY****5.25.19 The T cell receptor functions in conjunction with the MHC**

---

**Key Terms**

A **cytotoxic T cell** is a T lymphocyte (usually CD8<sup>+</sup>) that can be stimulated to kill cells containing intracellular pathogens, such as viruses.

A **helper T cell** is a T lymphocyte that activates macrophages and stimulates B cell proliferation and antibody production. Helper T cells usually express cell surface CD4 but not CD8.

A **DP thymocyte** is a double positive thymocyte. It is an immature T cell that expresses cell surface CD4 and CD8. Selection of DP thymocytes in the thymus yields mature T cells expressing either CD4 or CD8.

**CD3** is a complex of proteins that associates with the T cell antigen receptor's  $\alpha$  and  $\beta$  chains. Each complex consists of one each of the  $\delta$ ,  $\epsilon$ ,  $\gamma$  chains and two  $\zeta$  chains.

**Key Concepts**

- The TCR recognizes a short peptide that is bound in a groove of an MHC protein on the surface of the presenting cell.

---

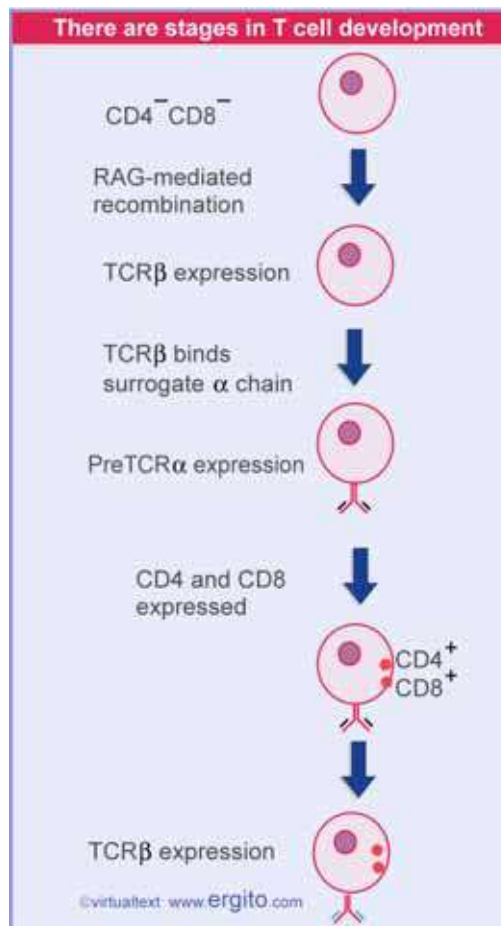

T cells with  $\alpha\beta$  receptors are divided into several subtypes that have a variety of functions connected with interactions between cells involved in the immune response. **Cytotoxic T cells** (also known as killer T cells) possess the capacity to lyse an infected target cell. **Helper T cells** assist T cell-mediated target killing or B cell-mediated antibody-antigen interaction.

A major difference between the antibodies of B cells and the receptors of T cells is the way that they handle the antigen. An antibody recognizes a short region (an epitope) within the antigen. The T cell receptor binds to a small peptide (4-5 amino acids long) that has been processed from the antigen by cleavage reactions. The peptide fragment is "presented" to the T cell by an MHC protein. So the T cell simultaneously recognizes the foreign antigen and an MHC protein carried by the presenting cell, as illustrated previously in **Figure 25.2**. Both helper T cells and killer T cells work in this way, but they have different requirements for the presentation of antigen; different types of MHC protein are used in each case (see *Molecular Biology 5.25.20 The major histocompatibility locus codes for many genes of the immune system*). Helper T cells require antigen to be presented by an MHC class II protein, while killer T cells require antigen to be presented by an MHC class I protein.

The TCR  $\alpha\beta$  receptor is responsible for helper T cell function in humoral immunity, and for killer T cell function in cell-mediated immunity. This places upon it the responsibility of recognizing both the foreign antigen and the host MHC protein. The MHC protein binds a short peptide derived from the foreign antigen, and the TCR

then recognizes the peptide in a groove on the surface of the MHC. The MHC is said to *present* the peptide to the TCR. (The peptide is generated when the proteasome degrades the foreign protein to generate fragments of 8-10 residues long, as described in *Molecular Biology Supplement 8.32 The proteasome is a large machine that degrades ubiquitinated proteins.*) A given TCR has specificity for a particular MHC as well as for the foreign antigen. The basis for this dual capacity is one of the most interesting issues to be defined about the  $\alpha\beta$  TCR.

Recombination to generate functional TCR chains is linked to the development of the T lymphocyte, as summarized in **Figure 25.31**. The first stage is rearrangement to form an active TCR  $\beta$  chain. This binds a nonrearranging surrogate  $\alpha$  chain, called preTCR  $\alpha$ . At this stage, the lymphocyte has not expressed either of the surface proteins CD4 or CD8. The preTCR heterodimer then binds to the CD3 signaling complex (see below). Signaling from the complex triggers several rounds of cell division, during which  $\alpha$  chains are rearranged, and the CD4 and CD8 genes are turned on, so that the lymphocyte is converted from  $CD4^-CD8^-$  to  $CD4^+CD8^+$ . This point in development is called  $\beta$  *selection*. It generates **DP thymocytes**.

**Figure 25.31** T cell development proceeds through sequential stages.

$\alpha$  chain rearrangement continues in the DP thymocytes. The maturation process continues by both positive selection (for mature TCR complexes able to bind a

ligand) and by negative selection (against complexes that interact with inappropriate – self – ligands). Both types of selection involve interaction with MHC proteins. The DP thymocytes either die after ~3 days or become mature lymphocytes as the result of the selective processes. The surface TCR  $\alpha \beta$  heterodimer becomes crosslinked on the surface during positive selection (which rescues the thymocytes from cell death), and then, if they survive the subsequent negative selection, allows them to give rise to the separate T lymphocyte classes which are  $CD4^+CD8^-$  and  $CD4^-CD8^+$  (907).

The T cell receptor is associated with a complex of proteins called **CD3**, which is involved in transmitting a signal from the surface of the cell to the interior when its associated receptor is activated by binding antigen. Our present picture of the components of the receptor complex on a T cell is illustrated in **Figure 25.32**. The important point is that the interaction of the TCR variable regions with antigen causes the  $\zeta$  subunits of the CD3 complex to activate the T cell response. The activation of CD3 provides the means by which either  $\alpha \beta$  or  $\gamma \delta$  TCR signals that it has recognized an antigen. This is comparable to the constitution of the B cell receptor, in which immunoglobulin associates with the  $Ig \alpha \beta$  signaling chains (see **Figure 25.26**).

**Figure 25.32** The two chains of the T-cell receptor associate with the polypeptides of the CD3 complex. The variable regions of the TCR are exposed on the cell surface. The cytoplasmic domains of the  $\zeta$  chains of CD3 provide the effector function.

A central dilemma about T cell function remains to be resolved. Cell-mediated immunity requires two recognition processes. Recognition of the foreign antigen requires the ability to respond to novel structures. Recognition of the MHC protein is of course restricted to one of those coded by the genome, but, even so, there are many different MHC proteins. So considerable diversity is required in both recognition reactions. Although helper and killer T cells rely upon different classes

of MHC proteins, they use the same pool of  $\alpha$  and  $\beta$  gene segments to assemble their receptors. Even allowing for the introduction of additional variation during the TCR recombination process, it is not clear how enough different versions of the T cell receptor are made available to accommodate all these demands.

**IMMUNE DIVERSITY****5.25.20 The major histocompatibility locus codes for many genes of the immune system**

---

**Key Terms**

The **H2 locus** is the mouse major histocompatibility complex, a cluster of genes on chromosome 17. The genes encode proteins for antigen presentation, cytokines, and complement proteins.

The **HLA locus** is the human major histocompatibility complex, a cluster of genes on chromosome 6. The genes encode proteins for antigen presentation, cytokines, and complement proteins.

An **MHC class I protein** mostly presents, to CD8<sup>+</sup> T cells, peptides that are produced by proteolytic degradation in the cytosol.

**Transplantation antigen** is protein coded by a major histocompatibility locus, present on all mammalian cells, involved in interactions between lymphocytes.

An **MHC class II protein** mostly presents, to CD4<sup>+</sup> T cells, peptides that are produced by proteolytic degradation in the endocytic pathway.

Two mutants are said to **complement** each other when a diploid that is heterozygous for each mutation produces the wild type phenotype.

The **external domain** is the part of a plasma membrane protein that extends outside of the cell. Upon internalization, the protein's external domain extends into the lumen (the topological equivalent of the outside of the cell) of an organelle.

The **transmembrane region (transmembrane domain)** is the part of a protein that spans the membrane bilayer. It is hydrophobic and in many cases contains approximately 20 amino acids that form an  $\alpha$ -helix. It is also called the transmembrane domain.

The **cytoplasmic domain** is the part of a transmembrane protein that is exposed to the cytosol.

**Key Concepts**

- The MHC locus codes for the class I and class II proteins as well as for other proteins of the immune system.
- Class I proteins are the transplantation antigens that are responsible for distinguishing "self" from "nonself" tissue.
- An MHC class I protein is active as a heterodimer with  $\beta_2$  microglobulin.
- Class II proteins are involved in interactions between T cells.
- An MHC class II protein is a heterodimer of  $\alpha$  and  $\beta$  chains.

---

The major histocompatibility locus occupies a small segment of a single chromosome in the mouse (where it is called the **H2 locus**) and in man (called the

**HLA** locus). Within this segment are many genes coding for functions concerned with the immune response. At those individual gene loci whose products have been identified, many alleles have been found in the population; the locus is described as highly *polymorphic*, meaning that individual genomes are likely to be different from one another. Genes coding for certain other functions also are located in this region.

Histocompatibility antigens are classified into three types by their immunological properties. In addition, other proteins found on lymphocytes and macrophages have a related structure and are important in the function of cells of the immune system:

**MHC class I** proteins are the **transplantation antigens**. They are present on every cell of the mammal. As their name suggests, these proteins are responsible for the rejection of foreign tissue, which is recognized as such by virtue of its particular array of transplantation antigens. In the immune system, their presence on target cells is required for the cell-mediated response. The types of class I proteins are defined serologically (by their antigenic properties). The murine class I genes code for the H2-K and H2-D/L proteins. Each mouse strain has one of several possible alleles for each of these functions. The human class I functions include the classical transplantation antigens, HLA-A, B, C.

**MHC class II** proteins are found on the surfaces of both B and T lymphocytes as well as macrophages. These proteins are involved in communications between cells that are necessary to execute the immune response; in particular, they are required for helper T cell function. The murine class II functions are defined genetically as I-A and I-E. The human class II region (also called HLA-D) is arranged into four subregions, DR, DQ, DZ/DO, DP.

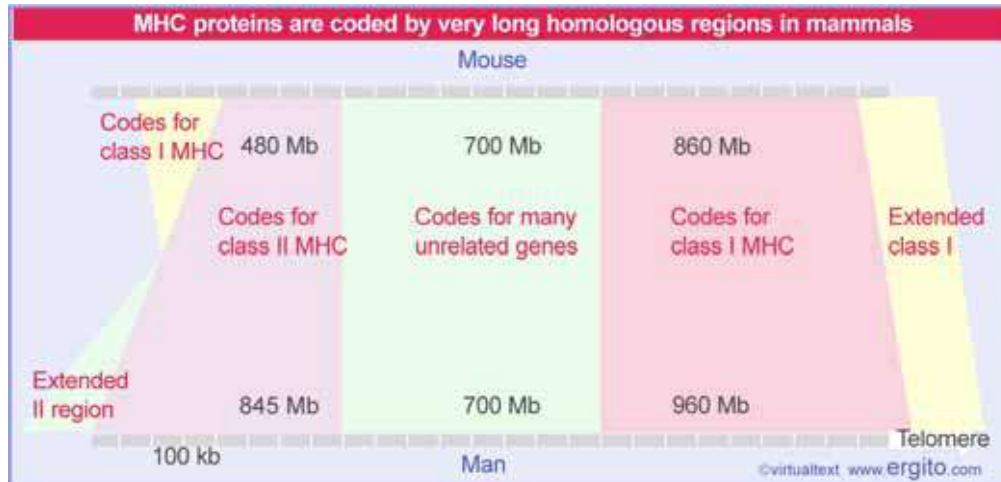

The **complement** proteins are coded by a genetic locus that is also known as the S region; S stands for serum, indicating that the proteins are components of the serum. Their role is to interact with antibody-antigen complexes to cause the lysis of cells in the classical pathway of the humoral response.

The *Qa* and *Tla* loci proteins are found on murine hematopoietic cells. They are known as differentiation antigens, because each is found only on a particular subset of the blood cells, presumably related to their function. They are structurally related to the class I H2 proteins, and like them are polymorphic.

We can now relate the types of proteins to the organization of the genes that code for them. The MHC region was originally defined by genetics in the mouse, where the classical H2 region occupies 0.3 map units. Together with the adjacent region where mutations affecting immune function are also found, this corresponds to a region of ~2000 kb of DNA (for review see 262; 265). The MHC region has been completely sequenced in several mammals, and also some birds and fish. By comparing these sequences, we find that the organization has been generally conserved (for review see 3772).

The gene organization in mouse and Man is summarized in **Figure 25.33**. The genomic regions where the class I and class II genes are located mark the original boundaries of the locus (going in the direction from telomere to centromere, right to left as shown in the figure). The genes in the region that separates the class I and class II genes code for a variety of functions; this is called the class III region.

Defining the ends of the locus varies with the species, and the region beyond the class I genes on the telomeric side is called the extended class I region. Similarly, the region beyond the class II genes on the centromeric side is called the extended class II region. The major difference between mouse and Man is that the extended class II region contains some class I (H2-K) genes in the mouse.

**Figure 25.33** The MHC region extends for >2 Mb. MHC proteins of classes I and II are coded by two separate regions. The class III region is defined as the segment between them. The extended regions describe segments that are syntenic on either end of the cluster. The major difference between mouse and Man is the presence of H2 class I genes in the extended region on the left. The murine locus is located on chromosome 17, and the human locus on chromosome 6.

There are several hundred genes in the MHC regions of mammals, but it is possible for MHC functions to be provided by far fewer genes, as in the case of the chicken, where the MHC region is 92 Kb and has only 9 genes (910).

As in comparisons of other gene families, we find differences in the exact numbers of genes devoted to each function. Because the MHC locus shows extensive variation between individuals, the number of genes may be different in different individuals. As a general rule, however, a mouse genome has fewer active H2 genes than a human genome. The class II genes are unique to mammals (except for one subgroup), and as a rule, birds and fish have different genes in their place. There are ~8 functional class I genes in Man and ~30 in the mouse. The class I region also includes many other genes. The class III regions are closely similar in Man and mouse.

All MHC proteins are dimers located in the plasma membrane, with a major part of the protein protruding on the extracellular side. The structures of class I and class II MHC proteins are related, although they have different components, as summarized in **Figure 25.34**.

**Figure 25.34** Class I and class II histocompatibility antigens have a related structure. Class I antigens consist of a single (  $\alpha$  ) polypeptide, with three external domains (  $\alpha 1$ ,  $\alpha 2$ ,  $\alpha 3$  ), that interacts with  $\beta 2$  microglobulin (  $\beta 2$  m). Class II antigens consist of two (  $\alpha$  and  $\beta$  ) polypeptides, each with two domains (  $\alpha 1$  &  $\alpha 2$ ,  $\beta 1$  &  $\beta 2$  ) with a similar overall structure.

Class II antigens consist of two chains,  $\alpha$  and  $\beta$ , whose combination generates an overall structure in which there are two extracellular domains.

All class I MHC proteins consist of a dimer between the class I chain itself and the  $\beta 2$ -microglobulin protein. The class I chain is a 45 kD transmembrane component that has three **external domains** (each  $\sim 90$  amino acids long, one of which interacts with  $\beta 2$  microglobulin), a **transmembrane region** of  $\sim 40$  residues, and a short **cytoplasmic domain** of  $\sim 30$  residues that resides within the cell.

The  $\beta 2$  microglobulin is a secreted protein of 12 kD. It is needed for the class I chain to be transported to the cell surface. Mice that lack the  $\beta 2$  microglobulin gene have no MHC class I antigen on the cell surface.

The organization of class I genes summarized in **Figure 25.35** coincides with the protein structure. The first exon codes for a signal sequence (cleaved from the protein during membrane passage). The next three exons code for each of the external domains. The fifth exon codes for the transmembrane domain. And the last three rather small exons together code for the cytoplasmic domain. The only difference in the genes for human transplantation antigens is that their cytoplasmic

domain is coded by only two exons.

**Figure 25.35** Each class of MHC genes has a characteristic organization, in which exons represent individual protein domains

The exon coding for the third external domain of the class I genes is highly conserved relative to the other exons. The conserved domain probably represents the region that interacts with  $\beta$ 2 microglobulin, which explains the need for constancy of structure. This domain also exhibits homologies with the constant region domains of immunoglobulins.

What is responsible for generating the high degree of polymorphism in these genes? Most of the sequence variation between alleles occurs in the first and second external domains, sometimes taking the form of a cluster of base substitutions in a small region. One mechanism involved in their generation is gene conversion between class I genes. Pseudogenes are present as well as functional genes.

The gene for  $\beta$ 2 microglobulin is located on a separate chromosome. It has four exons, the first coding for a signal sequence, the second for the bulk of the protein (from amino acids 3 to 95), the third for the last four amino acids and some of the nontranslated trailer, and the last for the rest of the trailer.

The length of  $\beta$ 2 microglobulin is similar to that of an immunoglobulin V gene; there are certain similarities in amino acid constitution; and there are some (limited) homologies of nucleotide sequence between  $\beta$ 2 microglobulin and Ig constant domains or type I gene third external domains. All the groups of genes that we have discussed in this chapter may have descended from a common ancestor that coded for a primitive domain.

**IMMUNE DIVERSITY****5.25.21 Innate immunity utilizes conserved signaling pathways**

---

**Key Terms**

**Adaptive immunity** is the response mediated by lymphocytes that are activated by their specific interaction with antigen. The adaptive immune response develops over several days as lymphocytes with antigen-specific receptors are stimulated to proliferate and become effector cells. It is responsible for immunological memory.

**Acquired immunity** is another term for adaptive immunity.

**Innate immunity** is the rapid response mediated by cells with non-varying (germline-encoded) receptors that recognize pathogen. The cells of the innate immune response act to eliminate the pathogen and initiate the adaptive immune response.

A **pathogen-associated molecular pattern is (PAMP)** a molecular structure on the surface of a pathogen. A given PAMP may be conserved across a large number of pathogens. During an immune response, PAMPs may be recognized by receptors on cells that mediate innate immunity.

A **lipopolysaccharide is (LPS)** a molecule containing both lipid and sugar components. It is present in the outer membrane of Gram-negative bacteria. It is also an endotoxin responsible for inducing septic shock during an infection.

An **endotoxin** is a toxin that is present on the surface of Gram-negative bacteria (as opposed to exotoxins, which are secreted). LPS is an example of an endotoxin.

A **Toll-like receptor is (TLR)** a plasma membrane receptor that is expressed on phagocytes and other cells and is involved in signaling during the innate immune response. TLRs are related to IL-1 receptors.

The **leucine-rich region is (LLR)** a motif found in the extracellular domains of some surface receptor proteins in animal and plant cells.

**Key Concepts**

- Innate immunity is triggered by receptors that recognize motifs (PAMPs) that are highly conserved in bacteria or other infective agents.
- Toll-like receptors are commonly used to activate the response pathway.
- The pathways are highly conserved from invertebrates to vertebrates, and an analogous pathway is found in plants.

---

The immune response described in this chapter comprises a set of reactions that respond to a pathogen by selecting lymphocytes (B cells or T cells) whose receptors (antibodies or TCR) have a high affinity for the pathogen. The basis for this selective process is the generation of a very large number of receptors so as to create a high possibility of recognizing a foreign molecule. Receptors that recognize the body's

own proteins are screened out early in the process. Activation of the receptors on B cells triggers the pathways of the humoral response; activation of the receptors on T cells triggers the pathways of the cell-mediated response. The overall response to an antigen via selection of receptors on the lymphocytes is called **adaptive immunity** (or **acquired immunity**). The response typically is mounted over several days, following the initial activation of B cells or T cells that recognize the foreign pathogen. The organism retains a memory of the response, which enables it to respond more rapidly if it is exposed again to the same pathogen. The principles of adaptive immunity are similar through the vertebrate kingdoms, although details vary.

Another sort of immune response occurs more quickly and is found in a greater range of animals (including those that do not have adaptive immunity). **Innate immunity** depends on the recognition of certain, pre-defined patterns in foreign pathogens. These patterns are motifs that are conserved in the pathogens because they have an essential role in their function, but they are not found in higher eukaryotes. The motif is typically recognized by a receptor dedicated to the purpose of triggering the innate response upon an infection. Receptors that trigger the innate response are found on cells such as neutrophils and macrophages, and cause the pathogen to be phagocytosed and killed. The response is rapid, because the set of receptors is already present on the cells and does not have to be amplified by selection. It is widely conserved and is found in organisms ranging from flies to Man. When the innate response is able to deal effectively with an infection, the adaptive response will not be triggered. There is some overlap between the responses in that they activate some of the same pathways, so cells activated by the innate response may subsequently participate in the adaptive response.

The motifs that trigger innate immunity are sometimes called pathogen-associated molecular patterns (**PAMPs**). **Figure 25.36** shows that they are widely distributed across broad ranges of organisms. Formyl-methionine is used to initiate most bacterial proteins, but is not found in eukaryotes. The peptidoglycan of the cell wall is unique to bacteria. **Lipopolysaccharide (LPS)** is a component of the outer membrane of most gram-negative bacteria; also known as **endotoxin**, it is responsible for septic shock syndrome.

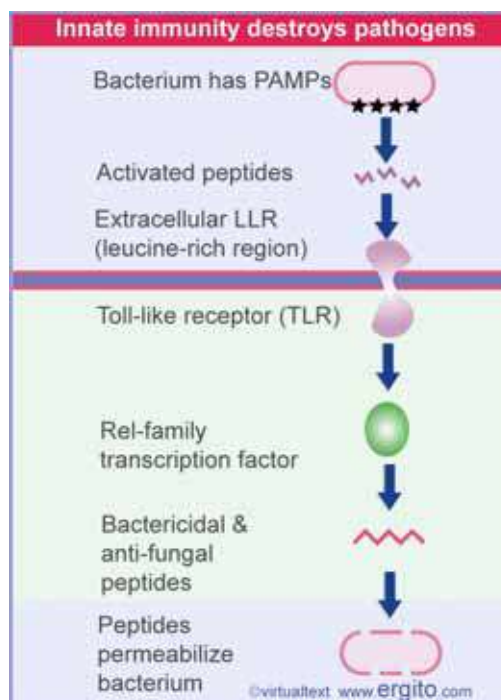

PAMPs are ubiquitous		
Organism	Pathogen	Location
All bacteria	formyl-Methionine	Most proteins
Most bacteria	peptidoglycan	Cell wall
Gram-negative bacteria	lipopolysaccharide	Cell wall
Yeast	zymosan	Cell wall

©virtualtext www.ergito.com

**Figure 25.36** Pathogen-associated molecular patterns (PAMPs) are compounds that are common to large ranges of bacteria or yeasts and are exposed when an infection occurs.

A key insight into the nature of innate immunity was the discovery of the involvement of **Toll-like receptors (TLR)** (for review see 2382). The receptor Toll, which is related to mammalian IL1 receptor, triggers the pathway in *Drosophila* that controls dorsal-ventral development (see *Molecular Biology 6.31.9 Dorsal-ventral development uses localized receptor-ligand interactions*). This leads to activation of the transcription factor dorsal, a member of the Rel family, which is related to the mammalian factor NF- $\kappa$ B. The pathway of innate immunity is parallel to the Toll pathway, with similar components. In fact, one of the first indications of the nature of innate immunity in flies was the discovery of the transcription factor Dif (dorsal-related immunity factor), which is activated by one of the pathways (2378).

Flies have no system of adaptive immunity, but are resistant to microbial infections (for review see 2385). This is because their innate immune systems trigger synthesis of potent antimicrobial peptides. Seven distinct peptides have been identified in *Drosophila*, where they are synthesized in the fat body (the equivalent organ to the liver). Two of the peptides are antifungal, five act largely on bacteria. The general mode of action is to kill the target organism by permeabilizing its membrane. All of these peptides are coded by genes whose promoters respond to transcription factors of the Rel family. **Figure 25.37** summarizes the components of the innate pathways in *Drosophila*.

**Figure 25.37** Innate immunity is triggered by PAMPs. In flies, they cause the production of peptides that activate Toll-like receptors. The receptors lead to a pathway that activates a transcription factor of the Rel family. Target genes for this factor include bactericidal and anti-fungal peptides. The peptides act by permeabilizing the membrane of the pathogenic organism.

Two innate response pathways function in *Drosophila*, one responding principally to

fungi, the other principally to gram-negative bacteria. Gram-positive bacteria may be able to trigger both pathways. **Figure 25.38** outlines the steps in each pathway. Fungi and gram-positive bacteria activate a proteolytic cascade that generates peptides that activate a Toll-like receptor. This is the NF- $\kappa$ B-like pathway. The dToll receptor activates the transcription factor Dif (a relative of NF- $\kappa$ B), leading ultimately to activation of the anti-fungal peptide drosomycin (2379; 2381). Gram-negative bacteria trigger a pathway via a different receptor that activates the transcription factor Relish, leading to production of the bactericidal peptide attacin (2380). This pathway is called the Imd pathway after one of its components, a protein that has a "death domain" related to those found in the pathways for apoptosis.

**Figure 25.38** One of the *Drosophila* innate immunity pathways is closely related to the mammalian pathway for activating NF- $\kappa$ B; the other has components related to those of apoptosis pathways.

The key agents in responding to the bacteria are proteins called PGRPs because of their high affinities for bacterial peptidoglycans. There are two types of these proteins. PGRP-SAs are short extracellular proteins. They probably function by activating the proteases that trigger the Toll pathway. PGRP-LCs are transmembrane proteins with an extracellular PGRP domain. Their exact role has to be determined.

The innate immune response is highly conserved (for review see 2459, 4381). Mice that are resistant to septic shock when they are treated with LPS have mutations in the Toll-like receptor TLR4 (2383). A human homologue of the Toll receptor can activate some immune-response genes, suggesting that the pathway of innate immunity may also function in Man (2384). The pathway downstream of the

Toll-like receptors is generally similar in all cases, typically leading to activation of the transcription factor NF-  $\kappa$ B. We do not yet know whether the upstream pathway is conserved, in particular whether the PAMPs function by generating ligands that in turn activate the Toll-like receptors or whether they might interact directly with them. The pathway upstream of the Toll-like receptors is different in mammals and flies, because the pathogens directly activate mammalian Toll-like receptors. In the case of LPS, the pathogen binds to the surface protein CD14; this enables CD14 to activate TLR4, triggering the innate response pathway (2383). There are ~20 receptors in the TLR (Toll-like receptor) class in the human genome, which gives some indication of how many pathogens can trigger the innate response.

Plants have extensive defense mechanisms, among which are pathways analogous to the innate response in animals (for review see 2387). The same principle applies that PAMPs are the motifs that identify the infecting agent as a pathogen. The proteins that respond to the pathogens are coded by a class of genes called the disease resistance genes. Many of these genes code for receptors that share a property with the TLR class of animal receptors: the extracellular domain has a motif called the **leucine-rich region (LLR)**. The response mechanism is different from animal cells, and is directed to activating a MAPK cascade. Many different pathogens activate the same cascade, which suggests that a variety of pathogen-receptor interactions converge at or before the activation of the first MAPK (2386).

**IMMUNE DIVERSITY****5.25.22 Summary**

---

Immunoglobulins and T cell receptors are proteins that play analogous functions in the roles of B cells and T cells in the immune system. An Ig or TCR protein is generated by rearrangement of DNA in a single lymphocyte; exposure to an antigen recognized by the Ig or TCR leads to clonal expansion to generate many cells which have the same specificity as the original cell. Many different rearrangements occur early in the development of the immune system, creating a large repertoire of cells of different specificities.

Each immunoglobulin protein is a tetramer containing two identical light chains and two identical heavy chains. A TCR is a dimer containing two different chains. Each polypeptide chain is expressed from a gene created by linking one of many V segments via D and J segments to one of a few C segments. Ig L chains (either  $\kappa$  or  $\lambda$ ) have the general structure V-J-C, Ig H chains have the structure V-D-J-C, TCR  $\alpha$  and  $\gamma$  have components like Ig L chains, and TCR  $\delta$  and  $\beta$  are like Ig H chains.

Each type of chain is coded by a large cluster of V genes separated from the cluster of D, J, and C segments. The numbers of each type of segment, and their organization, are different for each type of chain, but the principle and mechanism of recombination appear to be the same. The same nonamer and heptamer consensus sequences are involved in each recombination; the reaction always involves joining of a consensus with 23 bp spacing to a consensus with 12 bp spacing. The cleavage reaction is catalyzed by the RAG1 and RAG2 proteins, and the joining reaction is catalyzed by the same NHEJ pathway that repairs double-strand breaks in cells. The mechanism of action of the RAG proteins is related to the action of site-specific recombination catalyzed by resolvases.

Although considerable diversity is generated by joining different V, D, J segments to a C segment, additional variations are introduced in the form of changes at the junctions between segments during the recombination process. Changes are also induced in immunoglobulin genes by somatic mutation, which requires the actions of cytidine deaminase and uracil glycosylase. Mutations induced by cytidine deaminase probably lead to removal of uracil by uracil glycosylase, followed by the induction of mutations at the sites where bases are missing.

Allelic exclusion ensures that a given lymphocyte synthesizes only a single Ig or TCR. A productive rearrangement inhibits the occurrence of further rearrangements. Although the use of the V region is fixed by the first productive rearrangement, B cells switch use of  $C_H$  genes from the initial  $\mu$  chain to one of the H chains coded farther downstream. This process involves a different type of recombination in which the sequences between the VDJ region and the new  $C_H$  gene are deleted. More than one switch occurs in  $C_H$  gene usage. Class switching requires the same cytidine deaminase that is required for somatic mutation, but its role is not known. At an earlier stage of Ig production, switches occur from synthesis of a membrane-bound version of the protein to a secreted version. These switches are accomplished by alternative splicing of the transcript.

Innate immunity is a response triggered by receptors whose specificity is predefined for certain common motifs found in bacteria and other infective agents. The receptor that triggers the pathway is typically a member of the Toll-like class, and the pathway resembles the pathway triggered by Toll receptors during embryonic development. The pathway culminates in activation of transcription factors that cause genes to be expressed whose products inactivate the infective agent, typically by permeabilizing its membrane.

## CATALYTIC RNA

### 5.26.1 Introduction

---

#### Key Terms

A **ribozyme** is an RNA that has catalytic activity.

**RNA editing** describes a change of sequence at the level of RNA following transcription.

---

The idea that only proteins have enzymatic activity was deeply rooted in biochemistry. (Yet devotees of protein function once thought that only proteins could have the versatility to be the genetic material!) A rationale for the identification of enzymes with proteins lies in the view that only proteins, with their varied three-dimensional structures and variety of side-groups, have the flexibility to create the active sites that catalyze biochemical reactions. But the characterization of systems involved in RNA processing has shown this view to be an over-simplification.

Several types of catalytic reactions are now known to reside in RNA. **Ribozyme** has become a general term used to describe an RNA with catalytic activity, and it is possible to characterize the enzymatic activity in the same way as a more conventional enzyme. Some RNA catalytic activities are directed against separate substrates, while others are intramolecular (which limits the catalytic action to a single cycle).

Introns of the group I and group II classes possess the ability to splice themselves out of the pre-mRNA that contains them. Engineering of group I introns has generated RNA molecules that have several other catalytic activities related to the original activity.

The enzyme ribonuclease P is a ribonucleoprotein that contains a single RNA molecule bound to a protein. The RNA possesses the ability to catalyze cleavage in a tRNA substrate, while the protein component plays an indirect role, probably to maintain the structure of the catalytic RNA.

The common theme of these reactions is that the RNA can perform an intramolecular or intermolecular reaction that involves cleavage or joining of phosphodiester bonds *in vitro*. Although the specificity of the reaction and the basic catalytic activity is provided by RNA, proteins associated with the RNA may be needed for the reaction to occur efficiently *in vivo*.

RNA splicing is not the only means by which changes can be introduced in the informational content of RNA. In the process of **RNA editing**, changes are introduced at individual bases, or bases are added at particular positions within an mRNA. The insertion of bases (most commonly uridine residues) occurs for several genes in the mitochondria of certain lower eukaryotes; like splicing, it involves the breakage and reunion of bonds between nucleotides, but also requires a template for

coding the information of the new sequence.

## CATALYTIC RNA

### 5.26.2 Group I introns undertake self-splicing by transesterification

#### Key Terms

**Autosplicing (Self-splicing)** describes the ability of an intron to excise itself from an RNA by a catalytic action that depends only on the sequence of RNA in the intron.

#### Key Concepts

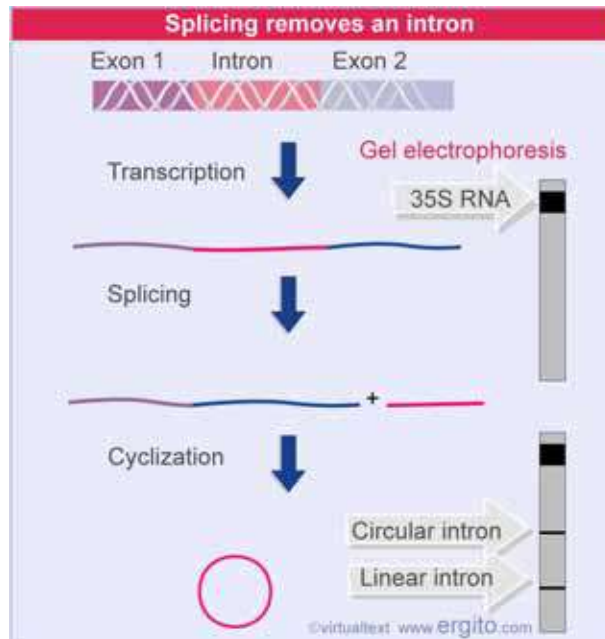

- The only factors required for autosplicing *in vitro* by group I introns are a monovalent cation, a divalent cation, and a guanine nucleotide.
- Splicing occurs by two transesterifications, without requiring input of energy.
- The 3' –OH end of the guanine cofactor attacks the 5' end of the intron in the first transesterification.
- The 3' –OH end generated at the end of the first exon attacks the junction between the intron and second exon in the second transesterification.
- The intron is released as a linear molecule that circularizes when its 3' –OH terminus attacks a bond at one of two internal positions.
- The G<sup>414</sup>–A<sup>16</sup> internal bond of the intron can also be attacked by other nucleotides in a *trans*-splicing reaction.

Group I introns are found in diverse locations. They occur in the genes coding for rRNA in the nuclei of the lower eukaryotes *Tetrahymena thermophila* (a ciliate) and *Physarum polycephalum* (a slime mold). They are common in the genes of fungal mitochondria. They are present in three genes of phage T4 and also are found in bacteria. Group I introns have an intrinsic ability to splice themselves. This is called **self-splicing** or **autosplicing**. (This property is found also in the group II introns discussed in *Molecular Biology* 5.24.11 *Group II introns autosplice via lariat formation*. (749))

Self-splicing was discovered as a property of the transcripts of the rRNA genes in *T. thermophila* (for an account of the discovery see *Great Experiments* 4.4 *RNA catalysis*). The genes for the two major rRNAs follow the usual organization, in which both are expressed as part of a common transcription unit. The product is a 35S precursor RNA with the sequence of the small rRNA in the 5' part, and the sequence of the larger (26S) rRNA toward the 3' end.

In some strains of *T. thermophila*, the sequence coding for 26S rRNA is interrupted by a single, short intron. When the 35S precursor RNA is incubated *in vitro*, splicing occurs as an autonomous reaction. The intron is excised from the precursor and accumulates as a linear fragment of 400 bases, which is subsequently converted to a

circular RNA. These events are summarized in **Figure 26.1**.

**Figure 26.1** Splicing of the *Tetrahymena* 35S rRNA precursor can be followed by gel electrophoresis. The removal of the intron is revealed by the appearance of a rapidly moving small band. When the intron becomes circular, it electrophoreses more slowly, as seen by a higher band.

*The reaction requires only a monovalent cation, a divalent cation, and a guanine nucleotide cofactor.* No other base can be substituted for G; but a triphosphate is not needed; GTP, GDP, GMP, and guanosine itself all can be used, so there is no net energy requirement. The guanine nucleotide must have a 3' -OH group (747).

The fate of the guanine nucleotide can be followed by using a radioactive label. The radioactivity initially enters the excised linear intron fragment. The G residue becomes linked to the 5' end of the intron by a normal phosphodiester bond.

**Figure 26.2** shows that three transfer reactions occur. In the first transfer, the guanine nucleotide behaves as a cofactor that provides a free 3' -OH group that attacks the 5' end of the intron. This reaction creates the G-intron link and generates a 3' -OH group at the end of the exon. The second transfer involves a similar chemical reaction, in which this 3' -OH then attacks the second exon. The two transfers are connected; no free exons have been observed, so their ligation may occur as part of the same reaction that releases the intron. The intron is released as a linear molecule, but the third transfer reaction converts it to a circle.

**Figure 26.2** Self-splicing occurs by transesterification reactions in which bonds are exchanged directly. The bonds that have been generated at each stage are indicated by the shaded boxes.

Each stage of the self-splicing reaction occurs by a transesterification, in which one phosphate ester is converted directly into another, without any intermediary hydrolysis. Bonds are exchanged directly, and energy is conserved, so the reaction does not require input of energy from hydrolysis of ATP or GTP. (There is a parallel for the transfer of bonds without net input of energy in the DNA nicking-closing enzymes discussed in *Molecular Biology 4.15 Recombination and repair*.)

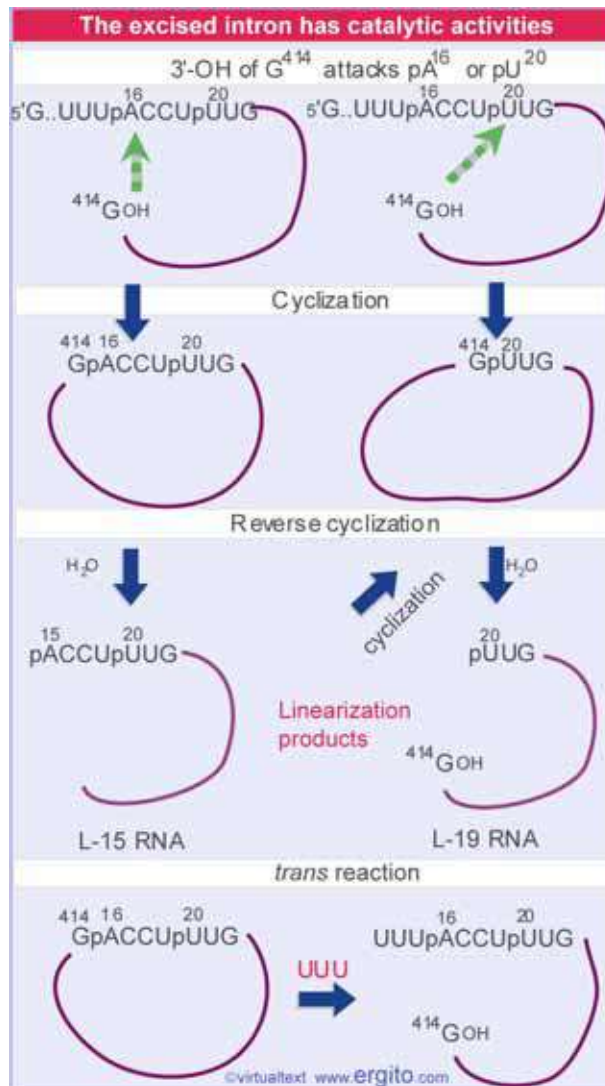

If each of the consecutive transesterification reactions involves no net change of energy, why does the splicing reaction proceed to completion instead of coming to equilibrium between spliced product and nonspliced precursor? The concentration of GTP is high relative to that of RNA, and therefore drives the reaction forward; and a change in secondary structure in the RNA prevents the reverse reaction.

*The in vitro system includes no protein so the ability to splice is intrinsic to the RNA.*

The RNA forms a specific secondary/tertiary structure in which the relevant groups are brought into juxtaposition so that a guanine nucleotide can be bound to a specific site and then the bond breakage and reunion reactions shown in **Figure 26.2** can occur. Although a property of the RNA itself, the reaction is assisted *in vivo* by proteins, which stabilize the RNA structure (748).

The ability to engage in these transfer reactions resides with the sequence of the intron, which continues to be reactive after its excision as a linear molecule. **Figure 26.3** summarizes its activities:

**Figure 26.3** The excised intron can form circles by using either of two internal sites for reaction with the 5' end, and can reopen the circles by reaction with water or oligonucleotides.

The intron can circularize when the 3' terminal G attacks either of two positions near the 5' end. The internal bond is broken and the new 5' end is transferred to the 3' -OH end of the intron. The *primary cyclization* usually involves reaction between the terminal G<sup>414</sup> and the A<sup>16</sup>. This is the most common reaction (shown as the third

transfer in **Figure 26.2**). Less frequently, the G<sup>414</sup> reacts with U<sup>20</sup>. Each reaction generates a circular intron and a linear fragment that represents the original 5' region (15 bases long for attack on A<sup>16</sup>, 19 bases long for attack on U<sup>20</sup>). The released 5' fragment contains the original added guanine nucleotide.

Either type of circle can regenerate a linear molecule *in vitro* by specifically hydrolyzing the bond (G<sup>414</sup>-A<sup>16</sup> or G<sup>414</sup>-U<sup>20</sup>) that had closed the circle. This is called a *reverse cyclization*. The linear molecule generated by reversing the primary cyclization at A<sup>16</sup> remains reactive, and can perform a secondary cyclization by attacking U<sup>20</sup>.

The final product of the spontaneous reactions following release of the intron is the L-19 RNA, a linear molecule generated by reversing the shorter circular form. This molecule has an enzymatic activity that allows it to catalyze the extension of short oligonucleotides (not shown in the figure, but see **Figure 26.8**).

The reactivity of the released intron extends beyond merely reversing the cyclization reaction. Addition of the oligonucleotide UUU reopens the primary circle by reacting with the G<sup>414</sup>-A<sup>16</sup> bond. The UUU (which resembles the 3' end of the 15-mer released by the primary cyclization) becomes the 5' end of the linear molecule that is formed. This is an *intermolecular* reaction, and thus demonstrates the ability to connect together two different RNA molecules.

This series of reactions demonstrates vividly that the autocatalytic activity reflects a generalized ability of the RNA molecule to form an active center that can bind guanine cofactors, recognize oligonucleotides, and bring together the reacting groups in a conformation that allows bonds to be broken and rejoined. Other group I introns have not been investigated in as much detail as the *Tetrahymena* intron, but their properties are generally similar (750; for review see 255; 256).

The autosplicing reaction is an intrinsic property of RNA *in vitro*, but to what degree are proteins involved *in vivo*? Some indications for the involvement of proteins are provided by mitochondrial systems, where splicing of group I introns requires the *trans*-acting products of other genes. One striking case is presented by the *cyt18* mutant of *N. crassa*, which is defective in splicing several mitochondrial group I introns. The product of this gene turns out to be the mitochondrial tyrosyl-tRNA synthetase! This is explained by the fact that the intron can take up a tRNA-like tertiary structure that is stabilized by the synthetase and which promotes the catalytic reaction (2512).

This relationship between the synthetase and splicing is consistent with the idea that splicing originated as an RNA-mediated reaction, subsequently assisted by RNA-binding proteins that originally had other functions. The *in vitro* self-splicing ability may represent the basic biochemical interaction. The RNA structure creates the active site, but is able to function efficiently *in vivo* only when assisted by a protein complex.

## CATALYTIC RNA

### 5.26.3 Group I introns form a characteristic secondary structure

---

#### Key Concepts

- Group I introns form a secondary structure with 9 duplex regions.
  - The core of regions P3, P4, P6, P7 has catalytic activity.
  - Regions P4 and P7 are both formed by pairing between conserved consensus sequences.
  - A sequence adjacent to P7 base pairs with the sequence that contains the reactive G.
- 

All group I introns can be organized into a characteristic secondary structure, with 9 helices (P1-P9). **Figure 26.4** shows a model for the secondary structure of the *Tetrahymena* intron. Two of the base-paired regions are generated by pairing between conserved sequence elements that are common to group I introns. P4 is constructed from the sequences *P* and *Q*; P7 is formed from sequences *R* and *S*. The other base-paired regions vary in sequence in individual introns. Mutational analysis identifies an intron "core," containing P3, P4, P6, and P7, which provides the minimal region that can undertake a catalytic reaction. The lengths of group I introns vary widely, and the consensus sequences are located a considerable distance from the actual splice junctions.

**Figure 26.4** Group I introns have a common secondary structure that is formed by 9 base paired regions. The sequences of regions P4 and P7 are conserved, and identify the individual sequence elements P, Q, R, and S. P1 is created by pairing between the end of the left exon and the IGS of the intron; a region between P7 and P9 pairs with the 3' end of the intron.

Some of the pairing reactions are directly involved in bringing the splice junctions into a conformation that supports the enzymatic reaction. P1 includes the 3' end of the left exon. The sequence within the intron that pairs with the exon is called the IGS, or internal guide sequence. (Its name reflects the fact that originally the region immediately 3' to the IGS sequence shown in the figure was thought to pair with the 3' splice junction, thus bringing the two junctions together. This interaction may occur, but does not seem to be essential.) A very short sequence, sometimes as short as 2 bases, between P7 and P9, base pairs with the sequence that immediately precedes the reactive G (position 414 in *Tetrahymena*) at the 3' end of the intron (752).

The importance of base pairing in creating the necessary core structure in the RNA is emphasized by the properties of *cis*-acting mutations that prevent splicing of group I introns. Such mutations have been isolated for the mitochondrial introns through mutants that cannot remove an intron *in vivo*, and they have been isolated for the *Tetrahymena* intron by transferring the splicing reaction into a bacterial environment. The construct shown in **Figure 26.5** allows the splicing reaction to be followed in *E. coli*. The self-splicing intron is placed at a location that interrupts the tenth codon of the  $\beta$ -galactosidase coding sequence. The protein can therefore be successfully translated from an RNA only after the intron has been removed.

**Figure 26.5** Placing the *Tetrahymena* intron within the  $\beta$ -galactosidase coding sequence creates an assay for self-splicing in *E. coli*. Synthesis of  $\beta$ -galactosidase can be tested by adding a compound that is turned blue by the enzyme. The sequence is carried by a bacteriophage, so the presence of blue plaques (containing infected bacteria) indicates successful splicing.

The synthesis of  $\beta$ -galactosidase in this system indicates that splicing can occur in conditions quite distant from those prevailing in *Tetrahymena* or even *in vitro*. One interpretation of this result is that self-splicing can occur in the bacterial cell. Another possibility is that there are bacterial proteins that assist the reaction.

Using this assay, we can introduce mutations into the intron to see whether they prevent the reaction. Mutations in the group I consensus sequences that disrupt their base pairing stop splicing. The mutations can be reverted by making compensating changes that restore base pairing.

Mutations in the corresponding consensus sequences in mitochondrial group I introns have similar effects. A mutation in one consensus sequence may be reverted by a mutation in the complementary consensus sequence to restore pairing; for example, mutations in the R consensus can be compensated by mutations in the S consensus.

Together these results suggest that the group I splicing reaction depends on the formation of secondary structure between pairs of consensus sequences within the intron. The principle established by this work is that *sequences distant from the splice junctions themselves are required to form the active site that makes self-splicing possible* (751).

**CATALYTIC RNA****5.26.4 Ribozymes have various catalytic activities**

---

**Key Concepts**

- By changing the substrate binding-site of a group I intron, it is possible to introduce alternative sequences that interact with the reactive G.
- The reactions follow classical enzyme kinetics with a low catalytic rate.
- Reactions using 2' -OH bonds could have been the basis for evolving the original catalytic activities in RNA.

---

The catalytic activity of group I introns was discovered by virtue of their ability to autosplice, but they are able to undertake other catalytic reactions *in vitro*. All of these reactions are based on transesterifications. We analyze these reactions in terms of their relationship to the splicing reaction itself.

The catalytic activity of a group I intron is conferred by its ability to generate a particular secondary and tertiary structure that creates active sites, equivalent to the active sites of a conventional (proteinaceous) enzyme. **Figure 26.6** illustrates the splicing reaction in terms of these sites (this is the same series of reactions shown previously in **Figure 26.2**).

**Figure 26.6** Excision of the group I intron in *Tetrahymena* rRNA occurs by successive reactions between the occupants of the guanosine-binding site and substrate-binding site. The left exon is red, and the right exon is purple.

The substrate-binding site is formed from the P1 helix, in which the 3' end of the first intron base pairs with the IGS in an intermolecular reaction. A guanosine-binding site is formed by sequences in P7. This site may be occupied either by a free guanosine nucleotide or by the G residue in position 414. In the first transfer reaction, it is used by free guanosine nucleotide; but it is subsequently occupied by G<sup>414</sup>. The second transfer releases the joined exons. The third transfer creates the circular intron.

Binding to the substrate involves a change of conformation; before substrate binding, the 5' end of the IGS is close to P2 and P8, but after binding, when it forms the P1

helix, it is close to conserved bases that lie between P4 and P5. The reaction is visualized by contacts that are detected in the secondary structure in **Figure 26.7**. In the tertiary structure, the two sites alternatively contacted by P1 are 37 Å apart, which implies a substantial movement in the position of P1.

**Figure 26.7** The position of the IGS in the tertiary structure changes when P1 is formed by substrate binding.

The L-19 RNA is generated by opening the circular intron (shown as the last stage of the intramolecular rearrangements shown in **Figure 26.3**). It still retains enzymatic abilities. These resemble the activities involved in the original splicing reaction, and we may consider ribozyme function in terms of the ability to bind an intramolecular sequence complementary to the IGS in the substrate-binding site, while binding either the terminal  $G^{414}$  or a free G-nucleotide in the G-binding site.

**Figure 26.8** illustrates the mechanism by which the oligonucleotide  $C_5$  is extended to generate a  $C_6$  chain. The  $C_5$  oligonucleotide binds in the substrate-binding site, while  $G^{414}$  occupies the G-binding site. By transesterification reactions, a C is transferred from  $C_5$  to the 3'–terminal G, and then back to a new  $C_5$  molecule. Further transfer reactions lead to the accumulation of longer cytosine oligonucleotides. The reaction is a true catalysis, because the L-19 RNA remains unchanged, and is available to catalyze multiple cycles. The ribozyme is behaving as a nucleotidyl transferase.

**Figure 26.8** The L-19 linear RNA can bind C in the substrate-binding site; the reactive G-OH 3' end is located in the G-binding site, and catalyzes transfer reactions that convert 2 C5 oligonucleotides into a C4 and a C6 oligonucleotide.

Some further enzymatic reactions are characterized in **Figure 26.9**. The ribozyme can function as a sequence-specific endoribonuclease by utilizing the ability of the IGS to bind complementary sequences. In this example, it binds an external substrate containing the sequence CUCU, instead of binding the analogous sequence that is usually contained at the end of the left exon. A guanine-containing nucleotide is present in the G-binding site, and attacks the CUCU sequence in precisely the same way that the exon is usually attacked in the first transfer reaction. This cleaves the target sequence into a 5' molecule that resembles the left exon, and a 3' molecule that bears a terminal G residue. By mutating the IGS element, it is possible to change the specificity of the ribozyme, so that it recognizes sequences complementary to the new sequence at the IGS region (for review see 257).

**Figure 26.9** Catalytic reactions of the ribozyme involve transesterifications between a group in the substrate-binding site and a group in the G-binding site.

Altering the IGS, so that the specificity of the substrate-binding site is changed to enable other RNA targets to enter, can be used to generate a ligase activity. An RNA terminating in a 3' -OH is bound in the substrate site, and an RNA terminating in a 5' -G residue is bound in the G-binding site. An attack by the hydroxyl on the phosphate bond connects the two RNA molecules, with the loss of the G residue.

The phosphatase reaction is not directly related to the splicing transfer reactions. An oligonucleotide sequence that is complementary to the IGS and terminates in a 3' -phosphate can be attacked by the G<sup>414</sup>. The phosphate is transferred to the G<sup>414</sup>, and an oligonucleotide with a free 3' -OH end is then released. The phosphate can then be transferred either to an oligonucleotide terminating in 3' -OH (effectively reversing the reaction) or indeed to water (releasing inorganic phosphate and completing an authentic phosphatase reaction).

The reactions catalyzed by RNA can be characterized in the same way as classical enzymatic reactions in terms of Michaelis-Menten kinetics. **Figure 26.10** analyzes the reactions catalyzed by RNA. The  $K_M$  values for RNA-catalyzed reactions are

low, and therefore imply that the RNA can bind its substrate with high specificity. The turnover numbers are low, which reflects a low catalytic rate. In effect, the RNA molecules behave in the same general manner as traditionally defined for enzymes, although they are relatively slow compared to protein catalysts (where a typical range of turnover numbers is  $10^3$ – $10^6$ ).

RNA catalysis is enzymatic			
Enzyme	Substrate	$K_M$ (mM)	Turnover (/min)
19 base virusoid	24 base RNA	0.0006	0.5
L-19 Intron	CCCCC	0.04	1.7
RNAase P RNA	pre-tRNA	0.00003	0.4
RNAase P complete	pre-tRNA	0.00003	29
RNAase T1	GpA	0.05	5,700
$\beta$ -galactosidase	lactose	4.0	12,500

©virtualtext www.ergito.com

**Figure 26.10** Reactions catalyzed by RNA have the same features as those catalyzed by proteins, although the rate is slower. The  $K_M$  gives the concentration of substrate required for half-maximum velocity; this is an inverse measure of the affinity of the enzyme for substrate. The turnover number gives the number of substrate molecules transformed in unit time by a single catalytic site.

How does RNA provide a catalytic center? Its ability seems reasonable if we think of an active center as a surface that exposes a series of active groups in a fixed relationship. In a protein, the active groups are provided by the side chains of the amino acids, which have appreciable variety, including positive and negative ionic groups and hydrophobic groups. In an RNA, the available moieties are more restricted, consisting primarily of the exposed groups of bases. Short regions are held in a particular structure by the secondary/tertiary conformation of the molecule, providing a surface of active groups able to maintain an environment in which bonds can be broken and made in another molecule. It seems inevitable that the interaction between the RNA catalyst and the RNA substrate will rely on base pairing to create the environment. Divalent cations (typically  $Mg^{2+}$ ) play an important role in structure, typically being present at the active site where they coordinate the positions of the various groups. They play a direct role in the endonucleolytic activity of virusoid ribozymes (see *Molecular Biology* 5.26.9 *Viroids have catalytic activity*).

The evolutionary implications of these discoveries are intriguing. The split personality of the genetic apparatus, in which RNA is present in all components, but proteins undertake catalytic reactions, has always been puzzling. It seems unlikely that the very first replicating systems could have contained both nucleic acid and protein.

But suppose that the first systems contained only a self-replicating nucleic acid with primitive catalytic activities, just those needed to make and break phosphodiester bonds. If we suppose that the involvement of 2' –OH bonds in current splicing reactions is derived from these primitive catalytic activities, we may argue that the original nucleic acid was RNA, since DNA lacks the 2' –OH group and therefore

could not undertake such reactions. Proteins could have been added for their ability to stabilize the RNA structure. Then the greater versatility of proteins could have allowed them to take over catalytic reactions, leading eventually to the complex and sophisticated apparatus of modern gene expression.

**CATALYTIC RNA****5.26.5 Some group I introns code for endonucleases that sponsor mobility**

---

**Key Terms**

**Intron homing** describes the ability of certain introns to insert themselves into a target DNA. The reaction is specific for a single target sequence.

**Key Concepts**

- Mobile introns are able to insert themselves into new sites.
- Mobile group I introns code for an endonuclease that makes a double-strand break at a target site.
- The intron transposes into the site of the double-strand break by a DNA-mediated replicative mechanism.

---

Certain introns of both the group I and group II classes contain open reading frames that are translated into proteins. Expression of the proteins allows the intron (either in its original DNA form or as a DNA copy of the RNA) to be *mobile*: it is able to insert itself into a new genomic site. Introns of both groups I and II are extremely widespread, being found in both prokaryotes and eukaryotes. Group I introns migrate by DNA-mediated mechanisms, whereas group II introns migrate by RNA-mediated mechanisms.

Intron mobility was first detected by crosses in which the alleles for the relevant gene differ with regard to their possession of the intron. Polymorphisms for the presence or absence of introns are common in fungal mitochondria. This is consistent with the view that these introns originated by insertion into the gene. Some light on the process that could be involved is cast by an analysis of recombination in crosses involving the large rRNA gene of the yeast mitochondrion.

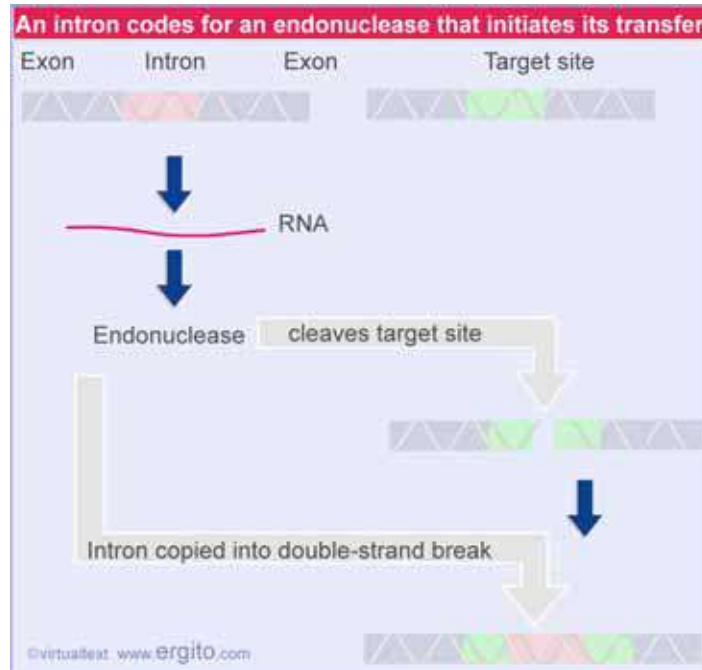

This gene has a group I intron that contains a coding sequence. The intron is present in some strains of yeast (called  $\omega^+$ ) but absent in others ( $\omega^-$ ). Genetic crosses between  $\omega^+$  and  $\omega^-$  are *polar*: the progeny are usually  $\omega^+$ .

If we think of the  $\omega^+$  strain as a donor and the  $\omega^-$  strain as a recipient, we form the view that in  $\omega^+ \times \omega^-$  crosses a new copy of the intron is generated in the  $\omega^-$  genome. As a result, the progeny are all  $\omega^+$ .

Mutations can occur in either parent to abolish the polarity. Mutants show normal segregation, with equal numbers of  $\omega^+$  and  $\omega^-$  progeny. The mutations indicate the nature of the process. Mutations in the  $\omega^-$  strain occur close to the site where the intron would be inserted. Mutations in the  $\omega^+$  strain lie in the reading frame of the intron and prevent production of the protein. This suggests the model of **Figure 26.11**, in which the protein coded by the intron in an  $\omega^+$  strain recognizes the site

where the intron should be inserted in an  $\omega^-$  strain and causes it to be preferentially inherited.

**Figure 26.11** An intron codes for an endonuclease that makes a double-strand break in DNA. The sequence of the intron is duplicated and then inserted at the break.

What is the action of the protein? The product of the  $\omega$  intron is an endonuclease *that recognizes the  $\omega^-$  gene as a target for a double-strand break*. The endonuclease recognizes an 18 bp target sequence that contains the site where the intron is inserted. The target sequence is cleaved on each strand of DNA 2 bases to the 3' side of the insertion site. So the cleavage sites are 4 bp apart, and generate overhanging single strands.

This type of cleavage is related to the cleavage characteristic of transposons when they migrate to new sites (see *Molecular Biology 4.16 Transposons*). The double-strand break probably initiates a gene conversion process in which the sequence of the  $\omega^+$  gene is copied to replace the sequence of the  $\omega^-$  gene. The reaction involves transposition by a duplicative mechanism, and occurs solely at the level of DNA. Insertion of the intron interrupts the sequence recognized by the endonuclease, thus ensuring stability.

Many group I introns code for endonucleases that make them mobile. Several different families of endonucleases are found; one common feature is the presence of the amino acid sequence LAGLIDADG near the active site (for review see 4515). Similar introns often carry quite different endonucleases. There are differences in the details of insertion; for example, the endonuclease coded by the phage T4 *td* intron cleaves a target site that is 24 bp upstream of the site at which the intron is itself inserted. The dissociation between the intron sequence and the endonuclease sequence is emphasized by the fact that the same endonuclease sequences are found in inteins (sequences that code for self-splicing proteins; see *Molecular*

*Biology 5.26.12 Protein splicing is autocatalytic).*

The variation in the endonucleases means that there is no homology between the sequences of their target sites. The target sites are among the longest and therefore the most specific known for any endonucleases (with a range of 14-40 bp). The specificity ensures that the intron perpetuates itself only by insertion into a single target site and not elsewhere in the genome. This is called **intron homing**.

Introns carrying sequences that code for endonucleases are found in a variety of bacteria and lower eukaryotes. These results strengthen the view that introns carrying coding sequences originated as independent elements.

**CATALYTIC RNA****5.26.6 Some group II introns code for reverse transcriptases**

---

**Key Concepts**

- Some group II introns code for a reverse transcriptase that generates a DNA copy of the RNA sequence that transposes by a retroposon-like mechanism.
- 

Most of the open reading frames contained in group II introns have regions that are related to reverse transcriptases. Introns of this type are found in organelles of lower eukaryotes and also in some bacteria. The reverse transcriptase activity is specific for the intron, and is involved in homing. The reverse transcriptase generates a DNA copy of the intron from the pre-mRNA, and thus allows the intron to become mobile by a mechanism resembling that of retroviruses (see *Molecular Biology 4.17.2 The retrovirus life cycle involves transposition-like events*). The type of retrotransposition involved in this case resembles that of a group of retroposons that lack LTRs, and which generate the 3' -OH needed for priming by making a nick in the target (see **Figure 17.20** in *Molecular Biology 4.17.12 LINES use an endonuclease to generate a priming end*).

The best characterized mobile group II introns code for a single protein in a region of the intron beyond its catalytic core. The typical protein contains an N-terminal reverse transcriptase activity, a central domain associated with maturase activity, and a C-terminal endonuclease domain. The endonuclease initiates the transposition reaction, and thus plays the same role in homing as its counterpart in a group I intron. The reverse transcriptase generates a DNA copy of the intron that is inserted at the homing site. The endonuclease also cleaves target sites that resemble, but are not identical to the homing site, at much lower frequency, leading to insertion of the intron at new locations (3330).

**Figure 26.12** illustrates the transposition reaction for a typical group II intron. The endonuclease makes a double-strand break at the target site. A 3' end is generated at the site of the break, and provides a primer for the reverse transcriptase. The intron RNA provides the template for the synthesis of cDNA. Because the RNA includes exon sequences on either side of the intron, the cDNA product is longer than the region of the intron itself, so that it can span the double-strand break, allowing the cDNA to repair the break. The result is the insertion of the intron (754; for review see 259).

**Figure 26.12** Reverse transcriptase coded by an intron allows a copy of the RNA to be inserted at a target site generated by a double-strand break.

## CATALYTIC RNA

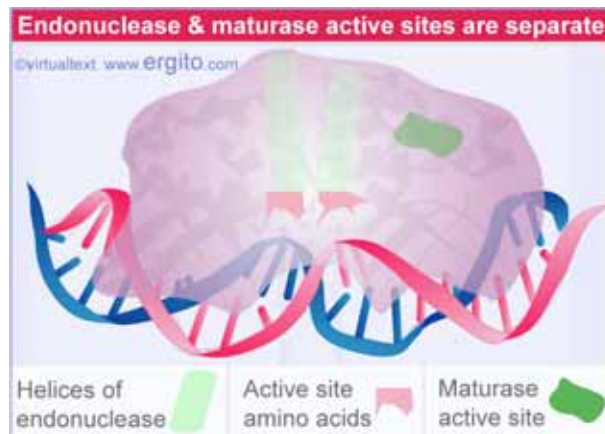

**5.26.7 Some autosplicing introns require maturases****Key Terms**

A **maturase** is a protein coded by a group I or group II intron that is needed to assist the RNA to form the active conformation that is required for self-splicing.

Both types of autosplicing intron may code for proteins involved in their perpetuation and homing, such as endonucleases in group I and reverse transcriptases in group II. In addition, both types of intron may code for **maturase** activities that are required to assist the splicing reaction (753).

The maturase activity is part of the single open reading frame coded by the intron. In the example of introns that code for homing endonucleases, the single protein product has both endonuclease and maturase activity. Mutational analysis shows that the two activities are independent (4516).

Structural analysis shows that the endonuclease and maturase activities are provided by different active sites in the protein, each coded by a separate domain (4517). The endonuclease site binds to DNA, but the maturase site binds to the intron RNA. **Figure 26.13** shows the structure of one such protein bound to DNA. A characteristic feature of the endonuclease is the presence of parallel  $\alpha$  helices, containing the hallmark LAGLIDADG sequences, leading to the two catalytic amino acids. The maturase activity is located some distance away on the surface of the protein.

**Figure 26.13** A homing intron codes for an endonuclease of the LAGLIDADG family that also has maturase activity. The LAGLIDADG sequences are part of the two  $\alpha$  helices that terminate in the catalytic amino acids close to the DNA duplex. The maturase active site is identified by an arginine residue elsewhere on the surface of the protein.

Introns that code for maturases may be unable to splice themselves effectively in the absence of the protein activity. The maturase is in effect a splicing factor that is

required specifically for splicing of the sequence that codes for it. It functions to assist the folding of the catalytic core to form an active site (3329).

The coexistence of endonuclease and maturase activities in the same protein suggests a route for the evolution of the intron. **Figure 26.14** suggests that the intron originated in an independent autosplicing element. The insertion into this element of a sequence coding for an endonuclease gave it mobility. However, the insertion might well disrupt the ability of the RNA sequence to fold into the active structure. This would create pressure for assistance from proteins that could restore folding ability. The incorporation of such a sequence into the intron would maintain its independence.

**Figure 26.14** The intron originated as independent sequence coding for a self-splicing RNA. The insertion of the endonuclease sequence created a homing intron that was mobile. Then the insertion of the maturase sequence enhanced the ability of the intron sequences to fold into the active structure for splicing.

Some group II introns that do not code for maturase activities may use comparable proteins that are coded by sequences in the host genome. This suggests a possible

route for the evolution of general splicing factors. The factor may have originated as a maturase that specifically assisted the splicing of a particular intron. The coding sequence became isolated from the intron in the host genome, and then it evolved to function with a wider range of substrates than the original intron sequence. The catalytic core of the intron could have evolved into an snRNA.

---

**CATALYTIC RNA****5.26.8 The catalytic activity of RNAase P is due to RNA**

---

**Key Concepts**

- Ribonuclease P is a ribonucleoprotein in which the RNA has catalytic activity.
- 

One of the first demonstrations of the capabilities of RNA was provided by the dissection of ribonuclease P, an *E. coli* tRNA-processing endonuclease. Ribonuclease P can be dissociated into its two components, the 375 base RNA and the 20 kD polypeptide. Under the conditions initially used to characterize the enzyme activity *in vitro*, both components were necessary to cleave the tRNA substrate.

But a change in ionic conditions, an increase in the concentration of  $Mg^{2+}$ , renders the protein component superfluous. *The RNA alone can catalyze the reaction!* Analyzing the results as though the RNA were an enzyme, each "enzyme" catalyzes the cleavage of multiple substrates. Although the catalytic activity resides in the RNA, the protein component greatly increases the speed of the reaction, as seen in the increase in turnover number (see **Figure 26.10**).

Because mutations in either the gene for the RNA or the gene for protein can inactivate RNAase P *in vivo*, we know that both components are necessary for natural enzyme activity. Originally it had been assumed that the protein provided the catalytic activity, while the RNA filled some subsidiary role, for example, assisting in the binding of substrate (it has some short sequences complementary to exposed regions of tRNA). But these roles are reversed!

---

**CATALYTIC RNA****5.26.9 Viroids have catalytic activity**

---

**Key Terms**

A **viroid** is a small infectious nucleic acid that does not have a protein coat.

A **virusoid (Satellite RNA)** is a small infectious nucleic acid that is encapsidated by a plant virus together with its own genome.

**Key Concepts**

- Viroids and virusoids form a hammerhead structure that has an self-cleaving activity.
- Similar structures can be generated by pairing a substrate strand that is cleaved by an enzyme strand.
- When an enzyme strand is introduced into a cell, it can pair with a substrate strand target that is then cleaved.

---

Another example of the ability of RNA to function as an endonuclease is provided by some small plant RNAs (~350 bases) that undertake a self-cleavage reaction. As with the case of the *Tetrahymena* group I intron, however, it is possible to engineer constructs that can function on external substrates (756).

These small plant RNAs fall into two general groups: viroids and virusoids. The **viroids** are infectious RNA molecules that function independently, without encapsidation by any protein coat. The **virusoids** are similar in organization, but are encapsidated by plant viruses, being packaged together with a viral genome. The virusoids cannot replicate independently, but require assistance from the virus. The virusoids are sometimes called **satellite RNAs**.

Viroids and virusoids both replicate via rolling circles (see **Figure 13.16**). The strand of RNA that is packaged into the virus is called the plus strand. The complementary strand, generated during replication of the RNA, is called the minus strand. Multimers of both plus and minus strands are found. Both types of monomer are generated by cleaving the tail of a rolling circle; circular plus strand monomers are generated by ligating the ends of the linear monomer.

Both plus and minus strands of viroids and virusoids undergo self-cleavage *in vitro*. The cleavage reaction is promoted by divalent metal cations; it generates 5' -OH and 2' -3' -cyclic phosphodiester termini. Some of the RNAs cleave *in vitro* under physiological conditions. Others do so only after a cycle of heating and cooling; this suggests that the isolated RNA has an inappropriate conformation, but can generate an active conformation when it is denatured and renatured.

The viroids and virusoids that undergo self-cleavage form a "hammerhead" secondary structure at the cleavage site, as drawn in the upper part of **Figure 26.15**.

The sequence of this structure is sufficient for cleavage. When the surrounding sequences are deleted, the need for a heating-cooling cycle is obviated, and the small RNA self-cleaves spontaneously. This suggests that the sequences beyond the hammerhead usually interfere with its formation.

**Figure 26.15** Self-cleavage sites of viroids and virusoids have a consensus sequence and form a hammerhead secondary structure by intramolecular pairing. Hammerheads can also be generated by pairing between a substrate strand and an "enzyme" strand.

The active site is a sequence of only 58 nucleotides. The hammerhead contains three stem-loop regions whose position and size are constant, and 13 conserved nucleotides, mostly in the regions connecting the center of the structure. The conserved bases and duplex stems generate an RNA with the intrinsic ability to cleave (757).

An active hammerhead can also be generated by pairing an RNA representing one side of the structure with an RNA representing the other side. The lower part of **Figure 26.15** shows an example of a hammerhead generated by hybridizing a 19 base molecule with a 24 base molecule. The hybrid mimics the hammerhead structure, with the omission of loops I and III. When the 19 base RNA is added to the 24 base RNA, cleavage occurs at the appropriate position in the hammerhead.

We may regard the top (24 base) strand of this hybrid as comprising the "substrate," and the bottom (19 base) strand as comprising the "enzyme." When the 19 base RNA is mixed with an excess of the 24 base RNA, multiple copies of the 24 base RNA are

cleaved. This suggests that there is a cycle of 19 base–24 base pairing, cleavage, dissociation of the cleaved fragments from the 19 base RNA, and pairing of the 19 base RNA with a new 24 base substrate. The 19 base RNA is therefore a ribozyme with endonuclease activity. The parameters of the reaction are similar to those of other RNA-catalyzed reactions (see **Figure 26.10**; for review see 258; 2270).

The crystal structure of a hammerhead shows that it forms a compact V-shape, in which the catalytic center lies in a turn, as indicated diagrammatically in **Figure 26.16**. An  $Mg^{2+}$  ion located in the catalytic site plays a crucial role in the reaction. It is positioned by the target cytidine and by the cytidine at the base of stem 1; it may also be connected to the adjacent uridine. It extracts a proton from the 2'–OH of the target cytidine, and then directly attacks the labile phosphodiester bond. Mutations in the hammerhead sequence that affect the transition state of the cleavage reaction occur in both the active site and other locations, suggesting that there may be a substantial rearrangement of structure prior to cleavage (758).

**Figure 26.16** A hammerhead ribozyme forms a V-shaped tertiary structure in which stem 2 is stacked upon stem 3. The catalytic center lies between stem 2/3 and stem 1. It contains a magnesium ion that initiates the hydrolytic reaction.

It is possible to design enzyme-substrate combinations that can form hammerhead structures, and these have been used to demonstrate that introduction of the appropriate RNA molecules into a cell can allow the enzymatic reaction to occur *in vivo*. A ribozyme designed in this way essentially provides a highly specific restriction-like activity directed against an RNA target. By placing the ribozyme under control of a regulated promoter, it can be used in the same way as (for example) antisense constructs specifically to turn off expression of a target gene under defined circumstances.

**CATALYTIC RNA****5.26.10 RNA editing occurs at individual bases**

---

**Key Terms**

**RNA editing** describes a change of sequence at the level of RNA following transcription.

**Key Concepts**

- Apolipoprotein-B and glutamate receptors have site specific deaminations catalyzed by cytidine and adenosine deaminases that change the coding sequence.

---

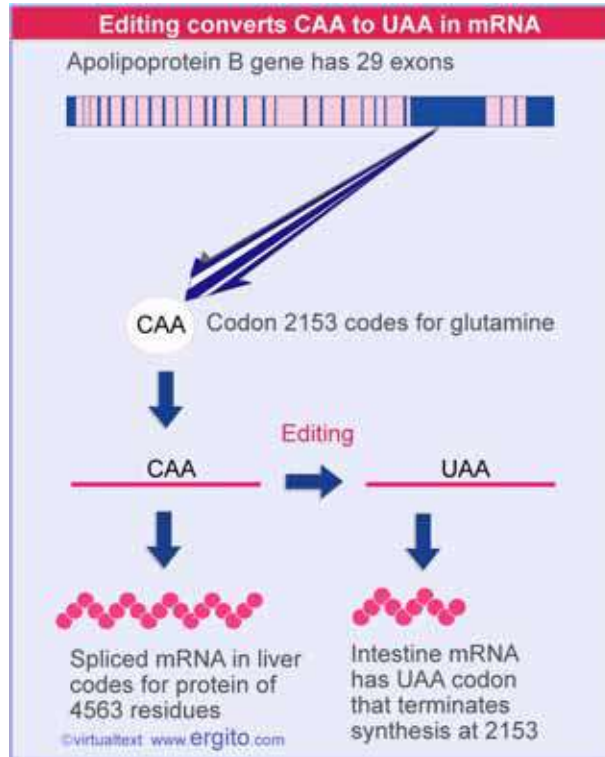

A prime axiom of molecular biology is that the sequence of an mRNA can only represent what is coded in the DNA. The central dogma envisaged a linear relationship in which a continuous sequence of DNA is transcribed into a sequence of mRNA that is in turn directly translated into protein. The occurrence of interrupted genes and the removal of introns by RNA splicing introduces an additional step into the process of gene expression: the coding sequences (exons) in DNA must be reconnected in RNA. But the process remains one of information transfer, in which the actual coding sequence in DNA remains unchanged.

Changes in the information coded by DNA occur in some exceptional circumstances, most notably in the generation of new sequences coding for immunoglobulins in mammals and birds. These changes occur specifically in the somatic cells (B lymphocytes) in which immunoglobulins are synthesized (see *Molecular Biology 5.25 Immune diversity*). New information is generated in the DNA of an individual during the process of reconstructing an immunoglobulin gene; and information coded in the DNA is changed by somatic mutation. The information in DNA continues to be faithfully transcribed into RNA.

**RNA editing** is a process in which *information changes at the level of mRNA*. It is revealed by situations in which the coding sequence in an RNA differs from the sequence of DNA from which it was transcribed. RNA editing occurs in two different situations, with different causes. In mammalian cells there are cases in which a substitution occurs in an individual base in mRNA, causing a change in the sequence of the protein that is coded. In trypanosome mitochondria, more widespread changes occur in transcripts of several genes, when bases are systematically added or deleted.

**Figure 26.17** summarizes the sequences of the apolipoprotein-B gene and mRNA in mammalian intestine and liver. The genome contains a single (interrupted) gene whose sequence is identical in all tissues, with a coding region of 4563 codons. This gene is transcribed into an mRNA that is translated into a protein of 512 kD representing the full coding sequence in the liver.

**Figure 26.17** The sequence of the apo-B gene is the same in intestine and liver, but the sequence of the mRNA is modified by a base change that creates a termination codon in intestine.

A shorter form of the protein, ~250 kD, is synthesized in intestine. This protein consists of the N-terminal half of the full-length protein. It is translated from an mRNA whose sequence is identical with that of liver except for a change from C to U at codon 2153. This substitution changes the codon CAA for glutamine into the ochre codon UAA for termination (759).

What is responsible for this substitution? No alternative gene or exon is available in the genome to code for the new sequence, and no change in the pattern of splicing can be discovered. We are forced to conclude that a change has been made directly in the sequence of the transcript.

Another example is provided by glutamate receptors in rat brain. Editing at one position changes a glutamine codon in DNA into a codon for arginine in RNA; the change affects the conductivity of the channel and therefore has an important effect on controlling ion flow through the neurotransmitter. At another position in the receptor, an arginine codon is converted to a glycine codon (760).

The editing event in apo-B causes C<sub>2153</sub> to be changed to U; both changes in the glutamate receptor are from A to I (inosine). These events are *deaminations* in which the amino group on the nucleotide ring is removed. Such events are catalyzed by enzymes called cytosine and adenosine deaminases, respectively. This type of editing appears to occur largely in the nervous system. There are 16 (potential) targets for cytosine deaminase in *D. melanogaster*, and all are genes involved in neurotransmission. In many cases, the editing event changes an amino acid at a

functionally important position in the protein.

What controls the specificity of an editing reaction? Enzymes that undertake deamination as such often have broad specificity – for example, the best characterized adenosine deaminase acts on any A residue in a duplex RNA region. Editing enzymes are related to the general deaminases, but have other regions or additional subunits that control their specificity. In the case of apoB editing, the catalytic subunit of an editing complex is related to bacterial cytidine deaminase, but has an additional RNA-binding region that helps to recognize the specific target site for editing. A special adenosine deaminase enzyme recognizes the target sites in the glutamate receptor RNA, and similar events occur in a serotonin receptor RNA (762).

The complex may recognize a particular region of secondary structure in a manner analogous to tRNA-modifying enzymes or could directly recognize a nucleotide sequence. The development of an *in vitro* system for the apo-B editing event suggests that a relatively small sequence (~26 bases) surrounding the editing site provides a sufficient target. **Figure 26.18** shows that in the case of the GluR-B RNA, a base-paired region that is necessary for recognition of the target site is formed between the edited region in the exon and a complementary sequence in the downstream intron. A pattern of mispairing within the duplex region is necessary for specific recognition. So different editing systems may have different types of requirement for sequence specificity in their substrates (761).

**Figure 26.18** Editing of mRNA occurs when a deaminase acts on an adenine in an imperfectly paired RNA duplex region.

**CATALYTIC RNA****5.26.11 RNA editing can be directed by guide RNAs****Key Terms**

A **guide RNA** is a small RNA whose sequence is complementary to the sequence of an RNA that has been edited. It is used as a template for changing the sequence of the pre-edited RNA by inserting or deleting nucleotides.

**Key Concepts**

- Extensive RNA editing in trypanosome mitochondria occurs by insertions or deletions of uridine.
- The substrate RNA base pairs with a guide RNA on both sides of the region to be edited.
- The guide RNA provides the template for addition (or less often deletion) of uridines.
- Editing is catalyzed by a complex of endonuclease, terminal uridylyltransferase activity, and RNA ligase.

Another type of editing is revealed by dramatic changes in sequence in the products of several genes of trypanosome mitochondria. In the first case to be discovered, the sequence of the cytochrome oxidase subunit II protein has a frameshift relative to the sequence of the *coxII* gene. The sequences of the gene and protein given in **Figure 26.19** are conserved in several trypanosome species. How does this gene function?

**Figure 26.19** The mRNA for the trypanosome *coxII* gene has a frameshift relative to the DNA; the correct reading frame is created by the insertion of 4 uridines.

The *coxII* mRNA has an insert of an additional four nucleotides (all uridines) around the site of frameshift (see *Great Experiments 4.7 RNA editing*). The insertion restores the proper reading frame; it inserts an extra amino acid and changes the amino acids on either side. No second gene with this sequence can be discovered, and we are forced to conclude that the extra bases are inserted during or after transcription (764). A similar discrepancy between mRNA and genomic sequences is found in genes of the SV5 and measles paramyxoviruses, in these cases involving the addition of G

residues in the mRNA.

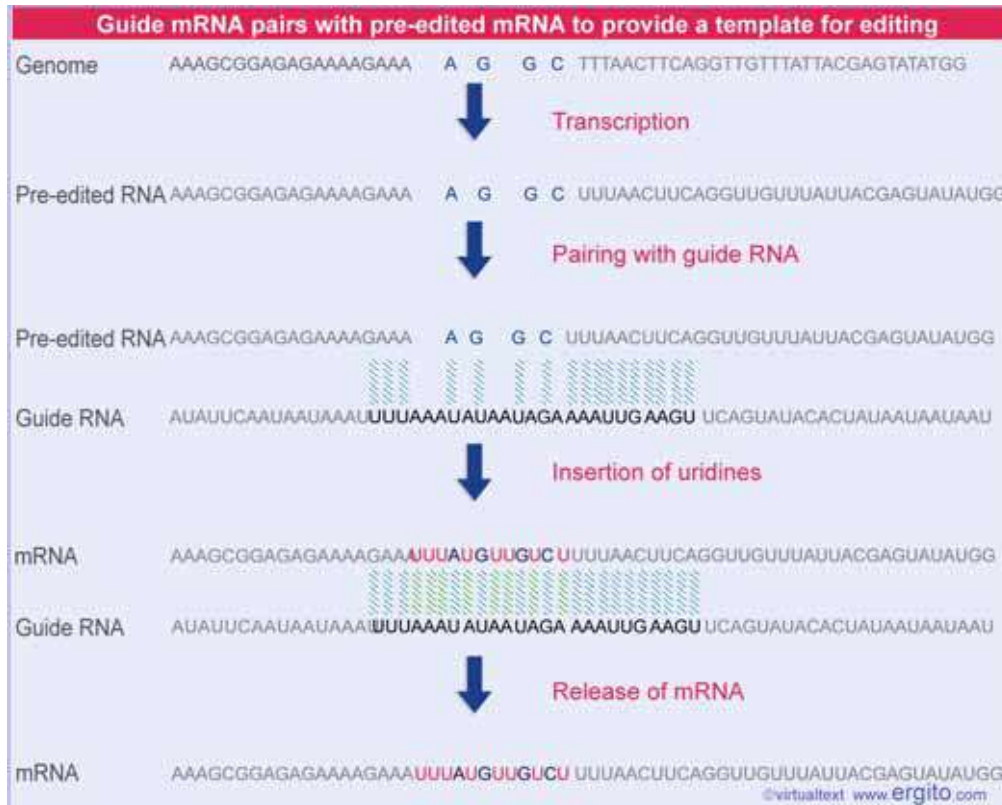

Similar editing of RNA sequences occurs for other genes, and includes deletions as well as additions of uridine. The extraordinary case of the *coxIII* gene of *T. brucei* is summarized in **Figure 26.20**.

**Figure 26.20** Part of the mRNA sequence of *T. brucei* *coxIII* shows many uridines that are not coded in the DNA (shown in red) or that are removed from the RNA (shown as T).

*More than half of the residues in the mRNA consist of uridines that are not coded in the gene.* Comparison between the genomic DNA and the mRNA shows that no stretch longer than 7 nucleotides is represented in the mRNA without alteration; and runs of uridine up to 7 bases long are inserted (1277).

What provides the information for the specific insertion of uridines? A **guide RNA** contains a sequence that is complementary to the correctly edited mRNA. **Figure 26.21** shows a model for its action in the cytochrome *b* gene of *Leishmania* (1280).

**Figure 26.21** Pre-edited RNA base pairs with a guide RNA on both sides of the region to be edited. The guide RNA provides a template for the insertion of uridines. The mRNA produced by the insertions is complementary to the guide RNA.

The sequence at the top shows the original transcript, or pre-edited RNA. Gaps show where bases will be inserted in the editing process. 8 uridines must be inserted into this region to create the valid mRNA sequence.

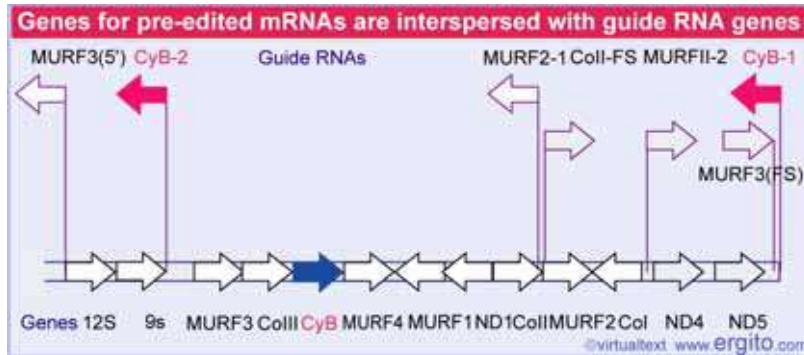

The guide RNA is complementary to the mRNA for a significant distance including and surrounding the edited region. Typically the complementarity is more extensive on the 3' side of the edited region and is rather short on the 5' side. Pairing between the guide RNA and the pre-edited RNA leaves gaps where unpaired A residues in the guide RNA do not find complements in the pre-edited RNA. The guide RNA provides a template that allows the missing U residues to be inserted at these positions. When the reaction is completed, the guide RNA separates from the mRNA, which becomes available for translation.

Specification of the final edited sequence can be quite complex; in this example, a lengthy stretch of the transcript is edited by the insertion altogether of 39 U residues, and this appears to require two guide RNAs that act at adjacent sites. The first guide RNA pairs at the 3'—most site, and the edited sequence then becomes a substrate for further editing by the next guide RNA.

The guide RNAs are encoded as independent transcription units. **Figure 26.22** shows a map of the relevant region of the *Leishmania* mitochondrial DNA. It includes the "gene" for cytochrome *b*, which codes for the pre-edited sequence, and two regions

that specify guide RNAs. Genes for the major coding regions and for their guide RNAs are interspersed.

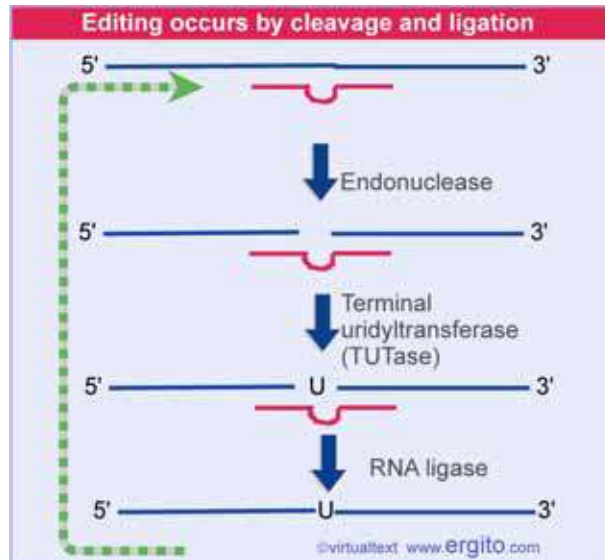

**Figure 26.22** The *Leishmania* genome contains genes coding for pre-edited RNAs interspersed with units that code for the guide RNAs required to generate the correct mRNA sequences. Some genes have multiple guide RNAs.

In principle, a mutation in either the "gene" or one of its guide RNAs could change the primary sequence of the mRNA, and thus of the protein. By genetic criteria, each of these units could be considered to comprise part of the "gene." Since the units are independently expressed, they should of course complement in *trans*. If mutations were available, we should therefore find that 3 complementation groups were needed to code for the primary sequence of a single protein.

The characterization of intermediates that are partially edited suggests that the reaction proceeds along the pre-edited RNA in the 3'–5' direction. The guide RNA determines the specificity of uridine insertions by its pairing with the pre-edited RNA.

Editing of uridines is catalyzed by a 20S enzyme complex that contains an endonuclease, a terminal uridylyltransferase (TUTase), and an RNA ligase, as illustrated in **Figure 26.23** (2399). It binds the guide RNA and uses it to pair with the pre-edited mRNA. The substrate RNA is cleaved at a site that is (presumably) identified by the absence of pairing with the guide RNA, a uridine is inserted or deleted to base pair with the guide RNA, and then the substrate RNA is ligated. UTP provides the source for the uridyl residue. It is added by the TUTase activity; it is not clear whether this activity, or a separate exonuclease, is responsible for deletion. [At one time it was thought that a stretch of U residues at the end of guide RNA might provide the source for added U residues or a sink for deleted residues, but transfer of U residues to guide RNAs appears to be an aberrant reaction that is not responsible for editing (767).]

**Figure 26.23** Addition or deletion of U residues occurs by cleavage of the RNA, removal or addition of the U, and ligation of the ends. The reactions are catalyzed by a complex of enzymes under the direction of guide RNA.

The structures of partially edited molecules suggest that the U residues are added one at a time, and not in groups. It is possible that the reaction proceeds through successive cycles in which U residues are added, tested for complementarity with the guide RNA, retained if acceptable and removed if not, so that the construction of the correct edited sequence occurs gradually. We do not know whether the same types of reaction are involved in editing reactions that add C residues.

**CATALYTIC RNA****5.26.12 Protein splicing is autocatalytic**

---

**Key Terms**

**Protein splicing** is the autocatalytic process by which an intein is removed from a protein and the exteins on either side become connected by a standard peptide bond.

**Extein** sequences remain in the mature protein that is produced by processing a precursor via protein splicing.

An **intein** is the part that is removed from a protein that is processed by protein splicing.

**Key Concepts**

- An intein has the ability to catalyze its own removal from a protein in such a way that the flanking exteins are connected.
- Protein splicing is catalyzed by the intein.
- Most inteins have two independent activities: protein splicing and a homing endonuclease.

---

**Protein splicing** has the same effect as RNA splicing: a sequence that is represented within the gene fails to be represented in the protein. The parts of the protein are named by analogy with RNA splicing: **exteins** are the sequences that are represented in the mature protein, and **inteins** are the sequences that are removed. The mechanism of removing the intein is completely different from RNA splicing. **Figure 26.24** shows that the gene is translated into a protein precursor that contains the intein, and then the intein is excised from the protein. About 100 examples of protein splicing are known, spread through all classes of organisms. The typical gene whose product undergoes protein splicing has a single intein.

**Figure 26.24** In protein splicing the exteins are connected by removing the intein from the protein.

The first intein was discovered in an archaeal DNA polymerase gene in the form of an intervening sequence in the gene that does not conform to the rules for introns (2327). Then it was demonstrated that the purified protein can splice this sequence out of itself in an autocatalytic reaction (2328). The reaction does not require input of energy and occurs through the series of bond rearrangements shown in **Figure 26.25**. It is a function of the intein, although its efficiency can be influenced by the exteins.

**Figure 26.25** Bonds are rearranged through a series of transesterifications involving the -OH groups of serine or proline or the -SH group of cysteine until finally the exons are connected by a peptide bond and the intein is released with a circularized C-terminus.

The first reaction is an attack by an -OH or -SH side chain of the first amino acid in the intein on the peptide bond that connects it to the first extein. This transfers the extein from the amino-terminal group of the intein to an N-O or N-S acyl connection. Then this bond is attacked by the -OH or -SH side chain of the first amino acid in the second extein. The result is to transfer extein1 to the side chain of the amino-terminal amino acid of extein2. Finally, the C-terminal asparagine of the intein cyclizes, and the terminal NH of extein2 attacks the acyl bond to replace it with a conventional peptide bond. Each of these reactions can occur spontaneously at very low rates, but their occurrence in a coordinate manner rapidly enough to achieve protein splicing requires catalysis by the intein (for review see 2267).

Inteins have characteristic features. They are found as in-frame insertions into coding sequences. They can be recognized as such because of the existence of homologous genes that lack the insertion. They have an N-terminal serine or cysteine (to provide the -XH side chain) and a C-terminal asparagine. A typical intein has a sequence of

~150 amino acids at the N-terminal end and ~50 amino acids at the C-terminal end that are involved in catalyzing the protein splicing reaction. The sequence in the center of the intein can have other functions.

An extraordinary feature of many inteins is that they have homing endonuclease activity. A homing endonuclease cleaves a target DNA to create a site into which the DNA sequence coding for the intein can be inserted (see **Figure 26.11** in *Molecular Biology 5.26.5 Some group I introns code for endonucleases that sponsor mobility*). The protein splicing and homing endonuclease activities of an intein are independent (2329).

We do not really understand the connection between the presence of both these activities in an intein, but two types of model have been suggested. One is to suppose that there was originally some sort of connection between the activities, but that they have since become independent and some inteins have lost the homing endonuclease. The other is to suppose that inteins may have originated as protein splicing units, most of which (for unknown reasons) were subsequently invaded by homing endonucleases. This is consistent with the fact that homing endonucleases appear to have invaded other types of units also, including most notably group I introns.

**CATALYTIC RNA****5.26.13 Summary**

---

Self-splicing is a property of two groups of introns, which are widely dispersed in lower eukaryotes, prokaryotic systems, and mitochondria. The information necessary for the reaction resides in the intron sequence (although the reaction is actually assisted by proteins *in vivo*). For both group I and group II introns, the reaction requires formation of a specific secondary/tertiary structure involving short consensus sequences. Group I intron RNA creates a structure in which the substrate sequence is held by the IGS region of the intron, and other conserved sequences generate a guanine nucleotide binding site. It occurs by a transesterification involving a guanosine residue as cofactor. No input of energy is required. The guanosine breaks the bond at the 5' exon-intron junction and becomes linked to the intron; the hydroxyl at the free end of the exon then attacks the 3' exon-intron junction. The intron cyclizes and loses the guanosine and the terminal 15 bases. A series of related reactions can be catalyzed via attacks by the terminal G-OH residue of the intron on internal phosphodiester bonds. By providing appropriate substrates, it has been possible to engineer ribozymes that perform a variety of catalytic reactions, including nucleotidyl transferase activities.

Some group I and some group II mitochondrial introns have open reading frames. The proteins coded by group I introns are endonucleases that make double-stranded cleavages in target sites in DNA; the cleavage initiates a gene conversion process in which the sequence of the intron itself is copied into the target site. The proteins coded by group II introns include an endonuclease activity that initiates the transposition process, and a reverse transcriptase that enables an RNA copy of the intron to be copied into the target site. These types of introns probably originated by insertion events. The proteins coded by both groups of introns may include maturase activities that assist splicing of the intron by stabilizing the formation of the secondary/tertiary structure of the active site.

Catalytic reactions are undertaken by the RNA component of the RNAase P ribonucleoprotein. Virusoid RNAs can undertake self-cleavage at a "hammerhead" structure. Hammerhead structures can form between a substrate RNA and a ribozyme RNA, allowing cleavage to be directed at highly specific sequences. These reactions support the view that RNA can form specific active sites that have catalytic activity.

RNA editing changes the sequence of an RNA after or during its transcription. The changes are required to create a meaningful coding sequence. Substitutions of individual bases occur in mammalian systems; they take the form of deaminations in which C is converted to U, or A is converted to I. A catalytic subunit related to cytidine or adenosine deaminase functions as part of a larger complex that has specificity for a particular target sequence.

Additions and deletions (most usually of uridine) occur in trypanosome mitochondria and in paramyxoviruses. Extensive editing reactions occur in trypanosomes in which as many as half of the bases in an mRNA are derived from editing. The editing reaction uses a template consisting of a guide RNA that is complementary to the mRNA sequence. The reaction is catalyzed by an enzyme complex that includes an

endonuclease, terminal uridyltransferase, and RNA ligase, using free nucleotides as the source for additions, or releasing cleaved nucleotides following deletion.

Protein splicing is an autocatalytic reaction that occurs by bond transfer reactions and input of energy is not required. The intein catalyzes its own splicing out of the flanking exteins. Many inteins have a homing endonuclease activity that is independent of the protein splicing activity.

## PROTEIN TRAFFICKING

### 6.27.1 Introduction

---

#### Key Terms

A **sorting signal (targeting signal)** is the part of a protein that allows it to be incorporated into a nascent transport vesicle. The vesicle moves the protein from one compartment to another. Sorting signals consist of either a short sequence of amino acids or a covalent modification.

---

A great variety of molecules move out of and into the cell. At one extreme of the size range, proteins may be secreted from the cell into the extracellular fluid or may be internalized from the cell surface. At the other extreme, ions such as  $K^+$ ,  $Na^+$ , and  $Ca^{2+}$  may be pumped out of or into the cell. In this chapter, we are concerned with the processes by which proteins are physically transported through membranous systems to the plasma membrane or other organelles, or from the cell surface to organelles within the cell. In *Molecular Biology 6.28 Signal transduction* we discuss the pathways by which an interaction at the surface can trigger internal pathways.

Proteins enter the pathway that leads to secretion by co-translational transfer to the membranes of the endoplasmic reticulum (for introduction see *Molecular Biology Supplement 32.6 ER and Golgi*). They are then transferred to the Golgi apparatus, where they are *sorted* according to their final intended destination. **Figure 27.1** summarizes the routes by which proteins are carried forward or diverted to other organelles. Their destinations are determined by specific **sorting signals**, which take the form of short sequences of amino acids or covalent modifications that are made to the protein.

**Figure 27.1** Proteins that enter the endoplasmic reticulum are transported to the Golgi and towards the plasma membrane. Specific signals cause proteins to be returned from the Golgi to the ER, to be retained in the Golgi, to be retained in the plasma membrane, or to be transported to endosomes and lysosomes. Proteins may be transported between the plasma membrane and endosomes.

The transport machinery consists of small membranous vesicles. A soluble protein is carried within the lumen of a vesicle, and an integral membrane protein is carried within its membrane. **Figure 27.2** illustrates the nature of the budding and fusion events by which the vesicles move between adjacent compartments. A vesicle buds off from a donor surface and then fuses with a target surface. Its proteins are released into the lumen or into the membrane of the target compartment, depending on their nature, and must be loaded into new vesicles for transport to the next compartment. The series of events is repeated at each transition between membrane surfaces, for example, during passage from the ER to the Golgi, or between cisternae of the Golgi stacks.

**Figure 27.2** Vesicles are released when they bud from a donor compartment and are surrounded by coat proteins (left). During fusion, the coated vesicle binds to a target compartment, is uncoated, and fuses with the target membrane, releasing its contents (right).

Once a protein enters a membranous environment, it remains in the membrane until it reaches its final destination. A membrane protein that enters the endoplasmic reticulum is inserted into the membrane with the appropriate orientation (N-terminal luminal, C-terminal cytosolic for group I proteins, the reverse for group II proteins). The orientation is retained as it moves through the system. The process starts in the same way irrespective of whether the protein is destined to reside in the Golgi, lysosome, or plasma membrane. In each case, it is transported in membrane vesicles along the secretory pathway to the appropriate destination, where some structural feature of the protein is recognized and it is permanently secured (or secreted from the cell).

Two important changes occur to a protein in the endoplasmic reticulum: it becomes folded into its proper conformation; and it is modified by glycosylation.

A protein is translocated into the ER in unfolded form. Folding occurs as the protein enters the lumen; probably a series of domains each folds independently as the protein passes through the membrane. Folding of a 50 kD protein is complete in <3-4 minutes, compared with the ~1 minute required to synthesize the chain (see *Molecular Biology Supplement 32.4 Protein folding*).

Folding in the ER is associated with modification and is assisted by accessory proteins. Addition of carbohydrate may be required for correct folding; in fact, this may be an important function of the modification. Reshuffling of disulfide bonds by the enzyme PDI (protein disulfide isomerase) may be involved. Association with chaperones in the ER may be necessary to recognize the partially folded forms of proteins as they emerge from transport through the membrane, and to assist them in acquiring their proper conformation. Some or all of these activities could be exercised by a complex of enzymes as a protein enters the ER; that is, the necessary functions all could associate with the protein as it translocates through the membrane. Calculations of the spontaneous rates of folding and oligomerization suggest that these accessory activities are needed to catalyze the process in order it to enable it to occur rapidly enough in the cell (for review see 286).

Multimeric glycoproteins usually oligomerize in the ER. In fact, oligomerization may be necessary for further transport. Oligomers are rapidly transported from the ER to the Golgi, but unassembled subunits or misassembled proteins are held back. Misfolded proteins are often associated with ER-specific chaperones. In due course, they are removed by degradation. So a protein is allowed to move forward into the Golgi only if it has been properly folded previously in the ER (for review see 283).

## PROTEIN TRAFFICKING

### 6.27.2 Oligosaccharides are added to proteins in the ER and Golgi

---

#### Key Terms

**Dolichol** is a lipid that consists of a long chain of isoprenoid units and is present in the membrane of the rough endoplasmic reticulum. It is part of the precursor in the synthesis of N-linked oligosaccharides. An oligosaccharide is assembled onto dolichol via a pyrophosphoryl linkage, then transferred to particular asparagine residues of a nascent polypeptide.

A **high mannose oligosaccharide** is an N-linked oligosaccharide that contains N-acetylglucosamine linked only to mannose residues. It is covalently added to transmembrane proteins in the rough endoplasmic reticulum and is trimmed and modified in the Golgi apparatus.

A **complex oligosaccharide** is an N-linked oligosaccharide that is made during transit through the Golgi apparatus. Mannose residues are trimmed from the high mannose precursor in the rough endoplasmic reticulum and cis Golgi, and other sugars are added by enzymes in the medial and trans Golgi cisternae to form a complex oligosaccharide.

The **inner core** is an intermediate in the synthesis of N-linked oligosaccharides. It is produced upon the removal of mannose residues from a high mannose oligosaccharide in the cis Golgi and is resistant to degradation by endoglycosidase H.

The **terminal region** is the part of an N-linked oligosaccharide that consists of all the sugar residues added subsequent to formation of the inner core.

#### Key Concepts

- A major function of the ER and Golgi is to glycosylate proteins as they pass through the system.
- N-linked oligosaccharides are initiated by transferring the saccharide from the lipid dolichol to an asparagine of the target protein in the ER.
- Sugars are trimmed in the ER to give a high mannose oligosaccharide.
- A complex oligosaccharide is generated in those cases in which further residues are added in the Golgi.

---

Virtually all proteins that pass through the secretory apparatus are glycosylated. Glycoproteins are generated by the addition of oligosaccharide groups either to the NH<sub>2</sub> group of asparagine (N-linked glycosylation) or to the OH group of serine, threonine, or hydroxylysine (O-linked glycosylation). N-linked glycosylation is initiated in the endoplasmic reticulum and completed in the Golgi; O-linked glycosylation occurs in the Golgi alone. The stages of N-glycosylation are illustrated in the next three figures.

The addition of all N-linked oligosaccharides starts in the ER by a common route, as illustrated in **Figure 27.3**. An oligosaccharide containing 2 N-acetyl glucosamine, 9 mannose, and 3 glucose residues is formed on a special lipid, **dolichol**. Dolichol is a highly hydrophobic lipid that resides within the ER membrane, with its active group facing the lumen. The oligosaccharide is constructed by adding sugar residues individually; it is linked to dolichol by a pyrophosphate group, and is transferred as a unit to a target protein by a membrane-bound glycosyl transferase enzyme whose active site is exposed in the lumen of the endoplasmic reticulum.

**Figure 27.3** An oligosaccharide is formed on dolichol and transferred by glycosyl transferase to asparagine of a target protein.

The acceptor group is an asparagine residue, located within the sequence Asn-X-Ser or Asn-X-Thr (where X is any amino acid except proline). It is recognized as soon as the target sequence is exposed in the lumen, when the nascent protein crosses the ER membrane.

Some trimming of the oligosaccharide occurs in the ER, after which a nascent glycoprotein is handed over to the Golgi. The oligosaccharide structures generated during transport through the ER and Golgi fall into two classes, determined by the fate of the mannose residues. Mannose residues are added only in the ER, although they can be trimmed subsequently.

- **High mannose oligosaccharides** are generated by trimming the sugar residues in the ER. **Figure 27.4** shows that almost immediately following addition of the oligosaccharide, the 3 glucose residues are removed by the enzymes glucosidases I and II. For proteins that reside in the ER, a mannosidase removes some of the mannose residues to generate the final structure of the oligosaccharide. The ER mannosidase attacks the first mannose quickly, and the next 3 more slowly; the total number of mannose residues that is removed varies with the individual substrate protein.
- **Complex oligosaccharides** result from additional trimming and further additions carried out in the Golgi. Golgi modifications occur in the fixed order illustrated in **Figure 27.5**. The first step is further trimming of mannose residues by Golgi mannosidase I. Then a single sugar residue is added by the enzyme N-acetyl-glucosamine transferase. Then Golgi mannosidase II removes further mannose residues. This generates a structure called the **inner core**, consisting of the sequence NAc-Glc-NAc-Glc-Man<sub>3</sub>. At this point, the oligosaccharide becomes resistant to degradation by the enzyme endoglycosidase H (Endo H). *Susceptibility to Endo H is therefore used as an operational test to determine when a glycoprotein has left the ER.*

**Figure 27.4** Sugars are removed in the ER in a fixed order, initially comprising 3 glucose and 1-4 mannose residues. This trimming generates a high mannose oligosaccharide.

**Figure 27.5** Processing for a complex oligosaccharide occurs in the Golgi and trims the original preformed unit to the inner core consisting of 2 N-acetyl-glucosamine and 3 mannose residues. Then further sugars can be added, in the order in which the transfer enzymes are encountered, to generate a terminal region containing N-acetyl-glucosamine, galactose, and sialic acid.

Additions to the inner core generate the **terminal region**. The residues that can be added to a complex oligosaccharide include N-acetyl-glucosamine, galactose, and sialic acid (N-acetyl-neuraminic acid). The pathway for processing and glycosylation is highly ordered, and the two types of reaction are interspersed in it. Addition of one sugar residue may be needed for removal of another, as in the example of the addition of N-acetyl-glucosamine before the final mannose residues are removed.

We do not know what determines how each protein undergoes its specific pattern of processing and glycosylation. We assume that the necessary information resides in the structure of the polypeptide chain; it cannot lie in the oligosaccharide, since all proteins subject to N-linked glycosylation start the pathway by addition of the same (preformed) oligosaccharide.

**PROTEIN TRAFFICKING****6.27.3 The Golgi stacks are polarized****Key Concepts**

- The Golgi stacks change in lipid and protein constitution proceeding from the *cis*-face near the ER to the *trans*-face near the plasma membrane.

The individual cisternae of the Golgi are organized into a series of *stacks*, somewhat resembling a pile of plates. A typical stack consists of 4-8 flattened cisternae. **Figure 27.6** shows an example. A major feature of the Golgi apparatus is its *polarity*. The *cis* side faces the endoplasmic reticulum; the *trans* side in a secretory cell faces the plasma membrane. The Golgi consists of compartments, which are named *cis*, *medial*, *trans*, and *TGN* (*trans-Golgi network*), proceeding from the *cis* to the *trans* face. Proteins enter a Golgi stack at the *cis* face and are modified during their transport through the successive cisternae of the stack. When they reach the *trans* face, they are directed to their destination.

**Figure 27.6** The Golgi apparatus consists of a series of individual membrane stacks. Photograph kindly provided by Alain Rambourg.

Membrane structure changes across the Golgi stack. The main difference is an increase in the content of cholesterol proceeding from *cis* to *trans*. As a result, fractionation of Golgi preparations generates a gradient in which the densest fractions represent the *cis* cisternae, and the lightest fractions represent the *trans* cisternae. The positions of enzymes on the gradient, and *in situ* immunochemistry with antibodies against individual enzymes, suggest that certain enzymes are differentially distributed proceeding from *cis* to *trans*. The difference between the *cis* and *trans* faces of the Golgi is clear, but it is not clear how the concept of compartments relates to individual cisternae; there may rather be a continuous series of changes proceeding through the cisternae.

Nascent proteins encounter the modifying enzymes as they are transported through the Golgi stack. **Figure 27.7** illustrates the order in which the enzymes function. This may be partly determined by the fact that the modification introduced by one enzyme is needed to provide the substrate for the next, and partly by the availability of the

enzymes proceeding through the cisternae.

**Figure 27.7** A Golgi stack consists of a series of cisternae, organized with *cis* to *trans* polarity. Protein modifications occur in order as a protein moves from the *cis* face to the *trans* face.

The addition of a complex oligosaccharide can change the properties of a protein significantly. Glycoproteins often have a mass with a significant proportion of oligosaccharide. What is the significance of these extensive glycosylations? In some cases, the saccharide moieties play a structural role, for example, in the behavior of surface proteins that are involved in cell adhesion. Another possible role could be in promoting folding into a particular conformation. One modification – the addition of mannose-6-phosphate – confers a targeting signal.

## PROTEIN TRAFFICKING

### 6.27.4 Coated vesicles transport both exported and imported proteins

---

#### Key Terms

**Exocytosis** is the process whereby cells secrete cargo molecules that are originally synthesized at the endoplasmic reticulum. Exocytosis occurs by the fusion of secretory vesicles with the plasma membrane.

**Endocytosis** is the process whereby cells internalize small molecules and particles from their surroundings. There are several forms of endocytosis, all of which involve the formation of a membranous vesicle from the plasma membrane.

**Coated vesicles** are formed by the pinching off of a coated pit from a membrane. The membrane of a coated vesicle has on its cytoplasmic surface proteins such as clathrin, COPI or COPII.

**Cargo** describes any macromolecule (such as RNA, soluble or membrane protein, lipid) that is transported from one compartment to another. Cargo may contain sequences or modifications that specify their destination. Some cargo molecules are carried in transport vesicles, but others (such as those that move between the nucleus and cytosol) are not.

**Anterograde transport** is the direction of membrane transport specified by the movement of macromolecules through the secretory pathway (from the rough endoplasmic reticulum, through the Golgi complex, and to their final destinations). It is also called forward transport.

**Retrograde transport** is the movement of material from the Golgi apparatus (or from the plasma membrane) to the endoplasmic reticulum.

#### Key Concepts

- Protein transport through the ER-Golgi system occurs in coated vesicles.
- Secreted proteins move in the forward, anterograde direction toward the plasma membrane.
- There is also movement within the system in the reverse, retrograde direction.
- Proteins that are imported through the plasma membrane also are incorporated in coated vesicles.
- Coated vesicles bud from a donor membrane surface and fuse with a target membrane surface.

---

Secreted and transmembrane proteins start on the route to localization when they are translocated into the endoplasmic reticulum during synthesis. Transport from the ER, through the Golgi, to the plasma membrane occurs in vesicles. A protein is incorporated into a vesicle at one membrane surface, and is released from the vesicle at the next membrane surface. Progress through the system requires a series of such

transport events. A protein changes its state of glycosylation as it passes through the Golgi from *cis* to *trans* compartments (for review see 277; 281).

Vesicles are used to transport proteins both out of the cell and into the cell. The secretion of proteins is called **exocytosis**; internalization of proteins is called **endocytosis**. The pathways for vesicle movement are pictured in **Figure 27.8**. The cycle for each type of vesicle is similar, whether they are involved in export or import of proteins: *budding from the donor membrane is succeeded by fusion with the target membrane*.

**Figure 27.8** Proteins are transported in coated vesicles. Constitutive (bulk flow) transport from ER through the Golgi takes place by COP-coated vesicles. Clathrin-coated vesicles are used for both regulated exocytosis and endocytosis.

Vesicles involved in transporting proteins have a protein layer surrounding their membranes, and for this reason are called **coated vesicles**. Examples are shown in the electron micrograph of **Figure 27.9**. Different types of vesicles are distinguished by the protein coats. The coat serves two purposes: it is involved with the processes of budding and fusion; and it enables the type of vesicle to be identified, so that it is directed to the appropriate target membrane. The coat may also play a role in the selection of proteins to be transported.

**Figure 27.9** Coated vesicles are released from the *trans* face of the Golgi. The diameter of a vesicle is ~70 nm. Photograph kindly provided by Lelio Orci.

One of the most remarkable features of protein trafficking is the conservation of the vesicular apparatus, including structural components of the vesicles, and proteins required for budding or fusion. Many of these functions have been identified through mutations of the *sec* genotype in *S. cerevisiae*, which are unable to export proteins through the ER-Golgi pathway (774). Many of the genes identified by *sec* mutants in yeast have direct counterparts in animal cells. In particular, the proteins involved in budding, fusion, and targeting in mammalian brain (where release of proteins from the cell provides the means of propagating nerve impulses) have homologues in the yeast secretory pathway (785).

The process of generating a vesicle requires a membrane bilayer to protrude a vesicle that eventually pinches off as a bud (see **Figure 27.2**). Such events require deformation of the membrane, as illustrated in **Figure 27.10**. Proteins concerned with this process are required specifically for budding, and become part of the coat.

**Figure 27.10** Vesicle formation results when coat proteins bind to a membrane, deform it, and ultimately surround a membrane vesicle that is pinched off.

*This is a static version of an interactive figure; see*

*<http://www.ergito.com/main.jsp?bcs=MBIO.6.27.4> to view properly.*

In the reverse reaction, fusion is a property of membrane surfaces. In order to fuse with a target membrane, a vesicle must be "uncoated" by removal of the protein layer. A coated vesicle recognizes its destination by a reaction between a protein in the vesicle membrane and a receptor in the target membrane.

A vesicle therefore follows a cycle in which it gains its coat, is released from a donor membrane, moves to the next membrane, becomes uncoated, and fuses with the target membrane. When a vesicle is generated, it carries proteins that were resident in (or associated with) the stretch of membrane that was pinched off. The interior of the

vesicle has the constitution of the lumen of the organelle from which it was generated. When the vesicle fuses with its target membrane, its components become part of that membrane or the lumen of the compartment. Proteins that are transported by vesicles (that is, which are not part of the structure of the vesicle itself) are called the **cargo**. Proteins must be sorted at each stage, when either they remain in the compartment or are incorporated into new vesicles and transported farther along the system.

The dynamic state of transport through the ER-Golgi system poses a dilemma. There is continuous movement of vesicles carrying proteins from the ER and through the Golgi. Movement in this direction is called *forward* or **anterograde transport**. It takes a typical protein ~20 minutes to pass through the system. A significant proportion of the membrane surface of the ER and Golgi is incorporated into vesicles that move to the plasma membrane. Such a flow of membrane should rapidly denude the Golgi apparatus and enormously enlarge the plasma membrane, yet both are stable in size. The net amount (and types) of lipid in each membrane must remain unperturbed in spite of vesicle movement.

The need to maintain the structure of the reticuloendothelial system suggests that there is a pathway for returning membrane segments from the Golgi to ER, so that there is no net flow of membrane. Movement in this direction is called **retrograde transport**. We do not yet understand the balance of forward and retrograde flow. One possibility is that some vesicles engaged in retrograde movement do not carry cargo, except for returning components to earlier parts of the system. Alternatively, reverse flow might occur by structures that have a high surface to volume ratio, such as tubules, which could thus return large amounts of material.

## PROTEIN TRAFFICKING

### 6.27.5 Different types of coated vesicles exist in each pathway

---

#### Key Terms

A **transition vesicle** is a small membrane-bounded compartment that mediates transport between organelles, especially the rough endoplasmic reticulum and Golgi complex. It is also known as a transport vesicle. COPI- and COPII-coated vesicles are transition vesicles.

A **COPI** coat consists of coatomer and ADP-ribosylation factor. COPI-coated vesicles are transport vesicles that bud from the cytoplasmic face of the Golgi complex and mediate retrograde transport from the Golgi complex to the endoplasmic reticulum. COPI-coated vesicles may also mediate transport between Golgi cisternae.

A **COPII** coat is made up of protein complexes comprising a GTPase (Sar1p) and two heterodimers (Sec 23/24 and Sec 13/31). COPII-coated vesicles are transport vesicles that bud from the cytoplasmic face of the rough endoplasmic reticulum and mediate anterograde transport to the Golgi apparatus.

**Constitutively secreted** macromolecules are transported to the plasma membrane or secreted at a relatively constant rate. They include lipids and soluble and membrane proteins that exit to the plasma membrane from the *trans*-Golgi network but are not secreted by regulated exocytosis.

A **secretory vesicle** is transport vesicle that carries newly synthesized proteins and lipids from the Golgi apparatus to the plasma membrane.

A **secretory granule** is a membrane-bounded compartment that contains molecules to be released from cells by regulated exocytosis (that is, the molecules are concentrated and stored in secretory granules, and are released only in response to a signal).

**Endocytic vesicles** are membranous particles that transport proteins through endocytosis; also known as clathrin-coated vesicles.

**Clathrin** proteins interact with adaptor proteins to form the coat on some of the vesicles that bud from the cytoplasmic face of the plasma membrane and the *trans*-Golgi network. Clathrin is composed of heavy and light chains that form triskelions, which then assemble into polyhedral curved lattices during the formation of clathrin-coated pits and vesicles.

A **clathrin-coated vesicle** is a membrane-bounded compartment that mediates endocytosis, formation of secretory granules at the *trans*-Golgi network, and transport from the *trans*-Golgi network to the endocytic pathway. In addition to clathrin, its major constituents include cargo and adaptor proteins.

The subunit of a clathrin coat is a **triskelion**. It is a three-legged structure; each leg is composed of a clathrin heavy chain and a clathrin light chain.

A **coated pit** is an infolding of membrane formed during clathrin-mediated endocytosis. It is pinched off to form a clathrin-coated vesicle.

---

**Adaptor** complexes bind to signals in the cytoplasmic tails of transmembrane cargo proteins and recruit clathrin molecules during the assembly of clathrin-coated pits. Different types of adaptor complexes function at different compartments. Each adaptor complex contains four different subunits.

**Adaptins** are the large subunits of the cytosolic adaptor protein complexes that mediate formation of clathrin-coated vesicles. There are several types of adaptin subunits.

**Coatomer** is the complex of coat proteins on COPI-coated vesicles. It consists of seven proteins.

### Key Concepts

- Clathrin-coated vesicles are used for endocytosis.
- The clathrin coat forms when triskelions form a lattice at a coated pit on the plasma membrane.
- The clathrin is joined to the membrane by an AP adaptor, which is a heterotetramer of adaptin subunits.
- Different types of AP adaptors are found in vesicles used in different locations.
- COPI coated vesicles have a coat consisting of a 7-component coatomer and are required for retrograde transport in the ER-Golgi system.
- COPII coated vesicles have a coat consisting of a different protein complex.
- Cargo proteins may be bound by components of the vesicle coat.

-----

Different groups of coated vesicles can be identified by the types of transport they undertake. In some cases, the vesicles can be distinguished by the biochemical components of their coats.

Newly synthesized proteins enter the ER and may be transported along the ER-Golgi system. This transport is undertaken by **transition vesicles**, and is common to all eukaryotic cells. Two different types of transition vesicles have been identified on the basis of their coats.

- The vesicles that were originally identified in transport between Golgi cisternae are now called **COPI**-coated vesicles. (COP is an acronym for coat protein.) They are involved in retrograde transport. It is an open question whether they also undertake anterograde transport (776).
- Transition vesicles that proceed from the ER to the Golgi have a different coat, called **COPII**. Their major role appears to be forward transport (777).
- Some proteins are **constitutively secreted**, moving from the *trans*-Golgi to the plasma membrane. The vesicles that undertake this process have not been characterized biochemically.

The export of some proteins is regulated. These proteins are packaged into **secretory vesicles**. These vesicles provide a storage medium, and release their contents at the plasma membrane only following receipt of a particular signal (triggered, for example, by a hormone or  $\text{Ca}^{2+}$ ). This occurs in cells that are specialized to produce the appropriate proteins. Vesicles that form at the *trans*-face of the Golgi for use in the regulated pathway may fuse to form **secretory granules**. They may also transport their cargoes to endosomes. Secretory vesicles may form at endosomes to transport proteins to the plasma membrane. The most common route for regulated transport is probably via the endosome.

Proteins enter the cell by packaging into **endocytic vesicles**, which are released from the plasma membrane, and transport their contents toward the interior of the cell. The cargo is released when the endocytic vesicle fuses with the membrane of a target compartment such as an endosome.

What controls the specificity of the cargo carried by a vesicle? It is necessary to distinguish those proteins that should be transported out of the compartment from resident proteins that should remain there. This may be a function of the coat. The COPII coat can cause vesicles to bud when liposomes are mixed with the coat proteins. When the liposomes contain membrane proteins that are resident in the ER and other membrane proteins that are involved in targeting vesicles to the Golgi, only the latter class enter the vesicles. This suggests that specificity may be determined by a direct interaction with the coat proteins.

Endocytic and secretory vesicles have **clathrin** as the most prominent protein in their coats, and are therefore known as **clathrin-coated vesicles**. Their structure is known in some detail. The 180 kD chain of clathrin, together with a smaller chain of 35 kD, forms a polyhedral coat on the surface of the coated vesicle. The subunit of the coat consists of a **triskelion**, a three-pronged protein complex consisting of 3 light and 3 heavy chains. The triskelions form a lattice-like network on the surface of the coated vesicle, as revealed in the electron micrograph of **Figure 27.11** (for review see 2273). Endocytic vesicles form and are coated at invaginations of the plasma membrane that are called **coated pits**. Similar structures can be observed at the *trans* face of the Golgi, where vesicles destined for endosomes and secretory vesicles originate (for review see 287).

**Figure 27.11** Coated vesicles have a polyhedral lattice on the surface, created by triskelions of clathrin. Photograph kindly provided by Tom Kirchhausen.

The structure of clathrin-coated vesicles is shown schematically in **Figure 27.12**. The inner shell of the coat is made by proteins called **adaptors**, which bind both to clathrin and to integral membrane proteins of the vesicle. Different types of adaptors identify coated vesicles with different origins. There are several types of adaptors. Each is identified as AP (for adaptor complex) and a number. The most abundant adaptor is AP2, which is found at plasma membrane coated pits and identifies endocytic vesicles. These vesicles also contain an additional adaptor protein, AP180, which controls the size of the vesicle (1002). AP4 is associated with the *trans*-Golgi network. AP1 (founding member of the family) is found on vesicles that transport 6-mannose-phosphate receptors from the *trans*-Golgi network to the endosomes (for review see 998).

**Figure 27.12** Clathrin-coated vesicles have a coat consisting of two layers: the outer layer is formed by clathrin, and the inner layer is formed by adaptors, which lie between clathrin and the integral membrane proteins.

Each AP is a heterotetramer. The individual subunits are called **adaptins**. The  $\beta$  adaptin usually binds to the clathrin skeleton (999). It may also interact with dileucine (KK) sorting signals in the membrane proteins (1001). The  $\mu$  adaptins recognize tyrosine-based sorting signals for internalization (1000). The best characterized case is  $\mu$ 2, where phosphorylation of the subunit triggers a conformational change that enables it to recognize the target motif in a protein that is to be endocytosed (3333). The  $\alpha$  or  $\gamma$  adaptins (and presumably also the  $\delta$  and  $\epsilon$  adaptins) are involved in interactions with the membrane where the vesicles are formed, that is, they are responsible for assembly of the full AP complex at the appropriate membrane, after which a clathrin coat assembles. The adaptor is therefore responsible not only for connecting the membrane of the vesicle to the clathrin skeleton, but also for incorporating the cargo proteins into the vesicle.

A variant of AP1, which contains the adaptin  $\mu$ 1B instead of the more common  $\mu$ 1A, is found in polarized epithelial cells, where it is involved in transporting proteins from the apical to the basolateral surface (for review see 292). We may expect that more variants like this will be discovered.

The variety of adaptor complexes, their localization to specific transport pathways, and their roles in recognizing cargo proteins, all argue that they are a key component of the targeting system that ensures that proteins are taken to the right location.

How many types of cargo protein can be carried by a single endocytic vesicle? It is

not yet clear how many types of vesicle exist and what variety they display on the coats and in their cargo. We do know that some endocytic vesicles carry more than one type of cargo protein. Generally they are viewed as fairly specific carriers.

The coats of the COPI-coated transition vesicles have 7 major protein components, called COPs. They exist as a high molecular weight complex (~700 kD), called **coatomer**, which is the precursor to the COP coat. The  $\beta$ -COP component has some homology to  $\beta$ - and  $\beta'$ -adaptins. This suggests a similar organization in which  $\beta$ -COP plays a similar role to the  $\beta$ - and  $\beta'$ -adaptins in connecting an outer coat protein (an analog of clathrin) to the membrane proteins in the vesicle.

COPI-coated vesicles appear to be capable of performing both anterograde and retrograde transport. Such vesicles can be found carrying types of cargo that are transported in either direction; but any individual vesicles carries only anterograde or retrograde cargo, not both. Certain mutations in COP proteins block retrograde transport, which suggests that COPI vesicles provide the sole (or at least major) capacity for retrograde transport. We do not know how COPI vesicles moving in one direction are distinguished from those moving in the opposite direction: presumably there is some further component that has yet to be identified. Both directions of transport are probably supported through every level of the Golgi stack (779).

The coats of COPII-coated vesicles consist of the protein complexes Sec23p/Sec24p (found as a 400 kD tetramer), Sec13p/Sec31p (which form a 700 kD complex), and Sar1p (777). There is no homology between the Sec protein components and the components of COPI-coated vesicles. Sar1p is a small GTP-binding protein that regulates coat formation, and Sec23p is the GAP (GTPase-activating protein) that acts on Sar1p (see *Molecular Biology 6.27.7 Vesicles can bud and fuse with membranes*). Sec24p is responsible for recruiting the cargo (3332).

Another class of vesicle has the AP3 coat, whose subunits ( $\delta$ ,  $\beta$ 3,  $\mu$ 3,  $\sigma$ 3) are related to those of the AP1 and AP2 adaptor complexes. This coat complex is found on some synaptic vesicles, which form at endosomes. This type of coat complex is also found on vesicles that transport cargo from the Golgi to lysosomes, and on storage vesicles (780).

## PROTEIN TRAFFICKING

### 6.27.6 Cisternal progression occurs more slowly than vesicle movement

---

#### Key Terms

**Cisternal maturation** is one of two popular models for the mechanism of cargo transport through the Golgi stack. It is also called cisternal migration or cisternal progression. In this model, a new Golgi cisterna forms at the *cis* face, then moves forward in the stack as the enzyme content of the cisterna changes from *cis* to *medial* to *trans*. Enzymes that belong in earlier cisternae are retrieved by retrograde transport vesicles.

#### Key Concepts

- An alternative model for ER-Golgi protein transport is that the stacks are mobile structures, and that *cis*-stacks mature into *trans*-stacks by a series of changes in lipid and protein composition.

---

Are coated vesicles responsible for all transport between membranous systems? There are conflicting models for the nature of forward transport from the ER, through Golgi cisternae, and then from the TGN to the plasma membrane.

The vesicular model for anterograde transport proposes that the Golgi cisternae are fixed structures that gain and lose proteins by the processes of vesicle fusion and budding. The process starts when COPII coated vesicles bud at the ER and transport cargo to the Golgi. It is still not clear whether the vesicles that transport proteins along the Golgi are COPII or COPI coated. The natures of the coat(s) of vesicles that proceed from the Golgi to the plasma membrane remain unknown (for review see 288; 290; 291).

An alternative model for anterograde transport suggests that there is **cisternal maturation**. Instead of being fixed structures, cisternae move from the *cis* side of the Golgi to the *trans* side, maturing into more *trans*-like types of cisternae by changes in their protein constitution. Evidence for cisternal maturation has been provided by following the fate of a substrate protein that is too large to be incorporated into vesicles. Procollagen type I assembles into rod-like triple helices that are ~300 nm long in the lumen of the ER. These rods can be followed as they move into the *cis*-Golgi and through the Golgi to the TGN. Because they remain intact, and are too large to be incorporated into vesicles (COP-coated vesicles are 60-90 nm in diameter), this means that the membrane-bound compartment containing the rods must itself have moved from the *cis* to the *trans* side of the Golgi. This shows at least the plausibility of cisternal maturation, although it does not demonstrate whether normal cargo proteins are carried by vesicles or also move by cisternal maturation (781).

To take the model for cisternal maturation to its extremes, the *cis*-Golgi could be formed by fusion between COPII coated vesicles that bud from the ER; this process might also involve larger tubules. The *cis*-Golgi cisternae would move steadily

forward until they mature into the *trans*-Golgi cisternae. At the TGN, secretory vesicles might form by fragmenting into tubular structures, without requiring any special type of coat. Of course, as cisternae mature, proteins that belong to more *cis*-like cisternae must be retrieved; this would occur by COPI-mediated retrograde vesicular transport.

The outstanding question is the relative quantitative importance of cisternal maturation and vesicular transport for the anterograde direction. It is likely that cisternal progression is much slower than vesicle movement. This may mean that there is a two-track system, in which proteins can be transported rapidly in vesicles, but this will be accompanied by the much slower maturation of *cis*-stacks into *trans*-stacks (for review see 1221).

Whichever model applies, the TGN provides the sorting center for directing proteins on the anterograde route to the plasma membrane, endosomes, or other membrane surfaces (for review see 279).

**PROTEIN TRAFFICKING****6.27.7 Vesicles can bud and fuse with membranes**

---

**Key Terms**

**Dynamin** is a cytosolic protein that is a GTPase and is required for clathrin-mediated vesicle formation. Although the exact role of dynamin is debated, dynamin polymers are involved in the scission of clathrin-coated pits from membranes. A variant of dynamin functions in mitochondrial septation.

**Key Concepts**

- Budding and fusion are controlled by a monomeric G protein, ARF/Sar1p.
- Budding requires ARF/Sar1p to be bound to GTP so that its N-terminus is available to insert into the membrane.
- Fusion occurs when the coat is destabilized by the hydrolysis of GTP.

---

Budding and fusion are essentially reversible reactions. Budding occurs when coat proteins assemble on a patch of membrane, ultimately causing its release as an independent vesicle. Fusion occurs when the coat proteins are removed, exposing the membrane surface, which can then fuse with a target membrane. Whether the coat proteins assemble or disassemble is controlled by the state of a monomeric G protein (for introduction see *Molecular Biology Supplement 32.10 G proteins*).

Budding of COPI, clathrin-coated, and AP3 vesicles is initiated by ARF (ADP-ribosylation factor). Sar1p is a closely related protein that serves the same role for COPII-coated vesicles. ARF is myristoylated at the N-terminus and can insert spontaneously into lipid bilayers. ARF-GTP is the active form; ARF-GDP is inactive. Sar1p behaves similarly, except that its N-terminus functions without requiring modification. ARF/Sar1p's activity (and ability to recycle) is controlled by GTP hydrolysis. The type of guanine nucleotide controls the conformation, so that the N-terminus is exposed only when GTP is bound. ARF/Sar1p is the key component that triggers both the budding and fusion processes in response to the condition of its guanine nucleotide.

**Figure 27.13** shows how the conformation of ARF/Sar1p is controlled by its guanine nucleotide in such a way that the N-terminus is available to sponsor membrane insertion only when GTP is bound. The N-terminus has an amphipathic helix that can insert its hydrophobic side chains into a lipid bilayer. Contacts with the  $\gamma$  phosphate of GTP change the localization of a pair of  $\beta$ -sheets. This causes them to move within the protein, releasing the N-terminal region, which then protrudes and can insert into the membrane (3334).

**Figure 27.13** The conformation of Sar1p is controlled by the guanine nucleotide. Its N-terminal sequence is a hydrophobic stretch that can insert into membranes. This sequence is bound to the  $\beta 2$ - $\beta 3$  sheets and localized internally in the GDP-bound conformation. When Sar1p is bound to GTP, the  $\beta 2$ - $\beta 3$  sheets change their position and release the N-terminus, which projects out of the protein so that it can bind to membranes.

**Figure 27.14** illustrates the initiation of budding when ARF/Sar1p is converted to the GTP-bound form. ARF/Sar1p is recruited to the appropriate membranes by interacting with a receptor (called ARF-GAP) that activates the factor. The receptor does not become a component of the vesicle, but acts catalytically to activate its target. The function of ARF/Sar1p is to provide the binding sites at which the other coat proteins can assemble; after ARF/Sar1p inserts into the membrane, the other coat proteins bind to it stoichiometrically. Coat proteins surround the membrane as a prerequisite for budding, but another function may be needed to complete the process of "pinching off."

**Figure 27.14** ARF and coatomer are required for the budding of COP-I-coated vesicles.

Formation of a vesicle is energetically unfavorable – the membrane must be deformed and finally a small sphere is pinched off. Most is known about the process during endocytosis. When clathrin polymerizes into a basket-like structure at a coated pit, it pulls the membrane inward toward the cytoplasm. Then it is necessary to release the vesicle by separating it at the "neck" where it is joined to the plasma membrane. This requires input of energy in order to deform the membrane

The first protein to be discovered that may act at the scission step was a GDP/GTP-binding protein called **dynamain**. The GDP-bound form of dynamain binds to the clathrin lattice. Replacement of the GDP by GTP (which is catalyzed by an exchange factor; see *Molecular Biology Supplement 32.10 G proteins*) causes the dynamain to form a ring around the neck of the forming vesicle. One model proposes that the dynamain uses hydrolysis of GTP to provide the energy for the deformation and scission. (Dynamain is also involved in septation of mitochondria; see *Molecular Biology 4.13.24 How do mitochondria replicate and segregate?*) Other proteins have also since been discovered that can accomplish vesiculation, including amphiphysin and endophilin. The common feature in all these proteins is their ability to bind to the membrane, typically by interacting with a phosphoinositide head of a lipid.

The original evidence for the involvement of dynamain was the discovery that the *Drosophila* mutation *shibire*, which causes a temperature-sensitive paralysis as the result of a block in endocytosis, lies in a gene for dynamain (2315). It is not clear whether dynamain is required for other vesicle trafficking, but one possibility is that different variants of dynamain (produced by alternative splicing) are required for different trafficking pathways (for review see 2301).

Fusion is a reversal of budding. The coat of the vesicle is an impediment to fusion, and must be removed. If we suppose that uncoated vesicles would have an ability to

fuse spontaneously with membranes in the cell, we can view the coat as a protective layer that preserves the vesicle until it reaches its destination. **Figure 27.15** shows that dissociation of the coat is triggered by hydrolysis of the GTP bound to ARF. This causes ARF to withdraw from the membrane of the vesicle. The coat of COPI-coated vesicles is unstable in the absence of ARF, so the coatomers then dissociate from the vesicle. In the case of clathrin-coated vesicles, the coat is stable, and further components, including a chaperone-like protein and an ATPase, are necessary to remove it. However, a significant proportion of the clathrin and the adaptors in the cell are found in a pool of free molecules, which suggests that both components are removed when vesicles become uncoated prior to fusion with their membrane targets.

**Figure 27.15** Vesicle uncoating is triggered by hydrolysis of GTP bound to ARF.

Components involved in the fusion between the donor membrane of the vesicle and the target membrane were identified via a mammalian protein called NSF, identified by its sensitivity to the sulfhydryl agent NEM (N-ethyl-maleimide). NSF is the homologue for the product of yeast gene *sec18*, which is required for vesicle fusion during movement of transition vesicles. Fusion requires a 20S complex that consists of NSF (a soluble ATPase), a SNAP (Soluble NSF-Attachment Protein), and SNAREs (*SNAP-receptors*) located in the membrane. The fusion particle is a basic part of the vesicular apparatus; it functions at all surfaces where vesicles fuse in the secretory and endocytic pathways. It functions in conjunction with the components necessary for vesicle-membrane recognition and uses ATP hydrolysis to allow them to recycle (782; 783; 784).

**PROTEIN TRAFFICKING****6.27.8 The exocyst tethers vesicles by interacting with a Rab**

---

**Key Terms**

The **exocyst** is a complex of 8 proteins that is found at sites on the plasma membrane where secretion occurs. It tethers secretory vesicles to the membrane as the first step in the process of membrane fusion.

**Rab** proteins are small Ras-like GTPases. Different Rabs are required for protein trafficking between different membrane compartments. Although their exact role is not clear, Rabs appear to regulate membrane targeting and fusion.

**Key Concepts**

- A tethering complex consists of a group of proteins that are localized to a target membrane and recognize a protein on a suitable vesicle.
- Rabs are prenylated monomeric G proteins that are specifically distributed to different membrane surfaces.
- One mode of action for a tethering complex is to recognize a specific Rab on the vesicle.

---

What controls the specificity of vesicle targeting? When a vesicle buds from a particular membrane, it has a specific target: vesicles leaving the ER have the *cis*-Golgi as their destination, vesicles leaving the *trans*-Golgi fuse with the plasma membrane, etc. The apparatus for budding and fusion is ubiquitous, so some additional component(s) must allow a vesicle to recognize the appropriate target membrane.

Specific interactions occur between the vesicle and its target membrane at more than one stage, as summarized in **Figure 27.16**. A vesicle approaches a membrane either by diffusion or by some transport mechanism. Tethering complexes are found in the vicinity of the membrane and make the initial recognition of a suitable vesicle. Monomeric GTP-binding proteins called Rabs are important in the tethering reaction. They are either recognized by the tethering apparatus or involved in its activation. Tethering basically holds the vesicle in the vicinity of the membrane, but does not itself cause fusion (for review see 3452). Tethering is followed by interactions between SNARE proteins that trigger fusion (see *Molecular Biology 6.27.9 SNARES are responsible for membrane fusion*).

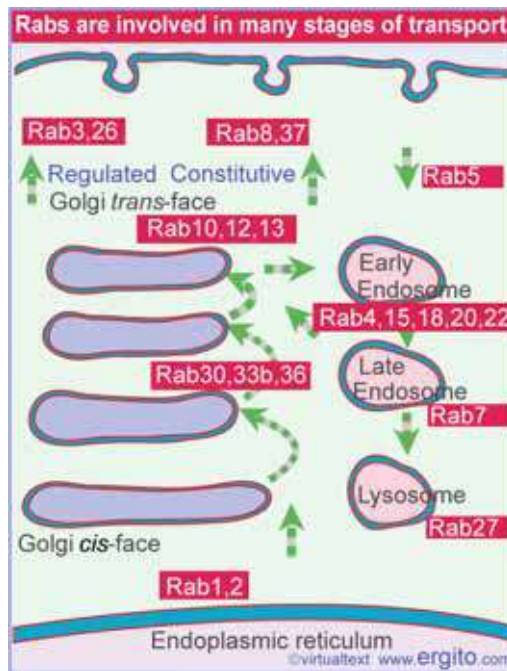

**Figure 27.16** A vesicle makes its first contact with a target membrane via a tethering complex. Rab proteins are involved in the tethering reaction. When the v-SNARE and t-SNARE come into close proximity, they interact to bring the vesicle into contact with the membrane. Then the membranes fuse.

The best characterized tethering complex is the **exocyst**, an assembly of eight protein subunits that were originally identified as the products of yeast genes in which mutation causes the accumulation of vesicles that should have released proteins through the plasma membrane (3454; 3455). The absence of any of the subunits makes the vesicles unable to fuse with the membrane, even though the fusion apparatus is not itself affected. The complex is localized at sites where exocytosis

occurs. The homologues of this complex in mammalian cells are called the Sec6/8 complex (3456).

The tethering complex recognizes an appropriate vesicle by interacting with a **Rab** protein on the vesicle. Rabs are attached to membranes via the addition of prenyl or palmityl groups at the C-terminus. There are ~30 Rabs, distributed to different membrane systems in the cell. **Figure 27.17** summarizes their distribution. Different Rabs are involved in ER to Golgi transport, in the constitutive and regulated pathways from the Golgi to the plasma membrane, and in stages of transport between endosomes (for review see 3450). For example, mutations in the yeast genes *YPT1* or *SEC4* that code for two such (related) proteins block transport and cause the accumulation of vesicles in the Golgi stacks or between Golgi and plasma membrane, respectively (for review see 289).

**Figure 27.17** Rab proteins affect particular stages of vesicular transport.

The Rabs are GTP-binding proteins that are active in the form bound to GTP; but hydrolysis of the GTP converts the protein to an inactive form. As with other monomeric G proteins, their activities are affected by other proteins that influence the hydrolysis of GTP (for introduction see *Molecular Biology Supplement 32.10 G proteins*). There may be GAP (GTP-hydrolyzing) activities specific for certain Rabs, GEF proteins that stimulate dissociation of the guanine nucleotide, and GDI proteins that prevent dissociation of guanine nucleotide.

The exocyst binds to Sec4p, which is a Rab found on secretory vesicles. The reaction involves several of the exocyst subunits. Two of the exocyst subunits (Sec10p and Sec15p) bind to activated (GTP-bound) Sec4p. This subcomplex binds to Sec3p, which is a component of the exocyst responsible for localization at polarized secretion sites. The result is to tether the vesicle at the secretion site.

**PROTEIN TRAFFICKING****6.27.9 SNARES are responsible for membrane fusion**

---

**Key Terms**

The **SNARE hypothesis** proposes that the specificity of a transport vesicle for its target membrane is mediated by the interaction of SNARE proteins. In this hypothesis, a SNARE on the vesicle (v-SNARE) binds specifically to its cognate SNARE on the target membrane (t-SNARE).

**Key Concepts**

- Vesicle-membrane fusion is specified by an interaction between a membrane-bound v-SNARE on the vesicle and t-SNARE on the target membrane.
- The SNAREs have a rod-like structure that lies parallel to the membrane surface.
- The v-SNARE and t-SNARE interact by a zipper-like reaction that creates a bundle of 4 helices parallel to the membrane, and which pulls the membranes into close contact.

---

The **SNARE hypothesis** proposes that the fusion reaction results from the interaction of a v-SNARE membrane protein carried by the vesicle with a t-SNARE membrane protein that is present on the target membrane (see *Great Experiments 6.6 The SNARE complex and its role in the specificity of membrane fusion*) (for review see 2299). Every membrane surface is marked by a particular constellation of SNAREs, as summarized in **Figure 27.18**, so that vesicle-membrane interactions are determined by pairwise combinations of v-SNAREs and t-SNAREs. This imposes further specificity at the step following the tethering reaction (for review see 3437).

**Figure 27.18** Each compartment or vesicle has a characteristic set of SNAREs. The constituent proteins fall into several families, including syntaxins (STX), VAMPs, and SNAP-25s.

**Figure 27.19** illustrates the interaction between SNAREs. The v-SNARE is a transmembrane protein carried by the vesicle. The t-SNARE includes two proteins; syntaxin is a transmembrane protein, and SNAP-25 is connected to the membrane by a fatty acyl linkage. (The name of SNAP-25 has an independent origin, and it has no connection with the SNAPs of the fusion particle.) Homologues to these SNAREs are found in other systems, including other animal cell types and yeast cells (785).

**Figure 27.19** Specificity for docking is provided by SNAREs. The v-SNARE carried by the vesicle binds to the t-SNARE on the plasma membrane to form a SNAREpin. NSF and SNAP remain bound to the far end of the SNAREpin during fusion. After fusion, ATP is hydrolyzed and NSF and SNAP dissociate to release the SNAREs.

The major part of each SNARE is exposed in the cytoplasm, and includes an extensive coiled-coil structure. Such structures commonly participate in protein-protein interactions. In fact, v-SNAREs can bind directly to the t-SNAREs *in vitro*, even without the other components of the fusion particle. The interaction between v-SNARE and t-SNARE is sufficient to sponsor membrane fusion. Liposomes containing v-SNAREs can fuse with liposomes containing t-SNAREs in the absence of any additional components. An energy source is not required, suggesting that activation energy is provided by changes in the conformation of the proteins. This *in vitro* reaction is slow, occurring over a time course of minutes. Comparison with the millisecond time course of fusion *in vivo* implies that other components will be needed to facilitate the reaction. But the basic apparatus involved in bringing the membranes together consists of the SNAREs. The idea that individual SNAREs influence the specificity of the reaction is supported by the observation that only certain pairs of SNAREs allow one liposome to interact with another (1183).

A SNARE complex has a rod-like structure ( $\sim 4 \times 14$  nm) in which the v-SNARE and t-SNARE are bound in parallel. Their membrane anchors are at the same end,

implying that the rod must lie in a plane between the two membrane surfaces. This structure is called a SNAREpin. **Figure 27.20** is based on the crystal structure, which shows that the complex consists of a 4-helix bundle. **Figure 27.21** shows a model for the SNAREpin superimposed at the appropriate scale on an electron micrograph of the complex (786).

**Figure 27.20** A SNAREpin forms by a 4-helix bundle. Photograph kindly provided by Axel Brunger.

**Figure 27.21** A SNAREpin complex protrudes parallel to the plane of the membrane. An electron micrograph of the complex is superimposed on the model. Photograph kindly provided by James Rothman.

The other components of the fusion particle bind to the far end of the complex. Hydrolysis of ATP and dissociation of the fusion complex is probably necessary not for fusion as such, but in order to release the SNAREs from the SNAREpin in order to allow them to be used again. (The 20S fusion complex was originally envisaged to play a role prior to fusion, possibly in providing the energy for fusion, but now we believe it is more likely to function post-fusion.)

It requires a lot of energy to fuse two membranes. When the v-SNARE and t-SNARE interact, they form the SNAREpin by a zipping reaction that moves along the rod. As this generates the 4-helical bundle, the facing leaflets of the two membranes are brought closer and closer, and ultimately they fuse together spontaneously to form the structure drawn in **Figure 27.22**. This stage is called hemifusion. The structure is energetically unstable because of the void space between the membranes. This leads to contacts between the two distal membrane layers. When they break down and reform, there is a small area of contact between the aqueous environment on either side. This is called the fusion pore. It rapidly expands and the membrane relaxes. The fusion pore is probably entirely lipid, with proteins acting to deform the exterior surface (for review see 3459). The energy for driving the transformation of the membrane may come from the interactions between the SNARE proteins (for review see 3437).

**Figure 27.22** When a SNAREpin forms, it pulls the apposing membrane leaflets into juxtaposition in a state of hemifusion.

## PROTEIN TRAFFICKING

### 6.27.10 The synapse is a model system for exocytosis

---

#### Key Terms

A **synapse** is a connection between a neuron and a target cell at which chemical information or electrical impulses may be transmitted.

#### Key Concepts

- The best characterized example of regulated exocytosis occurs at a synapse to release neurotransmitters from the donor neuron.
- 

The **synapse** has been especially useful for investigating fusion because it offers the advantage of large numbers of vesicles of the same type which fuse with the plasma membrane when a specific trigger is applied.

Impulses in the nervous system are propagated by the passage of material from a donor (or presynaptic) cell to a recipient (or postsynaptic cell). **Figure 27.23** illustrates a nerve terminal. An impulse in the donor cell triggers the exocytic pathway. Stored coated vesicles (called synaptic vesicles) move to the plasma membrane and release their contents of neurotransmitters into the extracellular fluid. The neurotransmitters in turn act upon receptors at the plasma membrane of the recipient cell.

**Figure 27.23** Neurotransmitters are released from a donor (presynaptic) cell when an impulse causes exocytosis. Synaptic (coated) vesicles fuse with the plasma membrane, and release their contents into the extracellular fluid.

*This is a static version of an interactive figure; see*

*<http://www.ergito.com/main.jsp?bcs=MBIO.6.27.10> to view properly.*

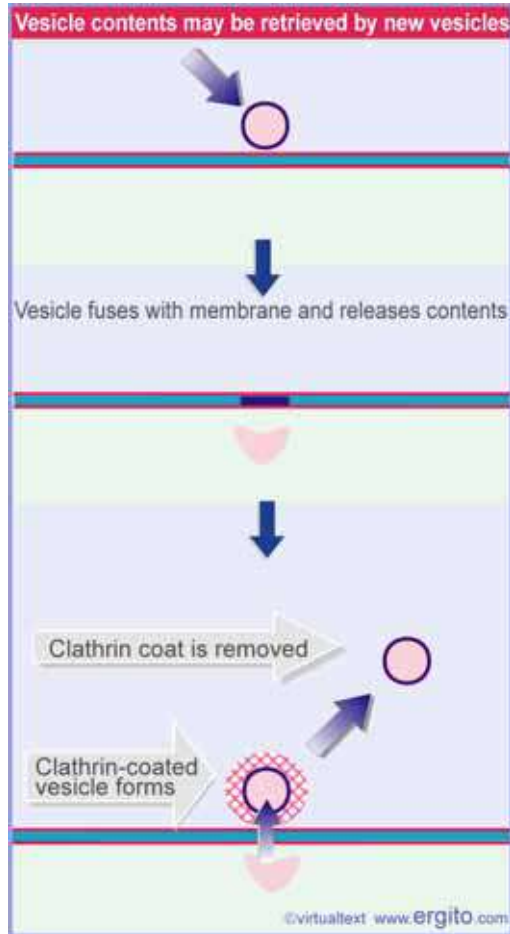

Exocytosis would lead to the accumulation of vesicle components in the plasma membrane if there were no means to retrieve them. There are two possibilities for the recycling of these vesicles, both of which may occur.

In the "kiss and run" model illustrated in **Figure 27.24**, a vesicle does not completely fuse with the plasma membrane, but contacts it transiently. The neurotransmitter is released through some sort of pore; then the vesicle reforms. Major questions about this pathway are how the vesicle maintains its integrity and what sort of structure forms the pore.

**Figure 27.24** The kiss and run model proposes that a synaptic vesicle touches the plasma membrane transiently, releases its contents through a pore, and then reforms.

In the fusion model illustrated in **Figure 27.25**, the vesicle fuses with the plasma membrane in the conventional manner, releasing its contents into the extracellular space. Recycling occurs by the formation of clathrin-coated vesicles at coated pits, that is, by the endocytic pathway. This may occur at large invaginations of the plasma membrane. The importance of endocytosis in this pathway is emphasized by the fact that inhibition of the formation of the clathrin-coated vesicles affects neurotransmitter release from synaptic vesicles. A major question about the pathway is the relationship between the endocytic and exocytic vesicles. The synaptic vesicles are not clathrin-coated. It is probable that the clathrin-coated endocytic vesicles give rise to synaptic vesicles by losing their clathrin coats, but synaptic vesicles may also form by other pathways (as in the case of AP3-coated vesicles). It is probably true that removal of the clathrin coat takes place quite soon after budding for all classes of clathrin-coated vesicles; the process of removal is not well defined.

**Figure 27.25** When synaptic vesicles fuse with the plasma membrane, their components are retrieved by endocytosis of clathrin-coated vesicles.

---

**PROTEIN TRAFFICKING****6.27.11 Protein localization depends on specific signals**

---

**Key Terms**

A **transport signal** is the part of a cargo molecule that is recognized by coat proteins or cargo receptors for incorporation into budding transport vesicles. Examples of transport signals are short amino acid sequences, secondary structure, and a protein modification such as phosphorylation.

A **retention signal** is the part (or parts) of a protein that locates it in the correct membrane and prevents it from leaving the compartment. An example is the transmembrane domain of Golgi resident proteins.

A **lysosome** is an organelle that contains hydrolytic enzymes and has an acidic lumen (pH as low as 4.5). Its primary function is the degradation of endocytosed material.

**Key Concepts**

- A membrane protein is incorporated into a vesicle when a transport signal consisting of a short sequence of amino acids in its cytoplasmic tail binds an adaptor protein of the vesicle.

---

Various types of signals influence transport through the ER-Golgi system. A protein that has no special signals will presumably enter vesicles at a rate determined by its concentration in the compartment, and may move in the anterograde direction by bulk flow. However, most proteins appear to have specific signals that facilitate or retard transport.

A typical cargo protein has a **transport signal** that is responsible for its entry into budding vesicles. **Figure 27.26** shows that the transport signal in a transmembrane protein is usually a region in its cytoplasmic domain that binds to an adaptor protein of the vesicle coat. **Figure 27.27** shows that the transport signal in a soluble cargo protein (for example, a secreted protein that passes through the lumen) is a region that binds to the luminal domain of a transmembrane cargo receptor, which in turn has an cytoplasmic domain that binds an adaptor protein. Interaction between the cargo and the coat thus directly or indirectly determines specificity of transport. Such mechanisms control anterograde transport from the ER to the cell surface and other destinations.

**Figure 27.26** A transport signal in a *trans*-membrane cargo protein interacts with an adaptor protein.

**Figure 27.27** A transport signal in a luminal cargo protein interacts with a transmembrane receptor that interacts with an adaptor protein.

A protein may be prevented from leaving a compartment by a **retention signal**. Such signals are often found in transmembrane regions, perhaps because aggregation between them creates a structure that is too large to be incorporated into a budding vesicle.

We have detailed information about several types of signal: a conformation that is required for proteins to be internalized by endocytosis; an amino acid sequence that targets proteins to the ER; and a modification that targets proteins to **lysosomes**

(small membranous bodies, where proteins are degraded).

Internalization of receptors via coated pits requires information in their cytoplasmic tails. The sequence for internalization is usually a short amino acid motif located near the C-terminus. Typically it makes a tight turn in the structure and exposes a tyrosine. Two signals of this sort are NPXY and YXRF. Although these are the basic signals for internalization, other sequences in the cytoplasmic tail influence the efficiency (789).

Enzymes that will be transported to lysosomes are recognized as targets for high mannose glycosylation, and are trimmed in the ER as described in **Figure 27.5**. Then *mannose-6-phosphate* residues are generated by a two-stage process in the Golgi. First the moiety is added to the 6 position of mannose by GlcNAc-phosphotransferase; then a glucosaminidase removes the N-acetyl-glucosamine (GlcNAc).

The action of the phosphotransferase provides the critical step in marking a protein for lysosomal transport. It occurs early in ER-Golgi transfer, possibly between the ER and the *cis* Golgi. The basis for the enzyme's specificity is its ability to recognize a structure that is common to lysosomal proteins. The structure consists of two short sequences, which are separated in the primary sequence, but form a common surface in the tertiary structure. Each of these sequences has a crucial lysine residue. The nature of this signal explains how proteins with little identity of sequence may share a common pathway for localization (788).

Lysosomal proteins continue to be transported along the Golgi stacks until they encounter receptors for mannose-6-phosphate. Recognition of mannose-6-phosphate targets a protein for transport in a coated vesicle to the lysosome. This final stage of sorting for the lysosome occurs in the *trans* Golgi, where the proteins are collected by specific transport vesicles that are coated with clathrin. The vesicles transport the lysosomal proteins to the late endosome, where they join the pathway for movement to the lysosome. A single pool of mannose-6-phosphate receptors is probably used for directing proteins to the lysosome whether they are newly synthesized or endocytosed. Most of the receptors in fact are located on endosomes, where they could recognize endocytosed proteins (for review see 280; 284).

**PROTEIN TRAFFICKING****6.27.12 ER proteins are retrieved from the Golgi**

---

**Key Concepts**

- The KDEL or KKXX C-terminal sequences are required for a soluble protein to be retained in the ER.
  - The KDEL signal binds to a receptor in the Golgi, which causes the receptor-KDEL protein to be transported back to the ER.
  - The KKXX signal binds to components of the coatmer of COP-I vesicles, which return the protein from the Golgi to the ER.
- 

Proteins that reside in the lumen of the endoplasmic reticulum possess a short sequence at the C-terminus, Lys-Asp-Glu-Leu (KDEL in single letter code). The alternative signals HDEL or DDEL are used in yeast. If this sequence is deleted, or if it is extended by the addition of other amino acids, the protein is secreted from the cell instead of remaining in the lumen. Conversely, if this tetrapeptide sequence is added to the C-terminus of lysozyme, the enzyme is held in the ER lumen instead of being secreted from the cell. This suggests that there is a mechanism to recognize the C-terminal tetrapeptide and cause it to be localized in the lumen (for review see 285; 282).

An interesting question emerges from the behavior of proteins that have an ER-localization signal. Does this signal cause a protein to be held so that it cannot pass beyond the ER or is it the target for a more active localization process? The model shown in **Figure 27.28** suggests that *the KDEL sequence causes a protein to be returned to the ER from an early Golgi stack* (for an account of the discovery see *Great Experiments 6.5 The discovery of the KDEL retrieval signal*).

**Figure 27.28** An (artificial) protein containing both lysosome and ER-targeting signals reveals a pathway for ER-localization. The protein becomes exposed to the first but not to the second of the enzymes that generates mannose-6-phosphate in the Golgi, after which the KDEL sequence causes it to be returned to the ER.

Because the modification of proteins as they pass through the Golgi is ordered, we can use the types of sugar groups that are present on any particular species as a marker for its progress on the exocytic pathway. When a KDEL sequence is added to a protein that usually is targeted to the lysosome (because its oligosaccharide gains mannose-6-P residues), it causes the protein to be held in the ER. But the protein is modified by the addition of GlcNAc-P, which happens only in the Golgi. The GlcNAc is not removed, so the protein cannot have proceeded far enough through the Golgi stacks to encounter the second of the enzymes in the mannose-6-P pathway. This suggests that KDEL is recognized by a receptor which is located in Golgi before the stack containing the second enzyme (787).

Mutations in the *S. cerevisiae* genes *ERD1* and *ERD2* prevent retention of proteins with the HDEL signal in the ER; instead the proteins are secreted from the cell. The products of both these genes are integral membrane proteins. The *ERD1* mutation causes a general defect in the Golgi; this supports the idea that sorting of the ER proteins occurs by salvage from the Golgi. The *ERD2* mutation identifies the receptor for the HDEL sequence. One model for its role is that it cycles between the Golgi salvage compartment and the ER. This idea is supported by the localization of the corresponding receptor in mammalian cells: it is found largely in the Golgi, but overexpression of a protein with KDEL sequence causes it to concentrate in the ER.

So binding of a KDEL-protein causes the receptor to move from Golgi to ER. It may have a high affinity for the HDEL sequence under the conditions prevailing in the Golgi, but a low affinity in the ER. This could enable ERD2 to seize proteins by their HDEL tails in the Golgi, and take them back to the ER, where they are then released (790; 791).

Another signal is responsible for the localization of transmembrane proteins in the ER. This is KKXX, and thus consists of two Lys residues, located in the cytoplasmic tail just prior to the C-terminus. The dilysine motif of KKXX proteins binds to the  $\beta'$  – and  $\alpha$ -COP components of coatamer. Yeast mutants that affect  $\beta'$  –,  $\alpha$ -, or  $\gamma$ -COP are defective in retrieval of KKXX proteins from the Golgi. This suggests that vesicles with the COP-I coat are involved in retrieving proteins from the Golgi and returning them to the ER, that is, COP-I vesicles are responsible for retrograde transport (778).

Overall protein transport is a unidirectional process: proteins enter the ER and are transported through the Golgi, unless stopped *en route*. COP-II-coated vesicles are thought to provide the major capacity for anterograde transport from the ER to the Golgi. COP-I-coated vesicles provide transport capacity along the Golgi stacks. However, both COP-I- and COP-II coated vesicles can be observed to bud from the ER, so there is the possibility that they are involved at multiple stages (perhaps in transporting different types of cargoes).

**PROTEIN TRAFFICKING****6.27.13 Brefeldin A reveals retrograde transport**

---

**Key Concepts**

- Brefeldin A blocks the action of COP-II vesicles and thereby prevents anterograde (forward) transport.
- 

Retrograde transport usually is obscured by anterograde transport, but is revealed when cells are treated with the drug brefeldin A (BFA), which specifically blocks the forward direction of transport. BFA blocks conversion of ARF from the GDP-bound to the GTP-bound form, and therefore prevents budding of coated vesicles. As a result of the block, a network of tubules forms between the cisternae of the Golgi (abolishing their usual independence) and joins them to the endoplasmic reticulum. There is resorption of most of the membranes of the *cis*-medial Golgi into the endoplasmic reticulum, which is accompanied by the redistribution of Golgi proteins into the ER, effecting a retrograde transport (775).

This happens because the COP-II vesicles involved in forward movement are more sensitive to the drug than the COP-I vesicles involved in retrograde movement. Retrograde transport may serve to retrieve membrane components to compensate for anterograde movement, and of course also provides for the retrieval of ER-proteins from the Golgi. It is possible there may also be other retrograde transport systems: certain toxins that are endocytosed at the plasma membrane can be found in the ER, but this retrograde transport does not appear to depend on the known systems.

The effects of brefeldin on ER-Golgi transport are universal, but in addition it inhibits other transport processes differently in different cells. In some cell types it inhibits transcytosis (transport from the basolateral surface to the apical surface in polarized cells); in other cells it inhibits transport from the *trans* Golgi network to endosomes. A related phenomenon is revealed by isolating cells that can grow in the presence of brefeldin. This identifies mutants in which transport is resistant in particular locations (such as endosomes or Golgi) but remains sensitive in others.

Brefeldin acts by binding to a common domain (the *Sec7* domain) in the exchange factors (GEFs) that are responsible for regenerating ARF-GTP from ARF-GDP. BFA stabilizes the association of the GEF with the GDP-bound form of the ARF. This causes the ARF to remain in its inactive state. The differing effects of BFA on individual transport processes probably means that there is a variety of GEFs that act on ARFs on different membrane surfaces, so that the apparatus involved in assembling coated vesicles is specific for individual types of surface. The characteristic susceptibility of each GEF explains the effect of brefeldin on budding from its particular membrane.

## PROTEIN TRAFFICKING

### 6.27.14 Vesicles and cargos are sorted for different destinations

---

#### Key Concepts

- Proteins are loaded into vesicles in the ER and are sorted only subsequently according to their destinations.
  - GPI-linked proteins are an exception and are sorted into separate vesicles in the ER.
- 

A key question is how the loading of cargo into vesicles is coordinated with the targeting of the vesicles to their destinations. The first issue is whether and when different types of cargos are sorted into different vesicles. Most sorting occurs in the Golgi, but some proteins are sorted in the ER.

Secretory proteins and plasma membrane proteins can be colocalized in vesicles released from the ER (2182). This suggests the general principle that proteins are packaged into vesicles in the ER irrespective of their final destination, and they are sorted only subsequently in the Golgi. However, there is at least one exception to this rule. Some proteins are linked to the extracellular side of the plasma membrane by glycosyl-phosphatidyl-inositol (GPI) (see *Molecular Biology Supplement 32.5 Membranes and membrane proteins*). GPI-linked proteins leave the ER in different vesicles from other secretory proteins, and so must be sorted from them at a very early stage (2181).

Other secreted and membrane-bound proteins appear to be transported in the same sets of vesicles from the ER through the Golgi to the *trans* face. **Figure 27.29** shows that at this point they are sorted into (at least) four groups of vesicles as defined by their destinations:

**Figure 27.29** Sorting in the ER distinguishes GPI-linked proteins from other proteins, which are sorted into different vesicles at the Golgi *trans* face according to their ultimate destinations.

- Constitutively secreted proteins go in vesicles directly to the plasma membrane.
- Proteins whose exocytosis is regulated enter vesicles that will fuse with the plasma membrane when an appropriate signal is given.
- Vesicles containing proteins that have been modified by addition of mannose-6-phosphate are directed to endosomes (from where they continue to lysosomes).
- Other vesicles may also be directed to endosomes.

## PROTEIN TRAFFICKING

### 6.27.15 Receptors recycle via endocytosis

---

#### Key Terms

**Endocytosis** is the process whereby cells internalize small molecules and particles from their surroundings. There are several forms of endocytosis, all of which involve the formation of a membranous vesicle from the plasma membrane.

An **endosome** is an organelle that functions to sort endocytosed molecules and molecules delivered from the trans-Golgi network and deliver them to other compartments, such as lysosomes. It consists of membrane-bounded tubules and vesicles.

**Early endosomes** are the first compartments of the endocytic pathway in which internalized molecules appear. They are slightly acidic (pH 6.5 to 6.8). In early endosomes, internalized molecules are sorted for recycling to the plasma membrane or for delivery to late endosomes and lysosomes.

**Late endosomes** are part of the endocytic pathway. They are formed upon the maturation of early endosomes, as proteins are recycled to the plasma membrane, and are more acidic than early endosomes.

**Transcytosis** is the transport of molecules from one type of plasma membrane domain to another in a polarized cell, such as a neuron and or epithelial cell.

#### Key Concepts

- Surface receptors are internalized by incorporation into clathrin-coated vesicles at a coated pit.
- Some receptors are internalized continuously, others are internalized upon binding ligand.
- Different receptors have different fates in the cell; the receptor and/or ligand may recycle to the surface or may be degraded.

---

The systems involved in importing proteins into the cell are closely related to those used for exporting secreted proteins. Ingestion of receptors starts by a common route, which leads to several pathways in which receptors have different fates. Some receptors are internalized continuously, but others remain exposed on the surface until a ligand is bound, which makes them susceptible to endocytosis. The signals that trigger internalization are different for ligand-independent and ligand-induced endocytosis.

In either case, the receptors slide laterally into coated pits, which are indented regions of the plasma membrane surrounded by clathrin. It is not clear whether simple lateral diffusion can adequately explain the movement into coated pits or whether some additional force is required. Coated pits invaginate into the cytoplasm and pinch off to form clathrin-coated vesicles. These vesicles move to early endosomes, are uncoated, fuse with the target membrane, and release their contents.

The process is called receptor-mediated **endocytosis** (for review see 278).

The immediate destination for endocytic (clathrin-coated) vesicles is the **endosome**, a rather heterogeneous structure consisting of membrane-bounded tubules and vesicles. There are at least two types of endosome, as indicated in **Figure 27.30**. **Early endosomes** lie just beneath the plasma membrane and are reached by endocytosed proteins within ~1 minute. **Late endosomes** are closer to the nucleus, and are reached within 5-10 minutes.

**Figure 27.30** Endosomes sort proteins that have been endocytosed and provide one route to the lysosome. Proteins are transported via clathrin-coated vesicles from the plasma membrane to the early endosome, and may then either return to the plasma membrane or proceed further to late endosomes and lysosomes. Newly synthesized proteins may be directed to late endosomes (and then to lysosomes) from the Golgi stacks. The common signal in lysosomal targeting is the recognition of mannose-6-phosphate by a specific receptor.

The early endosome provides the main location for sorting proteins on the endocytic pathway. Its role is a counterpart to that played by the Golgi for newly synthesized proteins. The interior of the endosome is acidic, with a  $\text{pH} < 6$ . Proteins that are transported to the endosome change their structure in response to the lowering of  $\text{pH}$ ; this change is important in determining their fate.

Receptors that have been endocytosed to the early endosome behave in one of two ways. They may return to the plasma membrane (by vesicular transport). Or they may be transported further to the lysosome, where they may be degraded. Transport to the lysosome is the default pathway, and applies to any material that does not

possess a signal specifically directing it elsewhere.

The lysosome contains the cellular supply of hydrolytic enzymes, which are responsible for degradation of macromolecules. Like endosomes, the lysosome is an acidic compartment (pH = 5).

The relationship between the various types of endosomes and lysosomes is not yet clear. Vesicles may be used to transport proteins along the pathway from one pre-existing structure to the next; or early endosomes may "mature" into late endosomes, which in turn "mature" into lysosomes. At all events, the pathway is unidirectional, and a protein that has left the early endosome for the late endosome will end up in the lysosome.

There are two routes to the lysosome. Proteins endocytosed from the plasma membrane may be directed via the early endosome to the late endosome. Newly synthesized proteins may be directed from the *trans* Golgi via the late endosome, as described above.

The fate of a receptor-ligand complex depends upon its response to the acidic environment of the endosome. Exposure to low pH changes the conformation of the external domain of the receptor, causing its ligand to be released, and/or changes the structure of the ligand. But the receptor must avoid becoming irreversibly denatured by the acid environment; the presence of multiple disulfide bridges in the external domain may play an important role in maintaining this unusual stability.

Four possible fates for a receptor-ligand complex are described in the alternative pathways of the next four figures:

- *Receptor recycles to the surface in coated vesicles, while the ligand is degraded.* **Figure 27.31** shows that this pathway is used by receptors that transport ligands into cells at high rates. A receptor recycles every 1-20 minutes, and can undertake >100 cycles during its lifetime of ~20 hours. The classic example of this pathway is the LDL receptor, whose ligands are the plasma low density lipoproteins apolipoprotein E and apolipoprotein B (collectively known as the LDLs). Apo-B is a very large (500 kD) protein that carries cholesterol and cholesterol esters. The LDL is released from its receptor in the endosome. The receptor recycles to the surface to be used again. The LDL and its cholesterol separate in the endosome; the LDL is sent on to the lysosome, where it is degraded, and the cholesterol is released for use by the cell. This constitutes the major route for removing cholesterol from the circulation. People with mutations in the LDL receptor accumulate large amounts of plasma cholesterol that cause the disease of familial hypercholesterolemia.
- *Receptor and ligand both recycle.* The transferrin receptor provides the classic example of this pathway, illustrated in **Figure 27.32**. The ligand for the receptor is the iron-carrying form of transferrin. When this reaches the endosome, the acid environment causes transferrin to release the iron. The iron-free ligand, called apo-transferrin, remains bound to the transferrin receptor, and recycles to the plasma membrane. In the neutral pH of the plasma membrane, apo-transferrin dissociates from the receptor. This leaves apo-transferrin free to bind another iron, while the transferrin receptor is available to internalize another

iron-carrying transferrin. Again this cycle is quite intensively used; a transferrin receptor recycles every 15-20 minutes, and has a half-life of >30 hours. It provides the cell with the means of taking up iron.

- *Receptor and ligand both are degraded.* The EGF receptor binds its ligand as a requirement for internalization. Although EGF and its receptor appear to dissociate at low pH, they are both carried on to the lysosome, where they may be degraded, as indicated in **Figure 27.33**. We do not know how and whether these events are related to the ability of EGF to change the phenotype of a target cell via binding to the receptor.
- *Receptor and ligand are transported elsewhere.* The route illustrated in **Figure 27.34** is available in certain polarized cells. A receptor-ligand combination is taken up at one cell surface, transported to the endosome, and then released for transport to the far surface of the cell. This is called **transcytosis**. By this means, receptors can transport immunoglobulins across epithelial cells.

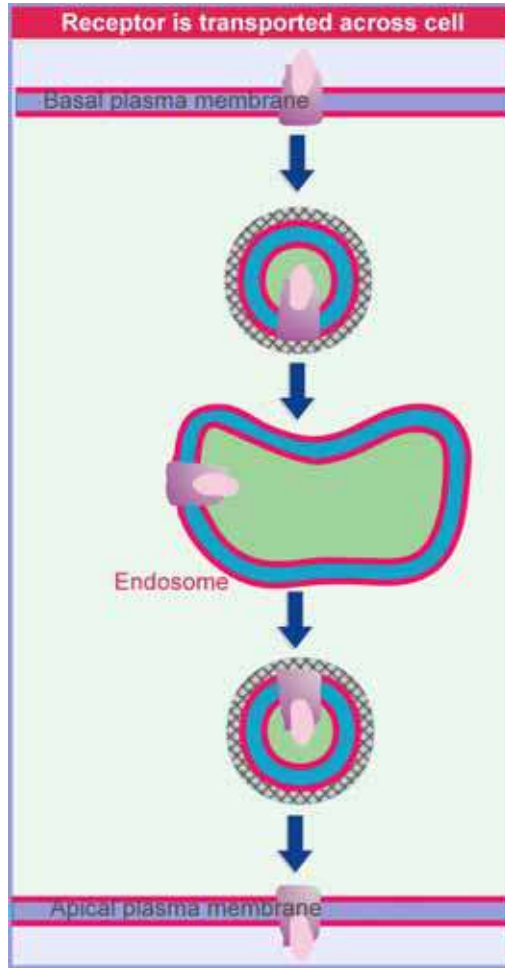

**Figure 27.31** LDL receptor transports apo-B (and apo-E) into endosomes, where receptor and ligand separate. The receptor recycles to the surface, apo-B (or apo-E) continues to the lysosome and is degraded, and cholesterol is released.

**Figure 27.32** Transferrin receptor bound to transferrin carrying iron releases the iron in the endosome; the receptor now bound to apo-transferrin (lacking iron) recycles to the surface, where receptor and ligand dissociate.

**Figure 27.33** EGF receptor carries EGF to the lysosome where both the receptor and ligand are degraded.

**Figure 27.34** Ig receptor transports immunoglobulin across the cell from one surface to the other.

Rapid recycling in general occurs for receptors that bring ligands into the cell, not for those that trigger pathways of signal transduction. Receptors involved in signaling changes from the surface are usually degraded if they are endocytosed.

## PROTEIN TRAFFICKING

### 6.27.16 Internalization signals are short and contain tyrosine

---

#### Key Concepts

- Signals for internalization are short (~4 amino acids), are located in the cytoplasmic tail near the plasma membrane, and usually contain a tyrosine residue that is exposed by the protein conformation.
- 

What features of protein structure are required for endocytosis? Mutations that prevent internalization can be used to identify the relevant sequences in the receptors. In fact, the characterization of an internalization defect provided evidence that entry into coated pits is needed for receptor-mediated endocytosis of LDL. In cells from human patients with such defects in the LDL receptor, the receptor gathers in small clusters over the plasma membrane, and cannot enter coated pits in the manner observed for wild-type cells.

The mutations responsible for this type of defect all affect the *cytoplasmic domain* of the receptor, which functions independently in sponsoring endocytosis. A recombinant protein whose extracellular domain is derived from influenza virus hemagglutinin, which is not usually endocytosed, can be internalized if it is provided with a cytoplasmic domain from an endocytosed receptor.

We do not yet have a clear view of all of the sorting signals that mediate endocytosis, but two features are common. The relevant region of the protein comprises a relatively short part of the cytoplasmic tail close to the plasma membrane. And the presence of a tyrosine residue in this region often is necessary. The most common motif is YXX  $\phi$  (where  $\phi$  is a hydrophobic amino acid). Removal of the tyrosine prevents internalization; conversely, substituting tyrosine in the relevant region of a protein that is not endocytosed (such as influenza virus hemagglutinin) allows it to be internalized.

Tyrosine is also found in another signal for internalization: NPXY (Asn-Pro-X-Tyr). The essential tyrosine can be replaced by other aromatic amino acids, but not by other types of amino acids. The NPXY motif is found in several group I proteins that are internalized, and is usually located close to the plasma membrane. (It was first identified in the LDL receptor.) It could be a general signal for endocytosis. In proteins that are internalized in response to ligand binding, the internalization signal may be generated by a change in conformation as a result of the binding.

Do internalized receptors interact directly with proteins on the vesicles that transport them? Clathrin forms an outer polyhedral layer on clathrin-coated vesicles, but other proteins form an inner layer. The adaptins recognize the appropriate sequences in the cytoplasmic domains of receptors that are to be internalized (see **Figure 27.12**). **Figure 27.35** illustrates a model in which, as a coated pit forms, the adaptins bind to the receptor cytoplasmic domain, immobilizing the receptor in the pit. As a result,

the receptor is retained by the coated vesicle when it pinches off from the plasma membrane.

**Figure 27.35** The cytoplasmic domain of an internalized receptor interacts with proteins of the inner layer of a coated pit.

---

## PROTEIN TRAFFICKING

### 6.27.17 Summary

---

Proteins that reside within the reticuloendothelial system or that are secreted from the plasma membrane enter the ER by cotranslational transfer directly from the ribosome. They are transported through the Golgi in the anterograde (forward) direction. Specific signals may cause them to be retained in the ER or a Golgi stack, or directed to other organelles such as endosomes. The default pathway is to be transported to the plasma membrane. Retrograde transport is less well characterized, but proteins that reside in the ER are retrieved from the Golgi by virtue of specific signals; an example is the C-terminal KDEL.

Proteins are transported between membranous surfaces as cargoes in membrane-bound coated vesicles. The vesicles form by budding from donor membranes; they unload their cargoes by fusing with target membranes. The protein coats are added when the vesicles are formed and must be removed before they can fuse with target membranes. Anterograde transport does not result in any net flow of membrane from the ER to the Golgi and/or plasma membrane, so membrane moving with anterograde transport must be returned to the ER by a retrograde mechanism.

Modification of proteins by addition of a preformed oligosaccharide starts in the endoplasmic reticulum. High mannose oligosaccharides are trimmed. Complex oligosaccharides are generated by further modifications that are made during transport through the Golgi, determined by the order in which the protein encounters the enzymes localized in the various Golgi stacks. Proteins are sorted for different destinations in the *trans* Golgi. The signal for sorting to lysosomes is the presence of mannose-6-phosphate.

Different types of vesicles are responsible for transport to and from different membrane systems. The vesicles are distinguished by the nature of their protein coats.

COP-I-coated vesicles are responsible for retrograde transport from the Golgi to the ER. COP-I vesicles are coated with coatamer. One of the proteins of coatamer,  $\beta$ -COP, is related to the  $\beta$ -adaptin of clathrin-coated vesicles, suggesting the possibility of a common type of structure between COP-I-coated and clathrin-coated vesicles.

COP-II vesicles undertake forward movement from the ER to Golgi. Vesicles that transport proteins along the Golgi stacks have not yet been identified. Vesicles responsible for constitutive (bulk) movement from the Golgi to the plasma membrane also have not been identified. An alternative model for anterograde transport proposes that *cis*-Golgi cisternae actually become *trans*-Golgi cisternae, so that there is a continuous process of cisternal maturation from the *cis* to the *trans* face.

In the pathway for regulated secretion of proteins, proteins are sorted into clathrin-coated vesicles at the Golgi *trans* face. Some vesicles may fuse into (larger)

secretory granules. Vesicles also move to endosomes, which control trafficking to the cell surface. Secretory vesicles are stimulated to unload their cargos at the plasma membrane by extracellular signals. Similar vesicles are used for endocytosis, the pathway by which proteins are internalized from the cell surface. The predominant protein in the outer coat of these vesicles is clathrin. The inner coat contains an adaptor complex, consisting of adaptin subunits, which bind to clathrin and to cargo proteins. There are (at least) three types of adaptor complex, with different specificities.

Budding and fusion of all types of vesicles is controlled by a small GTP-binding protein. This is ARF for clathrin and COP-I-coated vesicles, and Sar1P for COP-II-coated vesicles. When activated by GTP, ARF/Sar1p inserts into the membrane and causes coat proteins to assemble. This leads ultimately to budding. Further proteins, such as dynamin, may be required to "pinch off" the budding vesicle from the donor membrane. When ARF/Sar1p is inactivated because GTP is hydrolyzed to GDP, it withdraws from the membrane and the coat proteins either disassemble spontaneously (COP-coated vesicles) or are caused to do so by other proteins (clathrin-coated vesicles).

Vesicles initially recognize appropriate target membranes by a tethering reaction in which a tethering complex recognizes a Rab protein on the vesicle and brings the vesicle close to the membrane. Rabs are prenylated monomeric GTP-binding proteins. The fusion reaction is triggered when a v-SNARE on the vesicle pairs specifically with a t-SNARE on the target membrane. Pairing occurs by a coiled-coil interaction in which the SNARE complex lies parallel to the membrane surface. This causes the inner leaflets of the membranes to fuse to form a hemifusion complex; this is followed by fusion of the outer leaflets. The 20S fusion complex includes the soluble ATPase NSF and SNAP, and uses hydrolysis of ATP to release the SNAREs after pairing, which allows them to recycle.

Receptors may be internalized either continuously or as the result of binding to an extracellular ligand. Receptor-mediated endocytosis initiates when the receptor moves laterally into a coated pit. The cytoplasmic domain of the receptor has a signal that is recognized by proteins that are presumed to be associated with the coated pit. An exposed tyrosine located near the transmembrane domain is a common signal; it may be part of the sequence NPXY. When a receptor has entered a pit, the clathrin coat pinches off a vesicle, which then migrates to the early endosome.

The acid environment of the endosome causes some receptors to release their ligands; the ligands are carried to lysosomes, where they are degraded, and the receptors are recycled back to the plasma membrane by means of coated vesicles. A ligand that does not dissociate may recycle with its receptor. In some cases, the receptor-ligand complex is carried to the lysosome and degraded.

## SIGNAL TRANSDUCTION

### 6.28.1 Introduction

---

#### Key Terms

A **ligand** is an extracellular molecule that binds to the receptor on the plasma membrane of a cell, thereby effecting a change in the cytoplasm.

A **receptor** is a transmembrane protein, located in the plasma membrane, that binds a ligand in a domain on the extracellular side, and as a result has a change in activity of the cytoplasmic domain. (The same term is sometimes used also for the steroid receptors, which are transcription factors that are activated by binding ligands that are steroids or other small molecules.)

A **transporter** is a type of receptor that moves small molecules across the plasma membrane. It binds the molecules on its extracellular surface, and releases them into the cytoplasm.

**Internalization** is a process through which a ligand-receptor complex is brought into the cell.

**Endocytosis** is the process whereby cells internalize small molecules and particles from their surroundings. There are several forms of endocytosis, all of which involve the formation of a membranous vesicle from the plasma membrane.

**Signal transduction** describes the process by which a receptor interacts with a ligand at the surface of the cell and then transmits a signal to trigger a pathway within the cell.

A **second messenger** is a small molecule that is generated when a signal transduction pathway is activated. The classic second messenger is cyclic AMP, which is generated when adenylate cyclase is activated by a G protein (when the G protein itself was activated by a transmembrane receptor).

The ability of a species of kinase to phosphorylate itself is referred to as **autophosphorylation**. Autophosphorylation does not necessarily occur on the same polypeptide chain as the catalytic site; for example, in a dimer, each subunit may phosphorylate the other.

**G proteins** are guanine nucleotide-binding proteins. Trimeric G proteins are associated with the plasma membrane. When bound by GDP the trimer remains intact and is inert. When the GDP is replaced by GTP, the  $\alpha$  subunit is released from the  $\beta \gamma$  dimer. Either the  $\alpha$  monomer or the  $\beta \gamma$  dimer then activates or represses a target protein. Monomeric G proteins are cytosolic and work on the same principle that the form bound to GDP is inactive, but the form bound to GTP is active.

---

The plasma membrane separates a cell from the surrounding environment. It is permeable only to small lipid-soluble molecules, such as the steroid hormones, which can diffuse through it into the cytoplasm. It is impermeable to water-soluble material, including ions, small inorganic molecules, and polypeptides or proteins.

The response of the cell to hydrophilic material in the environment depends on

interactions that occur on the extracellular side of the plasma membrane. The hydrophilic material binds specifically to the extracellular domain of a protein embedded in the membrane. The extracellular molecule typically is called the **ligand**, and the plasma membrane protein that binds it is called the **receptor**.

Two fundamental types of response to an external stimulatory molecule that cannot penetrate the membrane are reviewed in **Figure 28.1**:

**Figure 28.1** Overview: information may be transmitted from the exterior to the interior of the cell by movement of a ligand or by signal transduction.

- *Material* – molecular or macromolecular – is physically transmitted from the outside of the membrane to the inside by transport through a proteinaceous channel in the lipid bilayer.
- A *signal* is transmitted by means of a change in the properties of a membrane protein that activates its cytosolic domain.

*The physical transfer of material* extends from ions to small molecules such as sugars, and to macromolecules such as proteins. Three major transport routes controlled by plasma membrane proteins are reviewed in **Figure 28.2**:

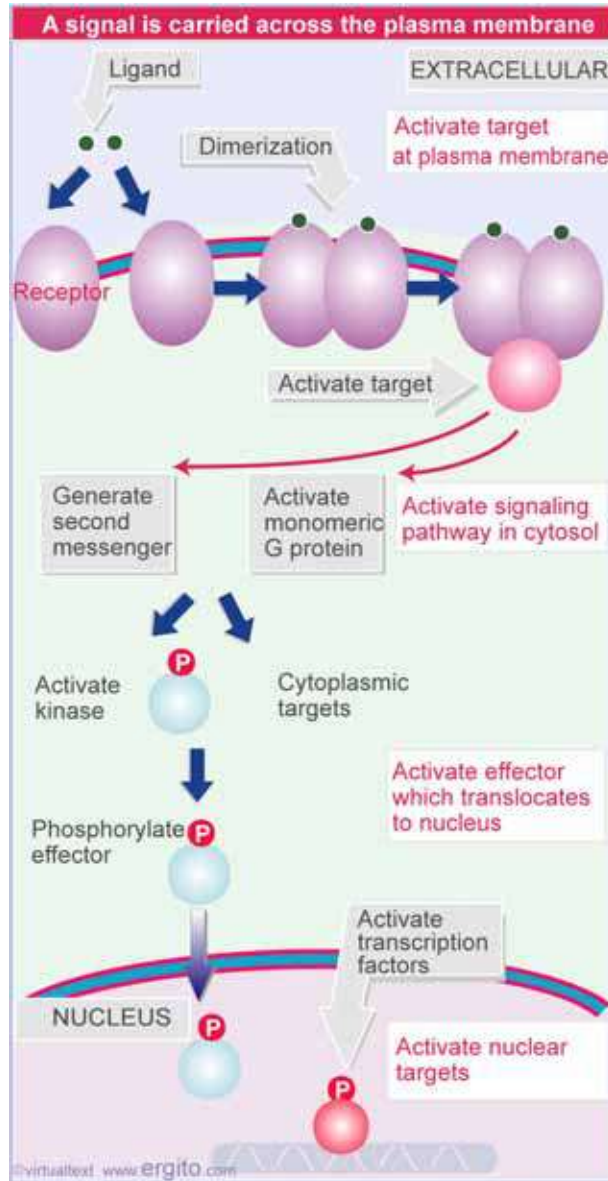

**Figure 28.2** Three means for transferring material of various sizes into the cell are provided by ion channels, receptor-mediated ligand transport, and receptor internalization.

- Channels control the passage of ions: different channels exist for potassium, sodium, and calcium ions. By opening and closing in response to appropriate signals, the channels establish ionic levels within the cell (a feature of particular significance for cells of the neural network).
- One means to import small molecules is for a receptor to transport the molecule from one side of the membrane to the other. **Transporters** are responsible for the import of small molecules (such as sugars) across the membrane. The target molecule binds to the receptor on the extracellular side, but then is released on the cytoplasmic side.
- Ligand-binding may trigger the process of **internalization**, in which the receptor-ligand combination is brought into the cell by the process of

**endocytosis.** In due course, the receptor and ligand are separated; the receptor may be returned to the surface for another cycle, or may be degraded. As described in *Molecular Biology 6.27.15 Receptors recycle via endocytosis*, endocytosis involves the passage of membrane proteins from one surface to another via coated vesicles.

*The transmission of a signal* involves the interaction of an extracellular ligand with a transmembrane protein that has domains on both sides of the membrane. Binding of ligand converts the receptor from an inactive to an active form. The basic principle of this interaction is that ligand binding on the extracellular side activates the receptor domain on the cytoplasmic side. The process is called **signal transduction**, because a signal has in effect been transduced across the membrane. The amplitude of the cytosolic signal is much greater than the original extracellular signal (the ligand), so signal transduction amplifies the original signal.

**Figure 28.3** illustrates the principle of signal transduction. A receptor typically is activated by being caused to dimerize when a ligand binds to its extracellular domain. Its cytosolic domain then interacts with a protein at the plasma membrane. This interaction most often takes one of two forms. It increases the quantity of a small molecule (called a **second messenger**) inside the cell. Or it directly activates a protein whose role is to activate other proteins; one common type of protein that is activated early in such pathways is a monomeric GTP-binding protein.

**Figure 28.3** A signal transduction pathway carries a signal from the cell surface into the cytoplasm and (sometimes) into the nucleus.

However a signal transduction pathway is initiated, a common means of propagating the pathway through the cytosol is to activate a protein kinase, which activates a series of other protein kinases. Ultimately the signal leads to the activation of effectors, which trigger changes in the cell. Some of the effectors act in the cytosol (for example, to affect the cytoskeleton), but some carry the signal into the nucleus, where the ultimate target is the activation of transcription factors that cause new patterns of gene expression.

The major signal transduction pathways that we discuss in this chapter are extensively conserved throughout animal evolution, and can be found in most or all animal cells. They are essentially absent from plants, which have evolved different

pathways for signal transduction.

Two major types of signal transduction are reviewed in **Figure 28.4**:

**Figure 28.4** A signal may be transduced by activating the kinase activity of the cytoplasmic domain of a transmembrane receptor or by dissociating a G protein into subunits that act on target proteins in the membrane.

- The receptor has a protein kinase activity in its cytosolic domain. The activity of the kinase is activated when ligand binds to the extracellular domain. The kinase phosphorylates its own cytoplasmic domain; this **autophosphorylation** enables the receptor to associate with and activate a target protein, which in turn acts upon new substrates within the cell. The most common kinase receptors are tyrosine kinases, but there are also some serine/threonine kinase receptors. Such pathways most often lead to activation of a GTP-binding protein that activates a cascade of cytosolic kinases.
- The receptor may interact with a trimeric **G protein** that is associated with the cytosolic face of the membrane (for introduction see *Molecular Biology Supplement 32.10 G proteins*). G proteins are named for their ability to bind guanine nucleotides. The inactive form of the G protein is a trimer bound to GDP. Receptor activation causes the GDP to be replaced with GTP; as a result, the G protein dissociates into a single subunit carrying GTP and a dimer of the

two other subunits. Either the monomer or the dimer then acts upon a target protein, often also associated with the membrane, which in turn reacts with a target(s) in the cytoplasm. This chain of events often stimulates the production of second messengers, the classic example being the production of cyclic AMP.

## SIGNAL TRANSDUCTION

### 6.28.2 Carriers and channels form water soluble paths through the membrane

---

#### Key Terms

A **concentration gradient** is a change in the concentration of a molecule or ion from one point to another. The gradient might be gradual (as in a solution that is not homogenous) or abrupt (created by a membrane).

An **electrical gradient** is a change in the amount of charge from one point to another.

A change in the concentration of ions from one point to another produces an **electrochemical gradient**. The term indicates that there is a change in the concentration of both electrical charge and of a chemical species.

**Passive transport** describes movement of molecules along their electrochemical gradient; no energy is required.

**Active transport** is an energy-consuming process that moves molecules against an electrochemical gradient. Energy for the movement is provided by hydrolysis of ATP.

A **carrier protein** moves directly a solute from one side of the plasma membrane to the other. In the process, the protein undergoes a conformational change.

A **uniporter** is a type of carrier protein that moves only one type of solute across the plasma membrane.

A **symporter** is a type of carrier protein that moves two different solutes across the plasma membrane in the same direction. The two solutes can be transported simultaneously or sequentially.

An **antiporter** is a type of carrier protein that simultaneously moves two different types of solutes in opposite directions across the plasma membrane.

An **ion channel** is a transmembrane protein which selectively allows the passage of one type of ion across the membrane. Ion channels are usually oligomers with a central aqueous pore through which the ion passes.

A channel which only allows passage of its substrate under certain conditions is referred to as "**gated**". Gated channels can exist in at least two conformations, one of which is open and the other closed.

**Ligand-gated** channels open or close in response to the binding of a specific molecule.

**Voltage-gated** channels are open or closed depending on the voltage across the membrane.

A **second messenger gated channel** is an ion channel whose activity is controlled by small signaling molecules inside the cell.

#### Key Concepts

- The electric gradient across the plasma membrane (inside is more negative) favors

---

entry of cations and opposes entry of anions.

- The concentration gradient depends on the ion, typically with low intracellular levels of  $\text{Na}^+$  and  $\text{Cl}^-$  and high levels of  $\text{K}^+$ .
- If the overall electrochemical gradient is favorable an ion can enter passively, otherwise it needs to be actively transported against the gradient.
- Carrier proteins that transport solutes across the membrane can be uniporters (one solute), symporters (two solutes) or antiporters (two solutes in opposite directions).
- Ion channels are water-soluble pores in the membrane that may be gated (controlled) by voltage or by ligands.

-----

The impermeability of the plasma membrane to water-soluble compounds enables different aqueous conditions to be maintained on either side. The ionic environment of the cytosol is quite different from the extracellular ionic milieu. Within the cytoplasm, different organelles offer different ionic environments. A striking example is the maintenance of an acid pH in endosomes and lysosomes, with immediate implications for the functions of the proteins that enter them (see *Molecular Biology 6.27.15 Receptors recycle via endocytosis*). Another example is the maintenance of a store of  $\text{Ca}^{2+}$  in the endoplasmic reticulum. (The nucleus is an exception to the rule that conditions in membrane-bounded organelles usually differ from the cytosol. The nucleoplasm essentially is subjected to the same conditions as the cytosol. This happens because the nuclear pores form relatively large openings in the nuclear envelope, through which ions and other small molecules can diffuse freely.)

A notable feature of the cytosolic environment is that there are more free cations (positively charged) (~150 mM) than anions (~10 mM). The reason is that many cellular constituents are negatively charged – for example, nucleic acids have multiple negative charges for every phosphate group in the phosphodiester backbone. The superfluity of cations therefore establishes electrical neutrality by balancing these fixed charges.

The intracellular concentrations of  $\text{Na}^+$  and  $\text{Cl}^-$  are low (~10 mM) while those outside the cell are high (>100 mM); and the situation for  $\text{K}^+$  is reversed. This creates a **concentration gradient** across the membrane for each ion.

The plasma membrane is electrically charged (due to the different phospholipid compositions of the inner and outer leaflets). There is an **electrical gradient** in which the inside is negative compared to the outside. This voltage difference favors the entry of cations and opposes the entry of anions.

Together the concentration gradient and electrical gradient constitute the **electrochemical gradient**, which is characteristic for each solute. A solute whose gradient is favorable can enter the cell when a channel opens; the gradient is sufficient to drive **passive transport** of a solute such as  $\text{Na}^+$  or  $\text{Cl}^-$  into the cell. But a solute that faces an unfavorable gradient requires **active transport** in which energy is used to pump it into the cell against the gradient.

The passage of ions (and other small solutes) through the plasma membrane is mediated by resident transmembrane proteins. A common feature of these proteins is their large size and the presence of multiple membrane-spanning regions, features which together argue that they provide a relatively static feature of the membrane. **Figure 28.5** illustrates two general means of transport across the membrane:

**Figure 28.5** A carrier (porter) transports a solute into the cell by a conformational change that brings the solute-binding site from the exterior to the interior, while an ion channel is controlled by the opening of a gate (which might in principle be located on either side of the membrane).

- A **carrier protein** binds a solute on one side of the membrane and then experiences a conformational change that transports the solute to the other side of the membrane. By binding the solute on one side and releasing it on the other, the carrier in effect directly transports the solute across the membrane. Several types of carriers are distinguished by the number of solutes that they transport, and the directions in which they transport them. Carriers that transport a single solute across the membrane are called **uniporters**; carriers that simultaneously or sequentially transport two different solutes are called **symporters**; and carriers that transport one solute in one direction while transporting a different solute in the opposite direction are called **antiporters**. Carrier proteins may be

used for passive transport or linked to an energy source to provide active transport. Energy for active transport is provided by hydrolysis of ATP, the classic example being the  $\text{Na}^+\text{-K}^+$  pump that functions as an antiporter, pumping sodium out of the cell and potassium into it. Another source of energy is the electrochemical gradient itself; a symporter brings  $\text{Na}^+$  into the cell together with some other solute, using the favorable gradient of sodium to overcome the unfavorable gradient of the other solute.

- An **ion channel** comprises a water-soluble pore in the membrane. Its activity is controlled by regulation of the opening and closing of the channel. When it is open, ions can diffuse passively, as driven by the electrochemical gradient. Ion channels allow *only* passive transport. The resting state of an ion channel is closed, and the **gates** that control channel activity usually open only briefly, in response to a specific signal. **Ligand-gated** channels are receptors that respond to binding of particular molecules, amongst which the neurotransmitters acetylcholine, glycine, GABA (  $\gamma$ -amino-butyric acid), and glutamate are prominent examples. **Voltage-gated** channels respond to electric changes, again a prominent feature of the neural system. **Second messenger gated channels** provide yet another means for signal transduction, one interesting example comprising channels that respond to activation of G proteins.

The structures of both carriers and channels present a paradox. They are transmembrane proteins that have multiple membrane-spanning domains, each consisting of a stretch of amino acids of sufficient hydrophobicity to reside in the lipid bilayer. Yet within these hydrophobic regions must be a highly selective, water-filled path that permits ions to travel through the membrane.

One solution to this problem lies in the structure of the transmembrane regions. Instead of comprising unremittingly hydrophobic stretches like those of single membrane-pass proteins, they contain some polar amino acids. They are likely to be organized as illustrated in **Figure 28.6** as amphipathic helices in which the hydrophobic face associates with the lipid bilayer, while the polar faces are aligned with one another to create the channel.

**Figure 28.6** A channel may be created by amphipathic helices, which present their hydrophobic faces to the lipid bilayer, while juxtaposing their charged faces away from the bilayer. In this example, the channel is lined with positive charges, which would encourage the passage of anions.

## SIGNAL TRANSDUCTION

### 6.28.3 Ion channels are selective

---

#### Key Terms

**Ion selectivity** refers to the specificity of an ion channel for a particular type of ion.

#### Key Concepts

- Channels typically consists of several protein subunits with the water-soluble pore at the axis of symmetry.
  - Selectivity is determined by the properties of the pore.
  - The gate acts by a mechanism resembling a ball and chain.
- 

The importance of the interior of the channel is indicated by the **ion selectivity**. Different channels permit the passages of different ions or groups of ions. The channels are extremely narrow, so ions must be stripped of their associated water molecules in order to pass through. The channel possesses a "filter" at the entrance to the pore that has specificity for its particular ion, presumably based upon its geometry and electrostatic charge.

The structures of particular ion channels are beginning to reveal their general features. A common feature is that the constituent proteins are large and have several membrane-spanning regions. A channel probably consists of a "ring" of 4, 5, or 6 subunits, organized in a symmetrical or quasi-symmetrical manner. The water-filled pore is found at the central axis of symmetry. The size of the pore generally increases with the number of subunits in the ring. The subunits are always related in structure, and sometimes are identical. They may consist of separate proteins or of related domains in a single large protein (for review see 296; 297).

Voltage-gated sodium channels have a single type of subunit, a protein of 1820 amino acids with a repetitive structure that consists of 4 related domains. Each domain has several membrane-spanning regions. The four domains are probably arranged in the membrane in a pseudo-symmetrical structure. Two smaller subunits are associated with the large protein.

Potassium channels have a smaller subunit, equivalent to one of the domains of the sodium channel; four identical subunits associate to create the channel. Six transmembrane domains are identified in the protein subunit by hydrophobicity analysis; they are numbered S1-S6. The S4 domain has an unusual structure for a transmembrane region: it is highly positively charged, with arginine or lysine residues present at every third or fourth position. The S4 motif is found in voltage-gated  $K^+$ ,  $Na^+$ , and  $Ca^{2+}$  channels, so it seems likely that it is involved with a common property, thought to be channel opening. Some potassium channels have only the S5-S6 membrane-spanning domains, and they appear to be basically shorter versions of the protein.

Analysis of the *shaker* potassium channel of the fly has revealed some novel features, illustrated in **Figure 28.7**. The region that forms the pore has been identified by mutations that alter the response to toxins that inhibit channel function. It occupies the region between transmembrane domains S5 and S6, forming two membrane-spanning stretches that are not organized in the usual hydrophobic  $\alpha$ -helical structure. The structure could be a rather extended  $\beta$ -hairpin. The state of the channel (open or closed) is controlled by the N-terminal end, which resembles a ball on a chain. The ball is in effect tethered to the channel by a chain, and plugs it on the cytoplasmic side. The length of the chain controls the rate with which the ball can plug the channel after it has been opened.

**Figure 28.7** A potassium channel has a pore consisting of unusual transmembrane regions, with a gate whose mechanism of action resembles a ball and chain.

A major question about potassium channels is how their selectivity is maintained.  $K^+$  and  $Na^+$  ions are (positively charged) spheres of 1.33 Å and 0.95 Å, respectively.  $K^+$  ions are selected over  $Na^+$  ions by a margin of  $10^4\times$ , but at the same time, up to  $10^8$  ions per second can move through the pore, basically close to the diffusion limit. The salient features of the pore of a potassium channel, based on the crystal structure, are summarized in **Figure 28.8**, and shown as a cutaway model in **Figure 28.9**. The pore is  $\sim 45$  Å long and consists of three regions. It starts inside the cell with a long internal pore, opens out into a central cavity of  $\sim 10$  Å diameter, and then passes to the extracellular space with a narrow selectivity filter. The lining of the inner pore and central cavity is hydrophobic, providing a relatively inert surface to a diffusing potassium ion. The central cavity is aqueous, and may serve to lower the electrostatic barrier to crossing the membrane (which is at its maximum in the center). The selectivity filter has negative charges and is lined with the polypeptide backbone. When a  $K^+$  ion loses its hydrating water on entering the filter, the contacts that it made with the water will be replaced by contacts with the oxygens of the polypeptide carbonyl groups. The size of the pore may be set so that a smaller sodium ion would not be close enough to make these substitute contacts (822).

**Figure 28.8** The pore of a potassium channel consists of three regions.

**Figure 28.9** A model of the potassium channel pore shows electrostatic charge (blue = positive, white = neutral, red = negative) and hydrophobicity (= yellow). Photograph kindly provided by Rod MacKinnon (see 822).

---

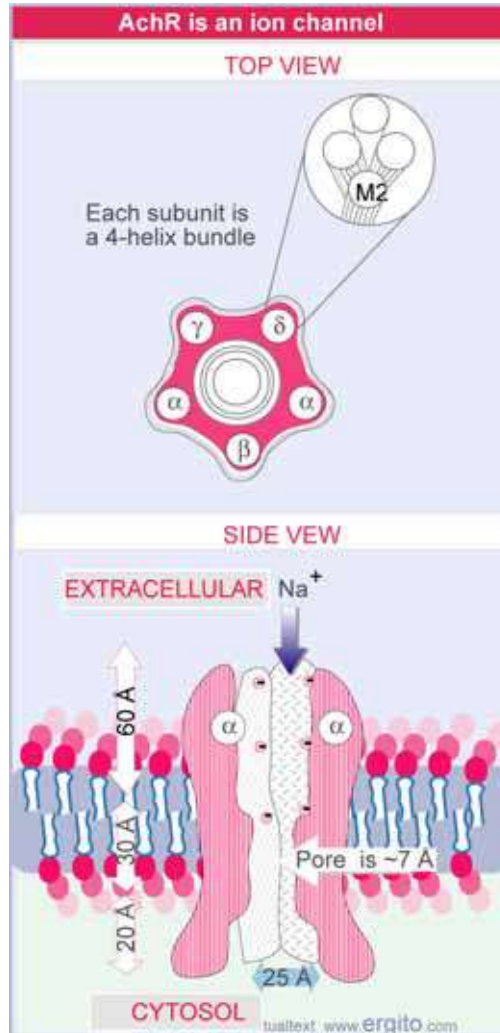

**SIGNAL TRANSDUCTION****6.28.4 Neurotransmitters control channel activity**

---

**Key Concepts**

- Neurotransmitter-gated receptors are ion channels that are controlled by neurotransmitters such as acetylcholine, glycine, or GABA.
  - The nicotinic acetylcholine receptor is a 5-subunit ion channel that admits several cations but is largely used to control  $\text{Na}^+$  uptake by the cell.
- 

Neurotransmitter-gated receptors form a superfamily of related proteins in the 5-member channel class. The nicotinic acetylcholine receptor has been characterized in the most detail, and is a pentamer with the structure  $\alpha_2 \beta \delta \gamma$ . As illustrated in **Figure 28.10**, the bulk of the 5 subunits projects above the plasma membrane into the extracellular space. The openings to the channel narrow from a diameter of  $\sim 25$  Å until reaching the pore itself. The entrance on the extracellular side is very deep,  $\sim 60$  Å; the distance on the cellular side is shorter, 20 Å. The pore extends through the 30 Å of the lipid bilayer and is only  $\sim 7$  Å in diameter.

**Figure 28.10** The acetylcholine receptor consists of a ring of 5 subunits, protruding into the extracellular space, and narrowing to form an ion channel through the membrane.

Ligand binding occurs on the  $\alpha$  subunits. Both  $\alpha$  subunits must bind an acetylcholine for the gate to open. Where is the gate? Since the channel is really narrow only in the region within the lipid bilayer, the gate seems likely to be located well within the receptor. Structural changes that occur upon opening seem greatest just by the cytoplasmic side of the lipid bilayer, so it is possible that the gate is located at the level of the phospholipid heads on the cytoplasmic boundary. So the acetylcholine receptor, like many other receptors, must transmit information about ligand binding internally, from the extracellular acetylcholine binding site to the near-cytoplasmic gate.

How does the gate function? It might consist of an electrostatic repulsion, in which positive groups are extruded into the channel to prevent passage of cations. Or it may take the form of a physical impediment to passage, in which a conformational change brings bulky groups to block the pore.

Ion selectivity may be determined by the walls of the wide entry passage. The walls lining the entrances to the pore have negatively charged groups; each subunit carries ~10 negative charges in its extracellular region. These charge clusters could modify the ionic environment at the entrance to the channel, concentrating the desired ions and diluting ions that are selected against. The structure of the acetylcholine receptor allows passage of  $\text{Na}^+$ ,  $\text{K}^+$ , or  $\text{Ca}^{2+}$  ions, but because of the prevailing gradients, its main use in practice is to allow the entry of  $\text{Na}^+$  into the cell.

The acetylcholine receptor is an example of a superfamily of receptors gated by neurotransmitters. All appear to have the same general organization, consisting of 5 subunits whose structures are related to one another. All the subunits are about the same size (~50 kD), and each is probably organized in the membrane as a bundle of 4 helices (each helix containing a transmembrane domain). In each case, one of the four transmembrane domains (called M2) has an amphipathic structure and seems likely to be involved in lining the walls of the pore itself. The presence of serine and threonine residues, and some paired acid-basic residues, may assist ion passage. The sequences of subunits of the glycine and GABA receptors are related to the acetylcholine receptor subunits. Some changes in the sequences seem likely to reflect the ion selectivity. So the glycine and GABA receptors have positively charged groups in the entrance walls, consistent with their transport of anions such as  $\text{Cl}^-$ .

## SIGNAL TRANSDUCTION

### 6.28.5 G proteins may activate or inhibit target proteins

---

#### Key Terms

A **receptor** is a transmembrane protein, located in the plasma membrane, that binds a ligand in a domain on the extracellular side, and as a result has a change in activity of the cytoplasmic domain. (The same term is sometimes used also for the steroid receptors, which are transcription factors that are activated by binding ligands that are steroids or other small molecules.)

**G proteins** are guanine nucleotide-binding proteins. Trimeric G proteins are associated with the plasma membrane. When bound by GDP the trimer remains intact and is inert. When the GDP is replaced by GTP, the  $\alpha$  subunit is released from the  $\beta\gamma$  dimer. Either the  $\alpha$  monomer or the  $\beta\gamma$  dimer then activates or represses a target protein. Monomeric G proteins are cytosolic and work on the same principle that the form bound to GDP is inactive, but the form bound to GTP is active.

An **effector** is the target protein for the activated G protein.

A **second messenger** is a small molecule that is generated when a signal transduction pathway is activated. The classic second messenger is cyclic AMP, which is generated when adenylate cyclase is activated by a G protein (when the G protein itself was activated by a transmembrane receptor).

A **serpentine** receptor has 7 transmembrane segments. Typically it activates a trimeric G protein.

#### Key Concepts

- Ligand binding to a serpentine membrane receptor causes it to activate a G protein.
- The G protein is a trimer bound to GDP in its inactive state.
- The mechanism of activation is that the receptor causes the GDP bound by the G-protein to be replaced with GTP.

---

G proteins transduce signals from a variety of receptors to a variety of targets. The components of the general pathway can be described as:

- The **receptor** is a resident membrane protein that is activated by an extracellular signal.
- A **G protein** is converted into active form when an interaction with the activated receptor causes its bound GDP to be replaced with GTP.
- An **effector** is the target protein that is activated (or – less often – inhibited) by the G protein; sometimes it is another membrane-associated protein.

- **Second messengers** are small molecules that are released as the result of activation of (certain types) of effectors.

Another terminology that is sometimes used to describe the relationship of the components of the transduction pathway is to say that the receptor is *upstream* of the G protein, while the effector is *downstream*.

The effectors linked to different types of G proteins are summarized in **Figure 28.11**. The important point is that there is a large variety of G proteins, activated by a wide variety of receptors. The activation of an individual G protein may cause it to stimulate or to inhibit a particular effector; and some G proteins act upon multiple effectors (causing the activation in turn of multiple pathways). Two of the classic G proteins are G<sub>s</sub>, which stimulates adenylyl cyclase (increasing the level of cAMP), and G<sub>t</sub>, which stimulates cGMP phosphodiesterase (decreasing the level of cGMP). The cyclic nucleotides are a major class of second messengers; another important group consists of small lipid molecules, such as inositol phosphate or DAG (diacylglycerol; for review see 306).

G proteins have various effectors			
G protein	Effector function	Second messenger	Example of receptor
s	Stimulates adenylyl cyclase	↑ cAMP	β-adrenergic
olf	Stimulates adenylyl cyclase	↑ cAMP	Odorant
i	Inhibits adenylyl cyclase	↓ cAMP	Somatostatin
	Opens K <sup>+</sup> channels	↑ Membrane potential	"
o	Closes Ca <sup>2+</sup> channels	↓ Membrane potential	m2 acetylcholine
t (transducin)	Stimulates cGMP phosphodiesterase	↓ cGMP	Rhodopsin
q	Activates phospholipase Cβ	↑ InsP3, DAG	m1 acetylcholine

**Figure 28.11** Classes of G proteins are distinguished by their effectors and are activated by a variety of transmembrane receptors.

Although the receptors that couple to G proteins respond to a wide variety of ligands, they have a common type of structure and mode of binding the ligand. They are **serpentine** receptors, with 7 transmembrane regions, and function as monomers. The greatest conservation of sequence is found in hydrophobic transmembrane regions, which in fact are used to classify the serpentine receptors into individual families (for review see 304; 3438).

The binding sites for small hydrophobic ligands lie in the transmembrane domains, so that the ligand becomes bound in the plane of the membrane. The smallest ligands, such as biogenic amines, may be bound by a single transmembrane segment. Larger ligands, such as extended peptides, may have more extensive binding sites in which extracellular domains provide additional points of contact. Large peptide hormones may be bound mainly by the extracellular domains.

When the ligand binds to its site, it triggers a conformational change in the receptor that causes it to interact with a G protein. A well characterized (although not typical)

case is that of rhodopsin, which contains a retinal chromophore covalently linked to an amino acid in a transmembrane domain. Exposure to light converts the retinal from the 11-*cis* to the all *trans* conformation, which triggers a conformational change in rhodopsin that causes its cytoplasmic domain to associate with the G<sub>t</sub> protein (transducin).

**SIGNAL TRANSDUCTION****6.28.6 G proteins function by dissociation of the trimer**

---

**Key Concepts**

- When GDP is replaced by GTP, a trimeric G protein dissociates into an  $\alpha$ -GTP subunit and a  $\beta \gamma$  dimer.
- It is most often the  $\alpha$  subunit that activates the next component (the effector) in the pathway.
- Less often the  $\beta \gamma$  activates the effector.

---

*G proteins are trimers whose function depends on the ability to dissociate into an  $\alpha$  monomer and a  $\beta \gamma$  dimer. The dissociation is triggered by the activation of an associated receptor. In its inactive state, the  $\alpha$  subunit of the G protein is bound to GDP. **Figure 28.12** shows that the activated receptor causes the GDP to be replaced by GTP. This causes the G protein to dissociate into a free  $\alpha$ -GTP subunit and a free  $\beta \gamma$  dimer. (The basic interactions of G proteins are reviewed in *Molecular Biology Supplement 32.10 G proteins*). They are found in all classes of eukaryotes.*

**Figure 28.12** Activation of G<sub>s</sub> causes the α subunit to activate adenylyl cyclase.

The interaction between receptor and G protein is catalytic. After a G protein has dissociated from an activated receptor, the receptor binds another (inactive) trimer, and the cycle starts again. So one ligand-receptor complex can activate many G protein molecules in a short period, amplifying the original signal.

The most common action for the next stage in the pathway calls for the activated α subunit to interact with the effector. In the case of G<sub>s</sub>, the α subunit activates adenylyl cyclase; in the case of G<sub>i</sub>, the α subunit activates cGMP phosphodiesterase. In other cases, however, it is the βγ dimer that interacts with the effector protein. In some cases, *both* the α subunit and the βγ dimer interact with effectors (for review see 295; 301; 312).

Consistent with the idea that it is more often the α subunits that interact with effectors, there are more varieties of α subunits (16 known in mammals) than of β (5) or γ subunits (11). However, irrespective of whether the α or βγ subunits carry the signal, *the common feature in all of these reactions is that a G protein usually acts upon an effector enzyme that in turn changes the concentration of some small molecule(s) in the cell.* (There are some other pathways in which G proteins behave by activating a kinase.)

In either the intact or dissociated state, G proteins are associated with the cytoplasmic face of the plasma membrane. But the individual subunits are quite hydrophilic, and none of them appears to have a transmembrane domain. The  $\beta \gamma$  dimer has an intrinsic affinity for the membrane because the  $\gamma$  subunit is prenylated. The  $\alpha_i$  and  $\alpha_o$  types of subunit are myristoylated, which explains their ability to remain associated with the membrane after release from the  $\beta \gamma$  dimer. The  $\alpha_s$  subunit is palmitoylated.

Because several receptors can activate the same G proteins, and since (at least in some cases) a given G protein has more than one effector, we must ask how specificity is controlled. The most common model is to suppose that receptors, G proteins, and effectors all are free to diffuse in the plane of the membrane. In this case, the concentrations of the components of the pathway, and their relative affinities for one another, are the important parameters that regulate its activity. We might imagine that an activated  $\alpha$ -GTP subunit scurries along the cytoplasmic face of the membrane from receptor to effector. But it is also possible that the membrane constrains the locations of the proteins, possibly in a way that restricts interactions to local areas. Such compartmentation could allow localized responses to occur (for review see 315).

## SIGNAL TRANSDUCTION

### 6.28.7 Protein kinases are important players in signal transduction

---

#### Key Terms

A **protein kinase** is a protein which transfers the terminal phosphate group from ATP onto another protein.

A **protein serine/threonine kinase** phosphorylates cytosolic proteins on either their serine or threonine residues.

A **protein tyrosine kinase** is a kinase enzyme whose target is a tyrosine amino acid in a protein.

A **dual specificity kinase** is a protein kinase that can phosphorylate tyrosine or threonine or serine amino acids.

**RTK** is an abbreviation for "receptor tyrosine kinase". These kinases are membrane-bound proteins with large cytoplasmic and extracellular domains. Specific binding of a ligand, such as a growth factor, to the extracellular domain causes the cytoplasmic domain to phosphorylate other proteins on tyrosine residues.

#### Key Concepts

- Protein kinases fall into groups that phosphorylate Ser/Thr or Tyr on target proteins.
- Receptor protein kinases are most often protein tyrosine kinases.
- Cytosolic protein kinases are most often protein Ser/Thr kinases.

---

There are many types of **protein kinases** involved in signal transduction. They all have the same basic catalytic activity: they add a phosphate group to an amino acid in a target protein. The phosphate is provided by hydrolyzing ATP to ADP. A protein kinase has an ATP-binding site and a catalytic center that can bind to the target amino acid (for review see 293; 294). The phosphorylation of the target protein changes its properties so that it in turn acts to carry the signal transduction pathway to the next stage.

Protein kinases can be classified both by the types of amino acids that they phosphorylate in the protein target and by their location in the cell.

Three groups of protein kinases are distinguished by the types of amino acid targets:

- **Protein serine/threonine kinases** are responsible for the vast majority of phosphorylation events in the cell. As their name indicates, they phosphorylate either serine or threonine in the target protein.

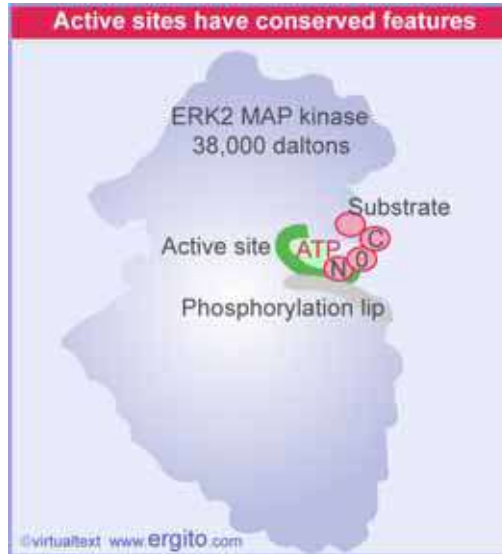

- **Protein tyrosine kinases** phosphorylate tyrosine in the target protein.
- **Dual specificity kinases** are less common and can phosphorylate target proteins on either tyrosine or serine/threonine.

Protein kinases are found in two types of location:

- *Cytosolic protein kinases* are most often Ser/Thr protein kinases. They are responsible for the vast majority of phosphorylation events in the cell. One particularly important class are the cdk (cyclin-dependent kinase) enzymes that control the cell cycle (see *Molecular Biology 6.29 Cell cycle and growth regulation*). Dual specificity kinases are found in the MAP kinase signal transduction pathway (see *Molecular Biology 6.28.16 A MAP kinase pathway is a cascade*). The products of some oncogenes, for which *src* is the paradigm, are protein tyrosine kinases (see *Molecular Biology 6.30.16 Src is the prototype for the proto-oncogenic cytoplasmic tyrosine kinases*).
- *Receptor protein kinases* are found in the plasma membrane. They have a domain on the exterior of the cell that binds a ligand, and a catalytic domain within the cell that can act on a target protein (for review see 2899; 2266). Most receptors with protein kinase activity are protein tyrosine kinases (abbreviated as **RTK** for receptor tyrosine kinase), although there are also some receptors of the Ser/Thr kinase class.

All kinases have an active site that binds ATP and a short sequence of the target protein that includes the amino acid to be phosphorylated. The sequence bound at the active site usually conforms to a consensus, typically 3-4 amino acids long. Recognition of the target protein also depends on interactions involving other regions of both the kinase and the target.

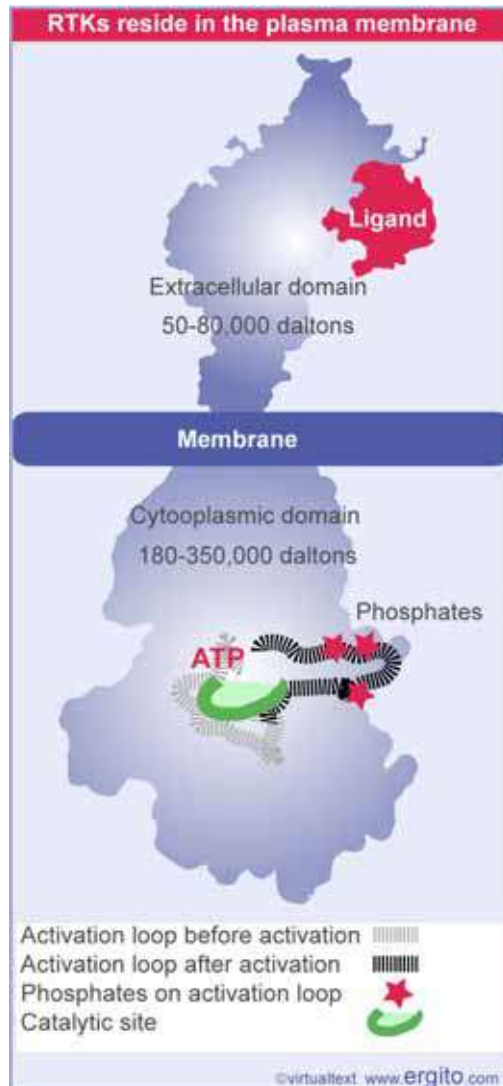

**Figure 28.13** illustrates the structure of a dual specificity kinase of the MAP kinase family, based on its crystal structure (2900; 2901). The active site consists of a short loop of the enzyme that forms a deep cleft. The sequence of the catalytic loop is generally conserved. ATP binds at the bottom of the cleft. Adjacent to the catalytic loop, on the surface of the enzyme, is a sequence called the phosphorylation lip; many kinases in this group have amino acids in this sequence whose phosphorylation activates the enzyme activity. The phosphorylation lip contacts the amino acid on the N-terminal side of the amino acid that is phosphorylated.

**Figure 28.13** The active site of a cytosolic kinase is identified by the catalytic loop (green). The target sequence for phosphorylation binds to the active site. Amino acid O is phosphorylated. The amino acid on the N-terminal side (indicated by N) is immediately adjacent to the phosphorylation lip, which is a sequence in the kinase that is often itself phosphorylated.

Receptor tyrosine kinases have some common features. The extracellular domain often has characteristic repeating motifs. It contains a ligand-binding site. The transmembrane region is a single short membrane-spanning alpha helix. The catalytic domain is large (~250 amino acids), and often occupies the bulk of the cytoplasmic region. Certain conserved features are characteristic of all kinase catalytic domains. Sometimes the catalytic domain is broken into two parts by an interruption of some other sequence (which may have an important function in selecting the substrate).

**Figure 28.14** illustrates the features of a receptor tyrosine kinase. Because the receptors are embedded in membranes, we do not yet have crystal structures of intact proteins. However, several extracellular and cytoplasmic domains have been independently crystallized (for review see 2266). The extracellular and cytoplasmic domains of the RTK group both show large variations in size (for review see 2899). The receptors are usually activated by binding a polypeptide ligand, which can be a significant size relative to the extracellular domain (the example in the figure shows the scale for an FGF ligand binding to its receptor; see 2902). The cytoplasmic domain of the RTK is large, and contains many sites involved in signaling, as well as the kinase catalytic domain. Crystal structures have identified the features of the active site (2903; 2904). At the active site, the catalytic loop is adjacent to an activation loop, which contains 2-3 tyrosines. When these tyrosines are phosphorylated, the activation loop swings away from the catalytic loop, freeing it to bind the substrate (for review see 2899).

**Figure 28.14** A receptor tyrosine protein kinase has an extracellular domain that binds a ligand, which is usually a polypeptide, and a cytoplasmic domain that includes a kinase region. ATP binds adjacent to the catalytic site. An important feature is the activation loop, which contains tyrosine residues whose phosphorylation activates the kinase activity. The activation loop containing these tyrosines changes its position when they are phosphorylated.

Phosphorylation usually activates the target protein, but this is not a golden rule – there are some cases in which phosphorylation inhibits the activity of the target. One way to reverse the effects of a phosphorylation event is for a phosphatase (typically a cytosolic phosphatase) to remove the phosphate that was added by a protein kinase (for review see 310). There are phosphatases with specificity for the appropriate amino acids to match each type of kinase. Most phosphatases are cytosolic, although there are some receptor phosphatases.

## SIGNAL TRANSDUCTION

### 6.28.8 Growth factor receptors are protein kinases

---

#### Key Terms

A **growth factor** is a ligand, usually a small polypeptide, that activates a receptor in the plasma membrane to stimulate growth of the target cell. Growth factors were originally isolated as the components of serum that enabled cells to grow in culture.

A **cytokine** is a small polypeptide that affects the growth of particular types of cells.

#### Key Concepts

- Binding of a ligand to the extracellular domain of a growth factor receptor activates the kinase activity of the cytoplasmic domain.
- The receptor may activate a second messenger or may activate a cascade of kinases.

---

Growth factor receptors take their names from the nature of their ligands, which usually are small polypeptides (casually called **growth factors**, more properly called **cytokines**) that stimulate the growth of particular classes of cells. The factors have a variety of effects, including changes in the uptake of small molecules, initiation or stimulation of the cell cycle, and ultimately cell division. The ligands most usually are secreted from one cell to act upon the receptor of another cell. Examples of secreted cytokines are EGF (epidermal growth factor), PDGF (platelet-derived growth factor), and insulin. In some cases, ligands instead take the form of components of the extracellular matrix, or membrane proteins on the surface of another cell (these are sometimes called counter-receptors).

The receptors share a general characteristic structure: they are group I integral membrane proteins, spanning the membrane once, with an N-terminal protein domain on the extracellular side of the membrane, and the C-terminal domain on the cytoplasmic side. Most receptors, such as those for EGF or PDGF, consist of single polypeptide chains. An exception is provided by receptors of the insulin family, which are disulfide-bonded dimers (each dimer being a group I protein).

The effector pathways that are activated by receptor tyrosine kinases (*RTKs*) fall into two groups:

- *An enzymatic activity is activated that leads to the production of a small molecule second messenger.* The second messenger may be the immediate product of an enzyme that is activated directly by the receptor, or may be produced later in the pathway. Lipids are common second messengers in these pathways. The enzymes include phospholipases (which cleave lipids from larger substrates) and kinases that phosphorylate lipid substrates. Some common pathways are summarized in **Figure 28.15**. The second messengers that are

released in each pathway act in the usual way to activate or inactivate target proteins.

- *The effector pathway is a cascade that involves a series of interactions between macromolecular components.* The most common components of such pathways are protein kinases; each kinase activates the next kinase in the pathway by phosphorylating it, and the ultimate kinases in the pathway typically act on proteins such as transcription factors that may have wide-ranging effects upon the cell phenotype.

RTKs act on different types of target proteins that generate second messengers		
Effector	Substrate	Products
PLC (phospholipase C) (3 families, PLC $\alpha$ , $\beta$ , $\gamma$ )	PIP2 (phosphatidylinositol 4,5-diphosphate)	DAG (diacylglycerol) + IP3 (inositol 1,4,5-triphosphate) DAG activates protein kinase C IP3 mobilizes Ca <sup>2+</sup>
PLA2 (phospholipase A2)	Phospholipids (phosphatidylcholine, phosphatidylethanolamine, phosphatidylinositol)	Arachidonic acid Converted to prostaglandins & leukotrienes
PI3 kinase (phosphatidylinositol-3 kinase)	Phosphatidyl inositol	PI3 (phosphatidyl inositol-3 phosphate)
PI4 kinase (phosphatidylinositol-4 kinase)	Phosphatidyl inositol	PI4 (phosphatidyl inositol-4 phosphate) Converted to PIP2 (phosphatidyl diphosphate)

**Figure 28.15** Effectors for receptor tyrosine kinases include phospholipases and kinases that act on lipids to generate second messengers.

The basic principle underlying the function of all types of effector pathway is that the signal is amplified as it passes from one component of the pathway to the next. When some components have multiple targets, the pathway branches, thus creating further diversity in the response to the original stimulus.

When a ligand binds to the extracellular domain of a growth factor receptor, the catalytic activity of the cytoplasmic domain is activated. *Phosphorylation of tyrosine is identified as the key event by which the growth factor receptors function because mutants in the tyrosine kinase domain are biologically inactive, although they continue to be able to bind ligand.*

## SIGNAL TRANSDUCTION

### 6.28.9 Receptors are activated by dimerization

---

#### Key Terms

The ability of a species of kinase to phosphorylate itself is referred to as **autophosphorylation**. Autophosphorylation does not necessarily occur on the same polypeptide chain as the catalytic site; for example, in a dimer, each subunit may phosphorylate the other.

#### Key Concepts

- Ligand binding to receptor monomers causes them to dimerize by interactions between the extracellular domains.
- Dimerization is made possible by the ability of membrane proteins to move laterally within the membrane bilayer.
- Dimerization activates the cytoplasmic domains by an autophosphorylation in which the kinase activity of each monomer phosphorylates the other monomer.

---

A key question in the concept of how a signal is transduced across a membrane is how binding of the ligand to the extracellular domain activates the catalytic domain in the cytoplasm. *The general principle is that a conformational change is induced that affects the overall organization of the receptor.* An important factor in this interaction is that membrane proteins have a restricted ability to diffuse laterally (in contrast with the continuous motion of the lipids in the bilayer). This enables their state of aggregation to be controlled by external events.

Lateral movement plays a key role in transmitting information from one side of the membrane to the other. **Figure 28.16** shows that binding of ligand induces a conformation change in the N-terminal region of a group I receptor that causes the extracellular domains to dimerize. This causes the transmembrane domains to diffuse laterally, bringing the cytoplasmic domains into juxtaposition. The stabilization of contacts between the C-terminal cytosolic domains causes a change in conformation that activates the kinase activity. In some cases, phosphorylation also causes the receptor to interact with proteins present on the cytoplasmic surface of a coated pit, leading to endocytosis of the receptor. An extreme case of lateral diffusion is seen in certain cases of receptor internalization, when receptors of a given type aggregate into a "cap" in response to an extracellular stimulus.

**Figure 28.16** The principle underlying signal transduction by a tyrosine kinase receptor is that ligand binding to the extracellular domain triggers dimerization; this causes a conformational change in the cytoplasmic domain that activates the tyrosine kinase catalytic activity.

*This is a static version of an interactive figure;  
see*

*<http://www.ergito.com/main.jsp?bcs=MBIO.6.28.9>  
to view properly.*

**Figure 28.17** shows that dimerization can take several forms (for review see 2898). The most common is that a ligand binds to one or to both monomers to induce them to dimerize (2905). A variation is that a dimeric ligand binds to two monomers to bring them together (2902). In the case of the insulin receptor family, the ligand binds to a dimeric receptor (which is stabilized by extracellular disulfide bridges) to cause an intramolecular change of conformation. The major consequence of dimerization is to allow transmission of a conformational change from the extracellular domain to the cytoplasmic domain without requiring a change in the structure of the transmembrane region (793; for review see 307; 2266).

**Figure 28.17** Binding of ligand to the extracellular domain can induce aggregation in several ways. The common feature is that this causes new contacts to form between the cytoplasmic domains.

Dimerization initiates the signaling pathway by triggering an **autophosphorylation** in the cytoplasmic domains of the receptor. When the two cytoplasmic domains are brought together in the dimer, each phosphorylates the other. It is necessary for *both* subunits to have kinase activity for the receptor to be activated; if one subunit is defective in kinase activity, the dimer cannot be activated.

Autophosphorylation has two consequences. Phosphorylation of tyrosines in the kinase domain causes the "activation loop" to swing away from the catalytic center,

thus activating the ability of the kinase to bind its substrate (see **Figure 28.14**). Phosphorylation of tyrosines at other regions of the cytoplasmic domain provides the means by which substrate proteins are enabled to bind to the receptor. The existence of these phosphorylated tyrosine(s) in specific signaling motifs causes the cytoplasmic domain to associate with its target proteins (see *Molecular Biology 6.28.10 Receptor kinases activate signal transduction pathways*; for review see 298; 305).

**SIGNAL TRANSDUCTION****6.28.10 Receptor kinases activate signal transduction pathways**

---

**Key Terms**

**Oncogenes** are genes whose products have the ability to transform eukaryotic cells so that they grow in a manner analogous to tumor cells. Oncogenes carried by retroviruses have names of the form *v-onc*.

**Key Concepts**

- Receptor activation causes phosphorylation of Tyr at several short sequence motifs in the cytoplasmic domain.
  - Different substrate proteins bind to particular motifs.
  - The substrate proteins may be docking proteins that bind other proteins, or signaling proteins that have an enzymatic activities that are activated by associating with the receptor.
- 

**Figure 28.18** shows that we can distinguish several types of proteins with which the activated receptor may interact:

**Figure 28.18** Phosphorylation of the intracellular domain of a receptor creates sites that bind cytosolic proteins. Three types of proteins that propagate signaling pathways are adaptors that bind other proteins, enzymes that are activated by associating with the receptor, and substrates, especially kinases, that are activated by being phosphorylated. Other targets can include structural proteins (not shown).

- The protein may be an intermediary that has no catalytic activity of its own, but serves merely to bring other proteins to the receptor. "Docking proteins" or

"adaptors" bind to an activated receptor, and then other proteins(s) bind to them, and may therefore become substrates for the receptor. By assembling complexes via such intermediaries, receptors can extend their range (for review see 2908).

- The protein may be a *target* that is activated by its association with the receptor, but which is not itself phosphorylated. For example, some enzymes are activated by binding to a receptor, such as PI3 kinase (see **Figure 28.15**).
- If the protein is a *substrate* for the enzyme, it becomes phosphorylated. If the substrate is itself an enzyme, it may be activated by the phosphorylation (example: c-Src or PLC  $\gamma$  ; see **Figure 28.15**). Sometimes the substrate is a kinase, and the pathway is continued by a cascade of kinases that successively activate one another.
- Some substrates may be end-targets, such as cytoskeletal proteins, whose phosphorylation changes their properties, and causes assembly of a new structure.

A receptor tyrosine kinase can initiate a signaling cascade at the membrane. However, in many cases, the activation of the kinase is followed by its internalization, that is, it is removed from the membrane and transported to the interior of the cell by endocytosis of a vesicle carrying a patch of plasma membrane. The relationship between kinase activity and endocytosis is unclear. Phosphorylation at particular residues may be needed for endocytosis; whether the kinase activity as such is needed may differ for various receptors. It is possible that endocytosis of receptor kinases serves principally to clear receptor (and ligand) from the surface following the response to ligand binding (thus terminating the response). However, in some cases, movement of receptors to coated pits followed by internalization could be necessary for them to act on the target proteins.

Because growth factor receptors generate signals that lead to cell division, their activation in the wrong circumstances is potentially damaging to an organism, and can lead to uncontrolled growth of cells. Many of the growth factor receptor genes are represented in the **oncogenes**, a class of mutant genes active in cancers. The mutant genes are derived by changes in cellular genes; often the mutant protein is truncated in either or both of its N-terminal or C-terminal regions. The mutant protein usually displays two properties: the tyrosine kinase has been activated; and there is no longer any response to the usual ligand. As a result, the tyrosine kinase activity of the receptor is either increased or directed against new targets (see *Molecular Biology 6.30.15 Growth factor receptor kinases can be mutated to oncogenes*).

## SIGNAL TRANSDUCTION

### 6.28.11 Signaling pathways often involve protein-protein interactions

---

#### Key Terms

An **SH2** domain (named originally as the *Src Homology* domain because it was identified in the *Src* product of the Rous sarcoma virus) is a region of ~100 amino acids that is bound by the SH2-binding domain of the protein upstream in a signal transduction cascade.

An **SH3** domain is used by some proteins that contain SH2 domains to enable them to bind to the next component downstream in a signal transduction cascade.

#### Key Concepts

- An SH2-binding site has a phospho-Tyrosine residue that is recognized by an SH2 domain.
- A receptor may have several SH2-binding sites, which are recognized by the SH2 domains of different signaling proteins.
- The signaling protein may have an SH3 domain that recognizes the next protein in the pathway.

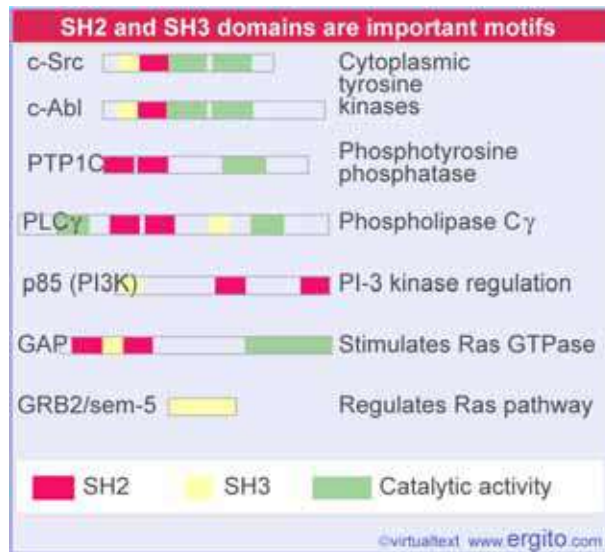

---

A common means for propagating a signal transduction pathway is for a protein specifically to recognize the next protein in the pathway by means of a physical interaction (for review see 2908). (This contrasts with the generation of a small molecule [second messenger] that interacts with the next protein in the pathway.) The usual mechanism for a protein-protein interaction in a signal pathway is for a domain in one protein to recognize a rather short motif in a second protein. The salient feature of the target motif may be its sequence or its structure. Phospho-Tyr residues are often components of such motifs, allowing the motif to be made active by phosphorylation or made inactive by dephosphorylation (for review see 3430). Another common feature of target motifs is the amino acid proline, which causes a characteristic turn in a polypeptide chain (for review see 2918).

Two motifs found in a variety of cytoplasmic proteins that are involved in signal transduction are used to connect proteins to the components that are upstream and downstream of them in a signaling pathway. The domains are named **SH2** and **SH3**, for *Src* homology, because they were originally described in the c-*Src* cytosolic tyrosine kinase (see *Molecular Biology* 6.30.16 *Src* is the prototype for the proto-oncogenic cytoplasmic tyrosine kinases; for review see 299; 302).

The presence of SH2 and SH3 domains in various proteins is summarized in **Figure 28.19**. The cytoplasmic tyrosine kinases comprise one group of proteins that have these domains; other prominent members are phospholipase C  $\gamma$  and the regulatory subunit (p85) of PI3 kinase (both targets for activation by receptor tyrosine kinases; see **Figure 28.15**). The extreme example of a protein with these domains is

Grb2/sem5, which consists *solely* of an SH2 domain flanked by two SH3 domains (see later).

**Figure 28.19** Several types of proteins involved in signaling have SH2 and SH3 domains.

Some proteins contain multiple SH2 domains, which increases their affinity for binding to phosphoproteins or confers the ability to bind to different phosphoproteins. A receptor may contain different SH2-binding sites, enabling it to activate a variety of target proteins. **Figure 28.20** summarizes the organization of the cytoplasmic domain of the PDGF receptor, which has ~10 distinct SH2-binding sites, each created by a different phosphorylation event. Different pathways may be triggered by the proteins that bind to the various phosphorylated residues (794).

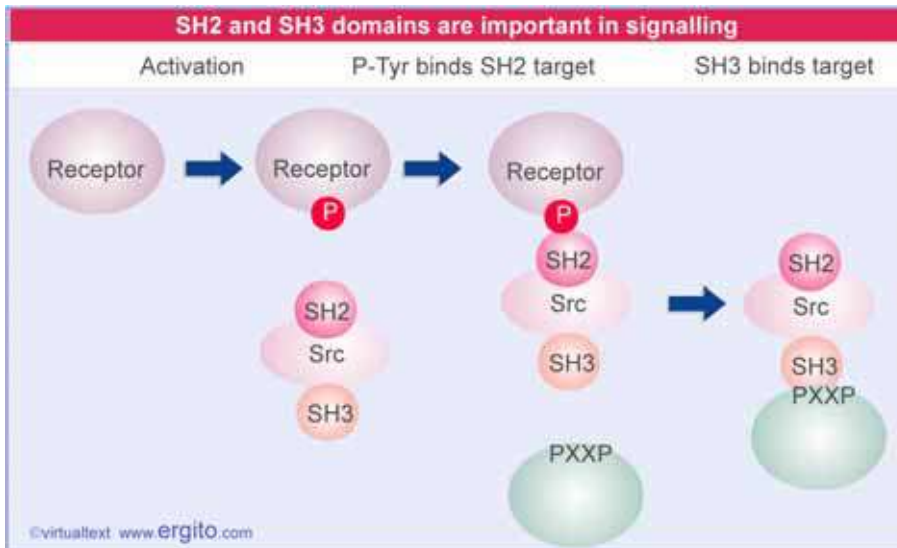

**Figure 28.20** Autophosphorylation of the cytosolic domain of the PDGF receptor creates SH2-binding sites for several proteins. Some sites can bind more than one type of SH2 domain. Some SH2-containing proteins can bind to more than one site. The kinase domain consists of two separated regions (shown in blue), and is activated by the phosphorylation site in it.

A protein that contains an SH2 domain is activated when it binds to an SH2-binding site. The activation may involve the SH2-containing protein directly (when it itself has an enzymatic activity) or may be indirect. The enzymatic activities that are regulated directly are most commonly kinases, phosphatases, or phospholipases. An example of a protein containing an SH2 domain that does not have a catalytic activity is provided by p85, the regulatory subunit of PI3 kinase; when p85 binds to a receptor, it is the associated PI3K catalytic subunit that is activated.

**Figure 28.21** shows that the **SH3** domain provides the effector function by which some SH2-containing proteins bind to a downstream component. The case of the "adaptor" Grb2 strengthens this idea; consisting only of SH2 and SH3 domains, it uses the SH2 domain to contact the component upstream in the pathway, and the SH3 domain to contact the component downstream. SH3 binds the motif PXXP in a

sequence-specific manner (see *Molecular Biology 6.28.13 Prolines are important determinants in recognition sites*). When an activated receptor binds Grb2, the SH3 domain of Grb2 binds to a target protein that contains the PXXP motif (805).

**Figure 28.21** SH2 and SH3 domains are used for protein-protein interactions in signal transduction cascades. Typically a phosphorylated receptor recognizes an SH2 target in its substrate, and an SH3 domain in the substrate then recognizes the next protein in the cascade.

SH3 domains often provide connections to small GTP-binding proteins (of which Ras is the paradigm). Another role that has been proposed for SH3 domains (and in particular for the SH3 domain of c-Src) is the ability to interact with proteins of the cytoskeleton, thus triggering changes in cell structure.

## SIGNAL TRANSDUCTION

### 6.28.12 Phosphotyrosine is the critical feature in binding to an SH2 domain

---

#### Key Terms

An **SH2** domain (named originally as the *Src Homology* domain because it was identified in the *Src* product of the Rous sarcoma virus) is a region of ~100 amino acids that is bound by the SH2-binding domain of the protein upstream in a signal transduction cascade.

An **SH2-binding site** is an area on a protein that interacts with the SH2 domain of another protein.

#### Key Concepts

- An SH2-binding site consists of phospho-Tyrosine and <5 amino acids on its C-terminal side.
- An SH2 domain forms a globular structure with a pocket that binds the phospho-Tyrosine of the SH2-binding site of the target protein.

---

The **SH2** domain is a region of ~100 amino acids that interacts with a target site in other proteins. The target site is called an **SH2-binding site**. **Figure 28.22** shows an example of a reaction in which SH2 domains are involved. Activation of a tyrosine kinase receptor causes autophosphorylation of a site in the cytosolic tail. Phosphorylation converts the site into an SH2-binding site. So a protein with a corresponding SH2 domain binds to the receptor only when the receptor is phosphorylated.

**Figure 28.22** Phosphorylation of tyrosine in an SH2-binding domain creates a binding site for a protein that has an SH2 domain.

An SH2 domain specifically binds to a particular SH2-binding site. The specificity of each SH2 domain is different (except for a group of kinases related to Src, which seem to share the same specificity). The typical SH2-binding site is only 3-5 amino acids long, consisting of a phosphotyrosine and the amino acids on its C-terminal side. SH2 binding is a high-affinity interaction, as much as  $10^3\times$  tighter than a typical kinase-substrate binding reaction (807).

The SH2 domain has a globular structure in which its N-terminal and C-terminal ends are close together, so that its structure is relatively independent of the rest of the protein. The phosphotyrosine in the SH2-binding site binds to a pocket in the SH2 domain, as illustrated in **Figure 28.23**.

**Figure 28.23** The crystal structure of an SH2 domain (purple strands) bound to a peptide containing phosphotyrosine shows that the P-Tyr (white) fits into the SH2 domain, and the 4 C-terminal amino acids in the peptide (backbone yellow, side chains green) also make contact. Photograph kindly provided by John Kuriyan.

**SIGNAL TRANSDUCTION****6.28.13 Prolines are important determinants in recognition sites****Key Concepts**

- An SH3 domain binds to the structure created by a PXXP amino acid sequence.
- Docking proteins often have a PTB domain that binds to the motif NPXpY in the receptor.
- A  $\beta$ -sheet in a PDZ domain binds a C-terminal  $\beta$ -strand in a target sequence.
- A WW domain recognizes a proline-rich target sequence.

**Figure 28.24** shows the interaction between an SH3 domain and a PXXP target sequence. The surface of the SH3 domain is hydrophobic and has three shallow grooves where the target sequence binds. The turns in the polypeptide chain at the proline residues create a helix (called the PPII helix), which seen in cross-section resembles a triangle with the two prolines on the base, and the other residues sticking up. The prolines fit into two of the grooves on the SH3 domain surface (for review see 2919). The PPII helix is quite similar when viewed from either the N-terminus or the C-terminus, and the ligands for SH3 domains are classified as class I or class II depending on which orientation is bound. Binding is influenced by hydrophobic and other residues in and adjacent to the core PXXP sequence.

**Figure 28.24** A PXXP sequence forms a helical structure in which the two flat prolines form a base and the intervening residues stick up out of the plane. The prolines bind to shallow grooves on the surface of the SH3 domain.

A domain that is often found in the targets of receptor kinases is the PTB (phosphotyrosine-binding motif). The PTB binds to the receptor at a motif that consists of a phosphotyrosine preceded by residues that form a  $\beta$ -turn, usually with the consensus Asn-Pro-X-phosphoY (2906). It functions somewhat differently from SH2 or SH3 in being used principally to bind "docking proteins". A docking protein

is an intermediary that recruits other proteins to the activated receptor. **Figure 28.25** shows that the docking protein uses its PTB to bind to a phosphorylated site on the receptor, and then other components of the signaling pathway in turn bind to other sites on it. The specificity with which the motif is recognized is determined by hydrophilic amino acids located a few amino acids on the N-terminal side of the phosphorylated Tyr in the receptor. The recognition reaction depends on peptide-peptide interactions, when the phosphopeptide forms an antiparallel  $\beta$ -strand juxtaposed to a  $\beta$ -sheet in the PTB (2907). The fact that it does not depend exclusively on the phosphorylation event is emphasized by the fact that some PTB domains can bind to nonphosphorylated motifs.

**Figure 28.25** A docking protein is an adaptor that connects an activated receptor to a signaling protein(s). It may have a PTB domain that recognizes the motif NPXpY in the receptor.

The use of antiparallel  $\beta$ -strand interactions in protein recognition is a common theme. **Figure 28.26** shows the example of PDZ domain recognition. A PDZ domain is a 90-100 amino acid region, often represented in multiple repeats in a protein. It is particularly important in the clustering of membrane proteins and in binding signaling proteins to membrane complexes. (It is named after three of the proteins in which these repeats are found.) It typically binds the last four amino acids at the C-terminus of a target protein. The consensus sequence for recognition is

X-Thr/Ser-X-Val-COOH. In the example shown in the figure, the target sequence binds between a  $\beta$ -strand and an  $\alpha$ -helix of the PDZ domain, and its terminal -COOH group is bound by the carboxy-binding loop (2916). Basically, the  $\beta$ -sheet of the PDZ domain is extended by adding the target peptide as an additional  $\beta$ -strand (for review see 2933).

**Figure 28.26** A peptide binds to a PDZ domain by inserting as an additional strand in an anti-parallel  $\beta$ -sheet. The strands of the  $\beta$ -sheet are shown as ribbons, with directionality indicated by the arrowheads. The peptide binds between one of the  $\beta$ -strands and an  $\alpha$ -helix in the PDZ domain. Its C-terminal end makes contacts with the COOH-binding loop.

SH3-binding sites and PDZ binding-sites have the opposite response to phosphorylation from SH2 binding-sites. Phosphorylation of a serine in the site prevents its recognition by the SH3 domain or PDZ domain, respectively.

The WW domain is another case in which a  $\beta$ -sheet interacts with a target peptide. The domain is ~38 amino acids, and has a high concentration of hydrophobic, aromatic, and proline residues. It binds target proline-rich target peptides. **Figure 28.27** shows an example in which the WW domain forms a  $\beta$ -sheet that interacts with the target consensus sequence PPXY (Pro-Pro-X-Tyr) (2917).

**Figure 28.27** A WW domain has a  $\beta$ -sheet consisting of three  $\beta$ -strands that interacts with a target peptide. The insertion shows how amino acids from two of the  $\beta$ -strands specifically interact with the target peptide. The characteristic feature is the insertion of the Trp from the WW domain between the two Pro residues in the target.

**SIGNAL TRANSDUCTION****6.28.14 The Ras/MAPK pathway is widely conserved**

---

**Key Terms**

A **MAP kinase (MAPK)** is a Ser/Thr protein kinase named for its original identification as a mitogen-activated kinase. There is a large group of cytosolic Thr/Ser protein kinases that form several signaling pathways. The name reflects their original isolation as mitogen-activated protein kinases.

**Key Concepts**

- The Ras/MAPK pathway starts with activation of the monomeric G protein Ras and then continues by a cascade in which a series of kinases activate one another.

---

The best characterized pathway that is initiated by receptor tyrosine kinases passes through the activation of a monomeric G protein to activate a cascade of cytosolic kinases. Although there are still some gaps in the pathway to fill in, and branches that have not yet been identified, the broad outline is clear, as illustrated in **Figure 28.28**.

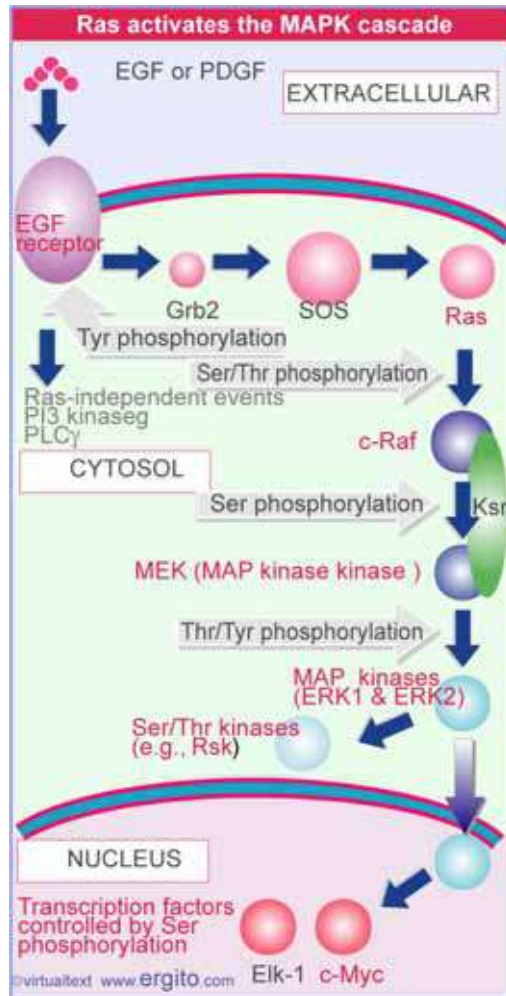

**Figure 28.28** Autophosphorylation triggers the kinase activity of the cytoplasmic domain of a receptor. The target protein may be recognized by an SH2 domain. The signal may subsequently be passed along a cascade of kinases.

In mammalian cells, the cascade is often initiated by activation of a tyrosine kinase receptor, such as the EGF or PDGF receptors. The receptor activates the Ras pathway by means of an "adaptor" protein. The activation of Ras leads to the activation of the Raf Ser/Thr kinase, which in turn activates the kinase MEK (formerly known as MAP kinase kinase); its name reflects the fact that it is the kinase that phosphorylates, and thereby activates, a **MAP kinase**.

The name of the family of MAP kinases reflects their identification as *mitogen-activated protein kinases*. One MAPK family has also been called ERKs, for extracellular signal-regulated. Some major effects of Ras are conveyed via this pathway, but there is also a branch at Ras, which involves the activation of other monomeric G proteins.

The cascade from MEK to the end products is sometimes known as the MAP kinase pathway. Each kinase in this part of the cascade phosphorylates its target kinase, and the phosphorylation event activates the kinase activity of the target enzyme, as illustrated in **Figure 28.29**. The cascade of phosphorylation events leads ultimately to the phosphorylation of transcription factors that trigger changes in cell phenotype varying from growth to differentiation, depending on the cell type. Other targets for the kinases include cytoskeletal proteins that may directly influence cell structure.

**Figure 28.29** A common signal transduction cascade passes from a receptor tyrosine kinase through an adaptor to activate Ras, which triggers a series of Ser/Thr phosphorylation events. Finally, activated MAP kinases enter the nucleus and phosphorylate transcription factors.

The relationship between components of the pathway can be tested by investigating the effects of one component upon the action of another. For example, a mutation that inactivates one component should make it impossible for the pathway to be activated by any components that act earlier. Using such tests allows components to be ordered in a pathway, and to determine whether one component is upstream or downstream of another.

The pathway has been characterized in several situations (see **Figure 28.38**): in terms of biochemical components responsible for growth of mammalian cultured cells, as the pathway involved in eye development in the fly *D. melanogaster*, as the pathway of vulval development in the worm *C. elegans*, and as the response to mating in the yeast *S. cerevisiae*.

The striking feature is that the pathway is activated by different means in each case (appropriate to the individual system), and it has different end effects in each system, but many of the intermediate components can be recognized as playing analogous roles. It is much as though Nature has developed a signal transduction cascade that can be employed wholesale by means of connecting the beginning to an appropriate stimulus and the end to an appropriate effector. The total pathway is sometimes known as the Ras pathway (named after one of the earlier components) or the Ras/MAPK pathway. Several of the components of this pathway in mammals are related to oncogenes, which suggests that the aberrant activation of this pathway at any one of various stages has a powerful potential to cause tumors.

**Figure 28.30** shows how the events initiating the cascade occur at the plasma membrane. The activated receptor tyrosine kinase associates with the SH2 domain of the adaptor protein Grb2, which binds to the receptor but is not phosphorylated. The SH3 domain of Grb2 then binds to the protein SOS, which then activates Ras. The sole role of Grb2 in activating SOS appears to be fulfilled by binding to it. The binding reaction brings SOS to the membrane, and thus into the vicinity of Ras (801). SOS causes the GDP on Ras to be replaced by GTP, which is sufficient to activate Ras. [Grb2 is not the only adaptor that can activate Ras; an alternative pathway is provided by the adaptor SHC. Which adaptor is used depends on the cell type (797; 798; 799).]

**Figure 28.30** The Ras cascade is initiated by a series of activation events that occur on the cytoplasmic face of the plasma membrane.

When a tyrosine kinase receptor is activated, its intracellular domain may be phosphorylated at more than one site, and each site may trigger a different pathway (see **Figure 28.20**). The most common consequence of a phosphorylation is to activate a signal transduction pathway, but in some cases it may have a negative effect, providing a feedback loop to limit the action of the pathway. These effects may be direct or indirect. **Figure 28.31** illustrates an example of a system in which two phosphorylations counteract each other. Torso is a receptor tyrosine kinase that activates the Ras pathway during *Drosophila* embryogenesis. Two sites become phosphorylated when it is activated. Phosphorylation of Y630 is required to activate the downstream pathway. Phosphorylation of Y918 provides negative regulation.

**Figure 28.31** Phosphorylation at different sites on a receptor tyrosine kinase may either activate or inactivate the signal transduction pathway.

The receptor binds the regulator RasGAP to the phosphorylated site Y918. This keeps RasGAP in an activated state in which it prevents Ras from functioning (see *Molecular Biology* 6.28.15 *The activation of Ras is controlled by GTP*). Y918 is phosphorylated constitutively (or when Torso is activated at a low level). Under these circumstances, the pathway is turned off.

High activation of Torso results in phosphorylation of Y630. This creates a binding site for the cytosolic phosphatase corkscrew (CSW). Corkscrew then dephosphorylates Y918. The result is to release RasGAP, which becomes ineffective, allowing Ras to function. So corkscrew is required for Torso to activate Ras.

Corkscrew may have a second role in the pathway, which is to recruit the adaptor that in turn binds to SOS, which activates Ras.

We see from this example that phosphorylated sites may influence the signaling pathway positively or negatively. The state of one phosphorylated site may in fact control the state of another site. An activating site may act indirectly (to inactivate an inhibitory site) as well as directly to recruit components of the signaling pathway.

**SIGNAL TRANSDUCTION****6.28.15 The activation of Ras is controlled by GTP**

---

**Key Concepts**

- Ras is a monomeric G protein that is active when bound to GTP and inactive when bound to GDP.
  - When GTP is hydrolyzed, the conformation of Ras changes.
  - Constitutively active forms of Ras have mutations that affect GTP binding.
  - SOS is the Ras-GEF that activates Ras by causing GDP to be replaced with GTP. SOS is activated by the adaptor Grb2, which is activated by a receptor.
  - Ras-GAP is the protein that triggers the GTPase activity and deactivates Ras.
- 

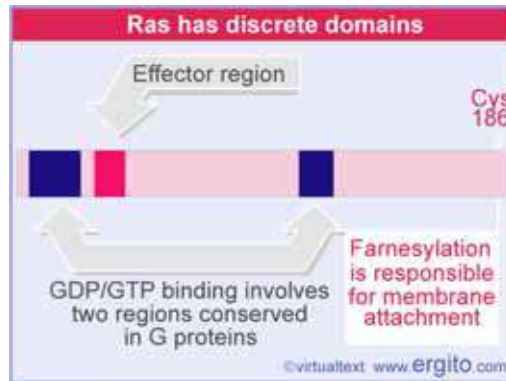

We turn now to the events involved in activating Ras. Ras is an example of a monomeric G protein (see *Molecular Biology Supplement 32.10 G proteins*). Other examples are found in protein trafficking (such as the Rabs) or in protein synthesis (such as EF-Tu). (The general principles by which such proteins are controlled are illustrated in **Figure S 33**.) The activity of the G protein depends on whether it is bound to GTP (active state) or bound to GDP (inactive state). Like trimeric G proteins, a monomeric G protein possesses an intrinsic GTPase activity that converts it from the active state to the inactive state.

**Figure 28.32** shows that two proteins control the conversion between the active and inactive states of Ras. Ras-GAP is the GAP (GTPase activating protein) that triggers the GTPase activity and thereby inactivates Ras in mammalian cultured cells. SOS is the Ras-GEF (guanine nucleotide exchange factor) that causes GDP to be replaced by GTP, and thereby activates Ras. [SOS is activated when phosphorylation of a receptor tyrosine kinase causes Grb2 to recruit it to the plasma membrane (see **Figure 28.30**) (796; for review see 300).]

**Figure 28.32** The relative amounts of Ras-GTP and Ras-GDP are controlled by two proteins. Ras-GAP inactivates Ras by stimulating hydrolysis of GTP. SOS (GEF) activates Ras by stimulating replacement of GDP by GTP, and is responsible for recycling of Ras after it has been inactivated.

The general structure of mammalian Ras proteins is illustrated in **Figure 28.33**. Three groups of regions are responsible for the characteristic activities of Ras:

**Figure 28.33** Discrete domains of Ras proteins are responsible for guanine nucleotide binding, effector function, and membrane attachment.

- The regions between residues 5-22 and 109-120 are implicated in guanine nucleotide binding by their homology with other G-binding proteins.
- Ras is attached to the cytoplasmic face of the membrane by farnesylation close to the C-terminus. Mutations that prevent the modification abolish oncogenicity, showing that membrane location is important for Ras function. After the farnesylation, the three C-terminal amino acids are cleaved from the protein, and the carboxyl group of the (now C-terminal) Cys<sup>186</sup> is methylated; also, other Cys residues in the vicinity are reversibly palmitoylated. These changes further increase affinity for the membrane.
- The effector domain (residues 30-40) is the region that reacts with the target molecule when Ras has been activated. This region is required for the oncogenic activity of Ras proteins that have been activated by mutation at position 12. The same region is required for the interaction with Ras-GAP.

The crystal structure of Ras protein is illustrated schematically in **Figure 28.34**. The regions close to the guanine nucleotide include the domains that are conserved in other GTP-binding proteins. The potential effector loop is located near the phosphates; it consists of hydrophilic residues, and is potentially exposed in the cytoplasm.

**Figure 28.34** The crystal structure of Ras protein has 6  $\beta$  strands, 4  $\alpha$  helices, and 9 connecting loops. The GTP is bound by a pocket generated by loops L9, L7, L2, and L1.

When GTP is hydrolyzed, there is a switch in the conformation of Ras protein. The change involves L4, which includes position 61, at which some oncogenic mutations occur. Mutations that activate Ras constitutively (these are oncogenic as discussed in *Molecular Biology 6.30.10 Ras proto-oncogenes can be activated by mutation at specific positions*) occur at position 12 in loop 1, and directly affect binding to GTP. The changes between the wild-type and oncogenic forms are restricted to these regions, and impede the ability of the mutant Ras to make the conformational switch when GTP is hydrolyzed. The primary basis for the oncogenic property, therefore, lies in the reduced ability to hydrolyze GTP.

When mitogenesis is triggered by activation of a growth factor, or when a cell is transformed into the tumorigenic state (see *Molecular Biology 6.30 Oncogenes and cancer*), there is a series of coordinated events, including changes in transcription and changes in cell structure. Activation of the Ras/MAPK pathway activates transcription factors that are responsible for one important set of changes. Other changes are triggered by the activation of a group of monomeric G proteins (Rac, Rho, and Cdc42). Each member of this group is responsible for particular types of structural change, as summarized in **Figure 28.35** (for review see 993).

**Figure 28.35** Changes in cell structure that occur during growth or transformation are mediated via monomeric G proteins.

The complete set of relationships that activates these factors is not known, but these structural changes generally can occur independently of the activation of Ras, suggesting that there are other pathways from growth factor receptors to the other monomeric G proteins.

Activation of Rho triggers the formation of actin stress fibers and their connection to the plasma membrane at sites called focal adhesions. Rho can be activated in response to addition of the lipid LPA (a component of serum), through activation of growth factors (818).

Rac can be activated by the activation of PI3 kinase (a kinase that phosphorylates a small lipid messenger) in response to (for example) activation of PDGF receptor. It stimulates membrane ruffling, formation of lamellipodia (transient structures that are driven by actin polymerization/depolymerization at the leading edge of the membrane), and progression into the G1 phase of the cell cycle. By an independent pathway it activates the stress kinases JNK and p38 (see *Molecular Biology 6.28.17 What determines specificity in signaling?*). [The two pathways can be distinguished by mutations in Rac that fail to activate one but not the other (819)].

Cdc42 activates the formation of filopodia (transient protrusions from the membrane that depend on actin polymerization), although we do not yet know in detail the pathway by which it is itself activated.

There is some crosstalk between these pathways, both laterally and vertically, as shown by the (grey) arrows in **Figure 28.35**. Rac can be activated by Ras. And Cdc42 can activate Rac, which in turn can activate Rho. This may help the coordination of the events they control; for example, lamellipodia often form along the membrane between two filopodia (making a web-like structure). All of these events are necessary for the full response to mitogenic stimulation, implying that the activation of multiple monomeric G proteins is required (820; 821).

**SIGNAL TRANSDUCTION****6.28.16 A MAP kinase pathway is a cascade**

---

**Key Concepts**

- There are at least three families of MAP kinases.
  - Ras activates the Ser/Thr kinase Raf, which activates the kinase MEK, which activates the ERK MAP kinase.
  - An alternative pathway is for a G protein to activate MEKK, which activates MEK.
  - Similar Ras/MAP kinase pathways are found in all eukaryotes.
  - The end result of activating a MAP kinase pathway is to activate transcription by phosphorylating nuclear proteins.
- 

One of the important features of signal transduction pathways is that they both diverge and converge, thus allowing different but overlapping responses to be triggered in different circumstances. Divergence may start with the initiating event. Activation of a receptor tyrosine kinase may itself trigger multiple pathways: for example, activation of EGF receptor activates the Ras pathway and also Ras-independent pathways involving second messengers (see **Figure 28.29**). There may also be "branches" later in a pathway (816).

Convergence of pathways is illustrated by the ability of different types of initiating signal to lead to the activation of MAP kinases. The original paradigm and best characterized example of a pathway leading to MAP kinase involves the activation of Ras, as summarized in **Figure 28.28**. Returning to the early events in this pathway, the next component after Ras is the Ser/Thr (cytosolic) kinase, Raf. The relationship between Ras and Raf has been puzzling. We know that Ras and Raf are on the same pathway, because both of them are required for the phosphorylation of the proteins later in the pathway (such as MAP kinase). Ras must be upstream of Raf because it is required for the activation of Raf in response to extracellular ligands. Similarly, Raf must be downstream of Ras because the pathway triggered by Ras can be suppressed by expression of a dominant-negative (kinase deficient) mutant of Raf. Ras is localized on the cytoplasmic side of the plasma membrane, and its activation results in binding of Raf, which as a result is itself brought to the vicinity of the plasma membrane. However, the events that then activate Raf, and in particular the kinase that phosphorylates it, are not yet known. The present model is that Ras activates Raf indirectly, perhaps because some kinase associated with the membrane is constitutively active (see **Figure 28.30**). The importance of localization of enzymatic activities is emphasized by the abilities of components both upstream and downstream of Ras (that is, SOS and Raf) to exercise their activating functions as a consequence of being brought from the cytosol to the plasma membrane (800; 802).

Raf activity leads to the activation of MEK. Raf directly phosphorylates MEK, which is activated by phosphorylation on two serine residues. MEK is an unusual enzyme with dual specificity, which can phosphorylate both threonine and tyrosine. Its target

is the ERK MAP kinase (869).

Both types of phosphorylation are necessary to convert a MAP kinase into the active state. There are at least 3 MAP kinase families, and they provide important switching points in their pathways. They are activated in response to a wide variety of stimuli, including stimulation of cell growth, differentiation, etc., and appear to play central roles in controlling changes in cell phenotype. The MAP kinases are serine/threonine kinases. After this point in the pathway, all the activating events take the form of serine/threonine phosphorylations.

The ultimate effect of the MAP kinase pathway is a change in the pattern of transcription. So the initiating event occurs at the cell surface, but the final readout occurs in the nucleus, where transcription factors are activated (or inactivated). This type of response requires a nuclear localization step. General possibilities for this step are illustrated in **Figure 28.36**. In the classic MAP kinase pathway, it is accomplished by the movement of a MAP kinase itself to the nucleus, where it phosphorylates target transcription factors. An alternative pathway is to phosphorylate a cytoplasmic factor; this may be a transcription factor that then moves to the nucleus or a protein that regulates a transcription factor (for example, by releasing it to go to the nucleus).

**Figure 28.36** A signal transduction cascade passes to the nucleus by translocation of a component of the pathway or of a transcription factor. The factor may translocate directly as a result of phosphorylation or may be released when an inhibitor is phosphorylated.

The MAP kinases have several targets, including other kinases, such as Rsk, which extend the cascade along various branches. The ability of some MAP kinases to translocate into the nucleus after activation extends the range of substrates. In the classic pathway, ERK1 and ERK2 are the targets of MEK, and ERK2 translocates into the nucleus after phosphorylation. The direct end of one branch of the cascade is provided by the phosphorylation of transcription factors, including, c-Myc and Elk-1 (which cooperates with SRF [serum response factor]). This enables the cascade to regulate the activity of a wide variety of genes. [The important transcription factor c-Jun is phosphorylated by another MAPK, called JNK; see *Molecular Biology* 6.28.17 *What determines specificity in signaling?* (813; for review see 309)].

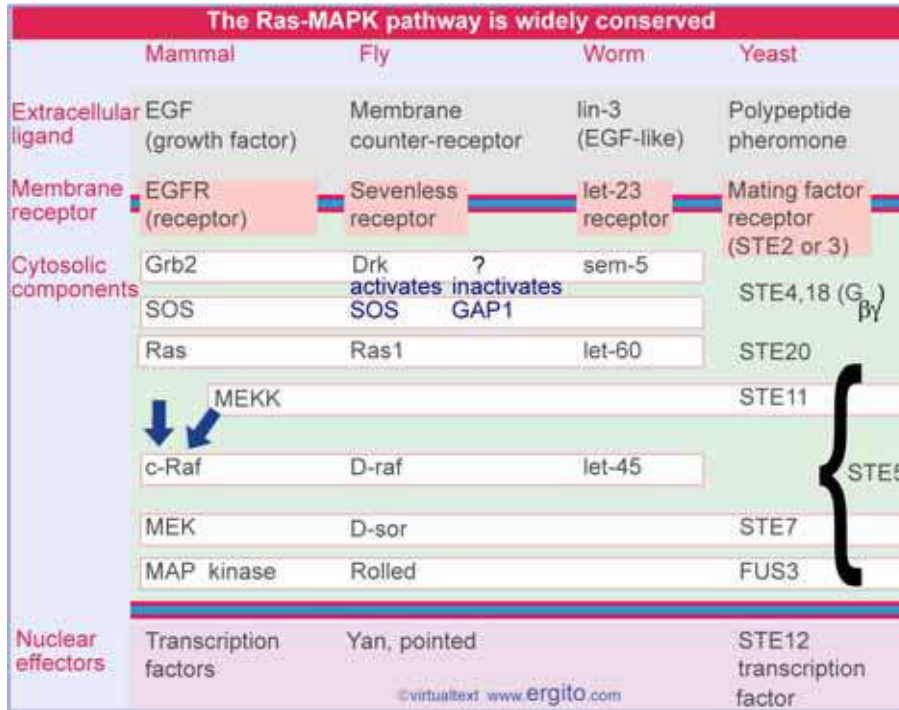

In the MAP kinase pathway, MEK provides a convergence point. Ras activates Raf, which in turn activates MEK. Another kinase that can activate MEK is MEKK (MEK kinase), which is activated by G proteins, as illustrated in **Figure 28.37**. (We have not identified the component(s) that link the activated G protein to the MEKK.)

So two principal types of stimulus at the cell surface – activation of receptor tyrosine kinases or of trimeric G proteins – both can activate the MAP kinase cascade. Formally, Raf and MEKK provide analogous functions in parallel pathways.

**Figure 28.37** Pathways activated by receptor tyrosine kinases and by serpentine receptors converge upon MEK.

The counterparts for the components of the pathways in several organisms are summarized in **Figure 28.38**. And although signaling pathways are generally different in plants from animals, the MAPK cascade is triggered by the plant systems for defense against pathogenic infection (see *Molecular Biology 5.25.21 Innate immunity utilizes conserved signaling pathways*).

**Figure 28.38** Homologous proteins are found in signal transduction cascades in a wide variety of organisms.

In mammals, fly, and worm, it starts by the activation of a receptor tyrosine kinase; in mammals and worms the ligand is a polypeptide growth factor, and in *D. melanogaster* retina it is a surface transmembrane protein on an adjacent cell (a "counter-receptor"). The pathway continues through Grb2 in mammals, and through close homologues in the worm and fly. At the next stage, a homologue of SOS functions in the fly in the same way as in mammals. The pathway continues through Ras-like proteins (that is, monomeric guanine nucleotide-binding proteins) in all three higher eukaryotes. Mutations in a homologue of GAP also may influence the pathway in *D. melanogaster*, suggesting that there are alternative regulatory circuits, at least in flies. An interesting feature is that, although the Ras-dependent pathway is utilized in a variety of cells, the mutations in the SOS and GAP functions in *Drosophila* are specific for eye development; this implies that a common pathway may be regulated by components that are tissue-specific. There is a high degree of conservation of function; for example, Grb2 can substitute for Sem-5 in worms (792; 795).

In yeast, the initiating event consists of the interaction of a polypeptide mating factor with a trimeric G protein, whose  $\beta \gamma$  dimer (STE2,3) activates the kinase STE20, which activates the MEKK, STE11. We do not know whether there are other components in addition to STE20 between G  $\beta \gamma$  and STE11, but the yeast pathway at present provides the best characterization of the route from a G protein to the MAP kinase cascade. The pathway then continues through components all of which have direct counterparts in yeast and mammals. STE7 is homologous to MEK, and FUS3 and KSSI code for kinases that share with MAP kinase the requirement for activation by phosphorylation on both threonine and tyrosine. Their targets in turn directly execute the consequences of the cascade.

The MAP kinase cascade shown in **Figure 28.38** is the best characterized, but there are also other, parallel cascades with related components. In yeast, in addition to the mating response pathway, cascades containing kinases homologous to MEKK, MEK, and MAPK respond to signaling initiated by changes in osmolarity, or activation of PKC (protein kinase C) in *S. cerevisiae* (for review see 308).

**SIGNAL TRANSDUCTION****6.28.17 What determines specificity in signaling?**

---

**Key Terms**

The **CD region (Common docking)** is a C-terminal region in a MAP kinase (separate from the active site) that is involved in binding to a target protein.

The **docking groove** is a region near to, but distinct from, the active site of a MAP kinase that is involved in binding to a target protein.

The **docking site (D domain)** is a region in a target protein that used by a MAP kinase to bind to it. The docking site has a high concentration of hydrophobic residues separated from two basic residues.

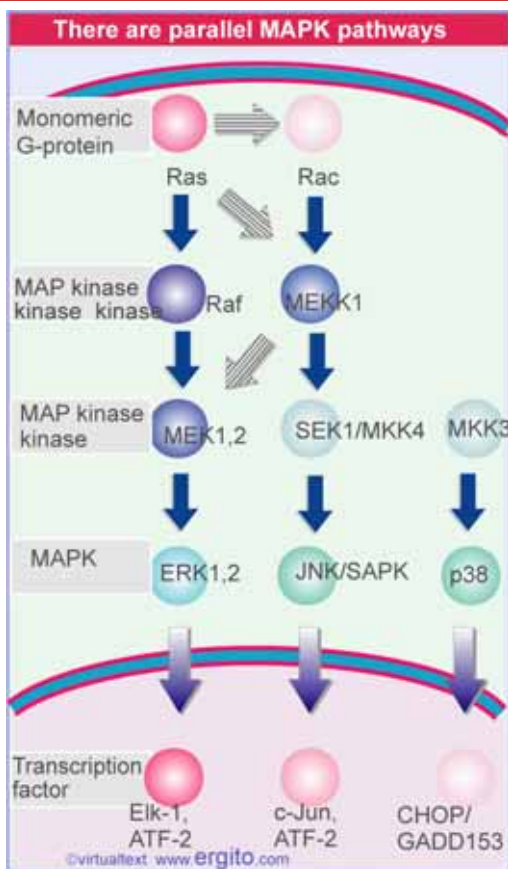

**Key Concepts**

- A MAP kinase has regions distinct from the active site that are involved in recognizing a substrate.
- Specificity in a MAP kinase pathway may be achieved by a scaffolding protein that binds several kinases that act successively.

---

The presence of multiple MAPK signaling pathways with analogous components is common. **Figure 28.39** summarizes the mammalian pathways. Each pathway functions in a linear manner, as indicated previously, but in addition there may be "crosstalk" between the pathways, when a component in one pathway can activate the subsequent component in other pathways as well as its own. Usually these "lateral" signals are weaker than those propagating down the pathway. At the very start of the pathway, there is also signaling from Ras to Rac. The strengths of these lateral signals, as well as the extent of activation of an individual pathway, may be important in determining the biological response.

**Figure 28.39** Three MAP kinase pathways have analogous components. Cross-talk between the pathways is shown by grey arrows.

The kinases in the MAPK pathways all share a similar mode of action. Each kinase has an active site that binds and phosphorylates a short target sequence containing serine or threonine followed by a proline. The activity of the enzyme is controlled by its state of phosphorylation at a short sequence (Thr-X-Tyr), where it can be activated by a kinase or deactivated by a phosphatase. Given the very short sequences that are involved, these reactions cannot in themselves provide much specificity for target selection. However, each MAP kinase belongs in one (or sometimes more) specific pathways and has a narrow specificity that is appropriate for that pathway (for review see 2841). For example, the substrate specificity of each MEK is quite narrow, and it is able to phosphorylate only one or a very few of the many MAP kinases.

Recognition of an appropriate substrate by a MAP kinase depends on two types of interactions: the catalytic site binds the substrate target sequence; and separate sites bind "docking" motifs in the target protein. **Figure 28.40** shows an example (characteristic of the ERK and p38 MAP kinases) in which two regions of the enzyme are involved in substrate recognition (2843; 2842; 2844). One region is the C-terminal **CD region** (an abbreviation for common docking). The other is the **docking groove**, which is nearby but distinct from, the catalytic active site. The regions that are recognized in the target proteins are called the **docking sites**. The best characterized type of docking site is called the D domain, and is found in many

of the target proteins for MAP kinases. It is characterized by a cluster of hydrophobic residues separated from two basic residues.

**Figure 28.40** A MAP kinase has an active site, a CD domain (pink), and a docking groove (red).

Another mechanism that is used to prevent a component of one MAP kinase cascade from activating a substrate in a parallel pathway is to localize the components. The first example of such a mechanism was provided by the yeast mating pathway. *STE5* in yeast is implicated in the cascade between *STE2,3* and *FUS3*, *KSS1*, but cannot be placed in a single position in the pathway. **Figure 28.41** shows that *STE5* binds to three of the kinases, *STE11* (MEKK), *STE7* (MEK), and *FUS3* (MAPK), suggesting that this complex has to form before each kinase can activate the next kinase in the pathway. Each of the kinases binds to a different region on *STE5*, which provides a scaffold. If the kinases can only function in the context of the *STE5* scaffold, they may be prevented from acting upon kinases in other pathways (808). Similarly, *Ksr* is a scaffolding protein that holds Raf and MEK together, so as to direct Raf to phosphorylate MEK (see **Figure 28.29**) (2374).

**Figure 28.41** STE5 provides a scaffold that is necessary for MEKK, MEK, and MAPK to assemble into an active complex. The complex is activated by STE20, which is localized at the plasma membrane by binding to Cdc42p, and activated by the G  $\beta$   $\gamma$  dimer.

Localization is important for holding the group of kinases together on the scaffold, and also for making them available to the upstream factors that activate the pathway. The monomeric G protein Cdc42p is localized on the inner side of the plasma membrane at the junction of the mother cell and the growing bud. It binds the kinase STE20 and localizes it to the cell cortex. Then the interaction of pheromone with its receptor causes the release of the G  $\beta$   $\gamma$  dimer, which also binds to STE20, activating the kinase. When STE20 phosphorylates STE11, the cascade begins (for review see 3006).

The use of scaffolds enables the same components to be employed in different pathways. **Figure 28.42** compares two of the pathways. One is the pheromone-induced activation of the kinases bound by STE5. The second is the response to osmotic pressure, when an activated receptor directly binds the scaffold protein. A difference in the construction of the osmotic pathway is that the scaffolding protein is itself one of the kinases in the cascade. The striking feature is that the first kinase in the osmoadaptation cascade is STE11, the same enzyme that is used in the same position in the pheromone pathway. The function of the osmotic pathway is exactly analogous to the pheromone pathway: STE20, bound to Cdc42p, acts on STE11 that is brought to it as part of a kinase complex. The difference is that STE11 is linked to Pbs2p and Hog1p in the osmoadaptation pathway, so that the ultimate kinase in the cascade is different, and therefore a different set of responses is produced.

**Figure 28.42** MAPK pathways differ in the first and last components, but may have common intermediate components. The components that are unique to the mating pathway are red, those that are unique to osmoadaptation are green, and those that are common to both pathways are gray.

Another example of a pathway that proceeds through a MAP kinase is provided by the activation of the transcription factor Jun in response to stress signals. **Figure 28.43** shows that activation of the kinase JNK involves both convergence and divergence. JNK is regulated by two classes of extracellular signals: UV light (typical of a stress response); and also as a consequence of activation of Ras (by an unidentified branch of the Ras pathway). JNK is a (distant) relative of MAP kinases such as the ERKs, showing the classic features of being activated by phosphorylation of Thr and Tyr, and phosphorylating its targets on Ser (817). The proteins JIP1,2 provide a scaffold that may ensure the integrity of the pathway leading to JNK activation (2236).

**Figure 28.43** JNK is a MAP-like kinase that can be activated by UV light or via Ras.

**SIGNAL TRANSDUCTION****6.28.18 Activation of a pathway can produce different results**

---

**Key Concepts**

- Transient activation of a MAP kinase may stimulate cell proliferation, whereas continued activation may trigger differentiation.
- 

Signal transduction generates differential responses to stimuli that vary qualitatively (by activating different pathways) or quantitatively (by activating pathways with different intensities or for different durations). An individual stimulus may activate one or more pathways. The strength of activation of any particular pathway may influence the response, since there are cases in which more intense or long-term stimulation of a single pathway gives a different response from less intense or short-term stimulation. One of our major aims is to understand how differences in such stimuli are transduced into the typical cellular responses.

What degree of amplification is achieved through the Ras/MAPK pathway? Typically an  $\sim 10\times$  amplification of signal can be achieved at each stage of a kinase cascade, allowing an overall amplification of  $>10^4$  through the pathway. However, the combination of the last three kinases into one complex would presumably restrict amplification at these stages. In mammalian cells, the pathway can be fully activated by very weak signals; for example, the ERK1,2 MAP kinases are fully activated when  $<5\%$  of the Raf protein molecules bind to Ras.

A puzzling feature of the Ras/MAPK pathway is that activation of the same pathway under different circumstances can cause different outcomes. When PC12 cells are treated with the growth factor NGF, they differentiate (by becoming neuronal-like) and stop dividing. When they are treated with EGF, however, they receive a signal for continued proliferation. In both cases, the principal signal transduction event is the activation of the ERK MAP kinase pathway. The differences in outcome might be explained, of course, by other (unidentified) pathways that are activated by the respective receptors. However, the major difference in the two situations is that NGF stimulation causes prolonged elevation of Ras-GTP, whereas EGF stimulation produces only a transient effect. (One reason for this difference is that EGF receptor is more susceptible to feedback mechanisms that reverse its activation.)

The idea that duration of the stimulus to the ERK MAPK pathway may be the critical parameter is supported by results showing that a variety of conditions that cause persistent activation of ERK MAP kinase all cause differentiation. By contrast, all conditions in which activation is transient lead instead to proliferation. More direct proof of the role of the ERK MAPK pathway is provided by showing that mutations constitutively activating MEK cause differentiation of PC12 cells. So activation of the ERK MAPK pathway is sufficient to trigger the differentiation response. Another point is made by the fact that the same MEK mutation has different effects in a different host cell; in fibroblasts, it stimulates proliferation. This is another example of the ability of a cell to connect the same signal transduction pathway to different

readouts (for review see 311).

How might the duration of the signal determine the type of outcome? The concentration of some active component in the pathway could increase with the duration of activation, and at some point would exceed a threshold at which it triggers a new response. One model for such an action is suggested by *Drosophila* development, in which increasing concentrations of a transcription factor activate different target genes, as the result of combinatorial associations with other factors that depend upon relative concentrations (see *Molecular Biology 6.31 Gradients, cascades, and signaling pathways*). Another possibility is suggested by the fact that prolonged activation is required before ERK2 translocates to the nucleus. The mechanism is unknown, but could mean that transient stimulation does not support the phosphorylation and activation of nuclear transcription factors, so the expression of new functions (such as those needed for differentiation) could depend upon the stimulus lasting long enough to cause translocation of ERK2 (809).

**SIGNAL TRANSDUCTION****6.28.19 Cyclic AMP and activation of CREB****Key Concepts**

- Cyclic AMP is produced when a G protein activates adenylate cyclase at the plasma membrane.
- Cyclic AMP binds to the regulatory subunit of PKA (protein kinase A), releasing the catalytic subunit, which moves to the nucleus.
- One of the major nuclear targets for PKA is the transcription factor CREB, which is activated by phosphorylation.

Cyclic AMP is the classic second messenger, and its connection to transcription is by the activation of CREB (cAMP response element binding protein). **Figure 28.44** shows how the pathway proceeds through the Ser/Thr kinase, PKA.

**Figure 28.44** When cyclic AMP binds to the R subunit of PKA, the C subunit is released; some C subunits diffuse to the nucleus, where they phosphorylate CREB.

The initial step in the pathway is activation of adenylate cyclase at the plasma

membrane by an activated G protein (see **Figure 28.11**). cAMP binds to the regulatory R subunit of PKA, which is anchored to membranes in the perinuclear region. This causes the R subunit to release the catalytic (C) subunit of PKA, which then becomes free to translocate to the nucleus. Translocation occurs by passive diffusion, and involves only a proportion of the released C subunits. In fact, the free C subunits phosphorylate targets in both the cytosol and nucleus.

The circuitry also has some feedback loops. The end-targets for PKA are also substrates for the phosphatase PPase I, which in effect reverses the action of PKA. However, PKA also has as a target a protein whose phosphorylation converts it into an inhibitor of PPase I, thus preventing the reversal of phosphorylation.

The transcription factor CREB is one of the major nuclear substrates for PKA. Phosphorylation at a single Ser residue greatly increases the activity of CREB bound to the response element CRE, which is found in genes whose transcription is induced by cAMP. The rate of transcription of these genes is directly proportional to the concentration of phosphorylated CREB in the nucleus. The kinetics of the response are limited by the relatively slow rate at which the free C subunit diffuses into the nucleus. Typically the phosphorylated C subunit reaches a maximum level in the nucleus after ~30 min, and then is slowly dephosphorylated (over several hours). Several circuits may be involved in the dephosphorylation, including direct control of phosphatases and indirect control by the entry into the nucleus of the protein PKI, which binds to the C subunit and causes it to be re-exported to the cytoplasm. The kinetics of activating PKA in the nucleus may be important in several situations, including learning, in which a weak stimulus of cAMP has only short-term effects, whereas a strong stimulus is required for long-term effects, including changes in transcription. This parallels the different consequences of short-term and long-term stimulation of the MAPK pathway (see *Molecular Biology 6.28.18 Activation of a pathway can produce different results*) (814; 815).

**SIGNAL TRANSDUCTION****6.28.20 The JAK-STAT pathway****Key Concepts**

- Some cytokine (growth factor) receptors activate JAK kinases.
- The JAK kinases phosphorylate STAT transcription factors.
- The activation of JAK and its activation of STAT occurs in a complex at the nuclear membrane.
- The phosphorylated STAT migrates to the nucleus where it activates transcription.

Some signal transduction pathways have large numbers of components (permitting a high degree of amplification) and many feedback circuits (permitting sensitive control of the duration and strength of the signal). The JAK-STAT pathway is much simpler, and consists of three components that function as illustrated in **Figure 28.45**.

**Figure 28.45** Cytokine receptors associate with and activate JAK kinases. STATs bind to the complex and are phosphorylated. They dimerize and translocate to the nucleus. The complex binds to DNA and activates transcription.

*This is a static version of an interactive figure; see <http://www.ergito.com/main.jsp?bcs=MBIO.6.28.20> to view properly.*

JAK-STAT pathways are activated by several cytokine receptors. These receptors do

not possess intrinsic kinase activities. However, binding of a cytokine causes its receptor to dimerize, which provides the signal to associate with and activate a JAK kinase. The JAK kinases take their name (originally Janus kinases) from the characteristic presence of two kinase domains in each molecule. Several members of the family are known (JAK1,2,3, etc.); each associates with a specific set of cytokine receptors. The interaction between the activated (dimeric) cytokine receptor and JAK kinase(s) in effect produces the same result as the ligand-induced dimerization of a tyrosine kinase receptor: the difference is that the receptor and kinase activities are provided by different proteins instead of by the same protein.

The JAK kinases are tyrosine kinases whose major substrates are transcription factors called STATs. There are >7 STATs; each STAT is phosphorylated by a particular set of JAK kinases. The phosphorylation occurs while the JAK is associated with the receptor at the plasma membrane. A pair of JAK kinases associates with an activated receptor, and both may be necessary for the pathway to function. An example is that stimulation by the interferon IFN  $\gamma$  requires both JAK1 and JAK2 (803; 804; for review see 303).

STAT phosphorylation leads to the formation of both homodimers and heterodimers. The basis for dimerization is a reciprocal interaction between an SH2 domain in one subunit and a phosphorylated Tyr in the other subunit (810).

The STAT dimers translocate to the nucleus, and in some cases associate with other proteins. They bind to specific recognition elements in target genes, whose transcription is activated (for review see 313).

Given a multiplicity of related cytokine receptors, JAK kinases, and STAT transcription factors, how is specificity achieved? The question is sharpened by the fact that many receptors can activate the same JAKs, but activate different STATs. Control of specificity lies with formation of a multipartite complex containing the receptor, JAKs, and STATs. The STATs interact directly with the receptor as well as with the JAKs, and an SH2 domain in a particular STAT recognizes a binding site in a particular receptor. So the major control of specificity lies with the STAT.

Stimulation of a JAK-STAT pathway is only transient. Its activation may be terminated by the action of a phosphatase. An example is the pathway activated by binding of erythropoietin (red blood cell hormone) to its receptor. This activates JAK2 kinase. Recruitment of another component terminates the reaction; the phosphatase SH-PTP1 binds via its SH2 domain to a phosphotyrosine site in the erythropoietin receptor. This site in the receptor is probably phosphorylated by JAK2. The phosphatase then dephosphorylates JAK2 and terminates the activation of the corresponding STATs. This creates a simple feedback circuit: erythropoietin receptor activates JAK2, JAK2 acts on a site in the receptor, and this site is recognized by the phosphatase that in turn acts on JAK2. This again emphasizes the way in which formation of a multicomponent complex may be used to ensure specificity in controlling the pathway (811).

**SIGNAL TRANSDUCTION****6.28.21 TGF  $\beta$  signals through Smads****Key Concepts**

- TGF  $\beta$  activates the heterodimeric type II receptor.
- The activated type II receptor phosphorylates the heterodimeric type I receptor.
- As part of the tetrameric complex, the type I receptor phosphorylates a cytosolic Smad protein.
- The Smad forms a dimer with a related protein (Smad4) which moves to the nucleus and activates transcription.

Another pathway in which phosphorylation at the membrane triggers migration of a transcription factor to the nucleus is provided by TGF  $\beta$  signaling (for review see 3650). The TGF  $\beta$  family contains many related polypeptide ligands. They bind to receptors that consist of two types of subunits, as illustrated in **Figure 28.46**. Both subunits have serine/threonine kinase activity. (Actually all serine/threonine receptor kinases are members of the TGF  $\beta$  receptor family.)

**Figure 28.46** Activation of TGF  $\beta$  receptors causes phosphorylation of a Smad, which is imported into the nucleus to activate transcription.

The ligand binds to the type II receptor, creating a receptor-ligand combination that has high affinity for the type I receptor. A tetrameric complex is formed in which the

type II receptor phosphorylates the type I receptor. (A variation occurs in a subset of these receptors that bind BMPs – bone morphogenetic proteins – which are members of the TGF  $\beta$  family. In this case, both type I and type II subunits have low affinity for the ligand, but the combination of subunits has high affinity.)

Once the active complex has formed, the type I receptor phosphorylates a member of the cytosolic Smads family. Typically a Smad activator is phosphorylated at the motif SSXS at the C-terminus. This causes it to form a dimer with the common partner Smad4. The heterodimer is imported into the nucleus, where it binds to DNA and activates transcription (812; for review see 314; 316).

The 9 Smad proteins fall into three functional categories. The pathway-specific activators are Smad2,3 (which mediate TGF  $\beta$ /activin signaling) and Smad1,5 (which activate BMP signaling). Smad4 is a universal partner which can dimerize with all of the pathway-specific Smads. Inhibitory Smads act as competitive inhibitors of the activator Smads, providing another level of complexity to the pathway. Each ligand in the TGF  $\beta$  superfamily activates a particular receptor that signals through a characteristic combination of Smads proteins. Various other proteins bind to the Smads dimers and influence their capacity to act on transcription.

Signaling systems of this type are important in early embryonic development, where they are part of the pathways that lead to development of specific tissues (typically bone formation and the development of mesoderm). Also, because TGF  $\beta$  is a powerful growth inhibitor, this pathway is involved in tumor suppression. The TGF  $\beta$  type II receptor is usually inactivated in hereditary nonpolyposis colorectal cancers, and mutations in Smad4 occur in 50% of human pancreatic cancers.

One striking feature of the JAK-STAT and TGF  $\beta$  pathways is the simplicity of their organization, compared (for example) with the Ras-MAPK pathway. The specificity of these pathways depends on variation of the components that assemble at the membrane – different combinations of JAK-STATs in the first case, different Smad proteins in the second. Once the pathway has been triggered, it functions in a direct linear manner. The component that is phosphorylated at the plasma membrane (STAT in the JAK-STAT pathway, Smad in the TGF  $\beta$  pathway) itself provides the unit that translocates to the nucleus to activate transcription – perhaps the ultimate demonstration of the role of localization

## SIGNAL TRANSDUCTION

### 6.28.22 Structural subunits can be messengers

---

It is a common need to carry a signal from an event at the cell surface to the nucleus. Activation of a receptor in the plasma membrane can stimulate a signaling pathway in many ways, but a common feature is that some component of the pathway either itself translocates to the nucleus or causes the translocation of another protein. The component that translocates can be distant in the pathway (as in the case of MAP kinases) or a protein that actually itself interacts with the receptor (as in the case of the TGF  $\beta$  or JAK-STAT pathways). A more extreme case is presented by some pathways in which the translocating component may be actually a structural subunit of the complex at the plasma membrane.

**Figure 28.47** shows a generic model for such a pathway. When a multisubunit complex is activated at the plasma membrane, one of its subunits is released. The subunit translocates to the nucleus, where (directly or indirectly) it activates transcription. A typical pattern is for the translocating subunit to activate a transcription factor that is already in the nucleus.

**Figure 28.47** Activation of a complex at the plasma membrane triggers release of a subunit that migrates to the nucleus to activate transcription.  
*This is a static version of an interactive figure; see <http://www.ergito.com/main.jsp?bcs=MBIO.6.28.22> to view properly.*

A pathway that follows this general model signals from the synapse (the connection between neurons in the nervous system). One of the multiprotein complexes that assembles at the synapse has cell surface proteins bound to a group of cytosolic proteins that include a MAGUK (membrane-associated guanylate kinase). The MAGUK has PDZ and SH3 domains (typically involved in protein-protein interactions), a protein kinase-like domain, and a guanylate kinase-like domain – all the hallmarks of a "scaffold" protein involved in assembling the components of the signaling complex. One example is the protein CASK in the nuclei of embryonic neurons. The guanylate kinase domain of CASK interacts with the nuclear transcription factor Tbr (955). This raises the possibility that CASK is a bifunctional protein: one function being in assembly of the cell surface complex, the other being in activating transcription in the nucleus.

## SIGNAL TRANSDUCTION

### 6.28.23 Summary

---

Lipids may cross the plasma membrane, but specific transport mechanisms are required to promote the passage of hydrophilic molecules. Integral proteins of the plasma membrane offer several means for communication between the extracellular milieu and the cytoplasm. They include ion channels, transporters, and receptors. All such proteins reside in the plasma membrane by means of hydrophobic domains.

Ions may be transported by carrier proteins, which may utilize passive diffusion or may be connected to energy sources to undertake active diffusion. The detailed mechanism of movement via a carrier is not clear, but is presumed to involve conformational changes in the carrier protein that directly or indirectly allow a substrate to move from one side of the membrane to the other. Ion channels can be used for passive diffusion (driven by the gradient). They may be gated (controlled) by voltage, extracellular ligands, or cytoplasmic second messengers. Channels typically have multiple subunits, each with several transmembrane domains; hydrophilic residues within the transmembrane domains face inward so as to create a hydrophilic path through the membrane.

Receptors typically are group I proteins, with a single transmembrane domain, consisting exclusively of uncharged amino acids, connecting the extracellular and cytosolic domains. Many receptors for growth factors are protein tyrosine kinases. Such receptors have a binding site for their ligand in the extracellular domain, and a kinase activity in their cytoplasmic domain. When a ligand binds to the receptor, it causes the extracellular domain to dimerize; most often the product is a homodimer, but there are some cases where heterodimers are formed. The dimerization of the extracellular domains causes the transmembrane domains to diffuse laterally within the membrane, bringing the cytoplasmic domains into contact. This results in an autophosphorylation in which each monomeric subunit phosphorylates the other.

The phosphorylation creates a binding site for the SH2 motif of a target protein. Specificity in the SH2-binding site typically is determined by the phosphotyrosine in conjunction with the 4-5 neighboring amino acids on its C-terminal side. The next active component in the pathway may be activated indirectly or directly. Some target proteins are adaptors that are activated by binding to the phosphorylated receptor, and they in turn activate other proteins. An adaptor typically uses its SH2 domain to bind the receptor and uses an SH3 domain to bind the next component in the pathway. Other target proteins are substrates for phosphorylation, and are activated by the acquisition of the phosphate group.

One group of effectors consists of enzymes that generate second messengers, most typically phospholipases and kinases that generate or phosphorylate small lipids. Another type of pathway consists of the activation of a kinase cascade, in which a series of kinases successively activate one another, leading ultimately to the phosphorylation and activation of transcription factors in the nucleus. The MAP kinase pathway is the paradigm for this type of response.

The connection from receptor tyrosine kinases to the MAP kinase pathway passes

through Ras. An adaptor (Grb2 in mammalian cells) is activated by binding to the phosphorylated receptor. Grb2 binds to SOS, and SOS causes GDP to be replaced by GTP on Ras. Ras is anchored to the cytoplasmic face of the membrane. The activated Ras binds the Ser/Thr kinase Raf, thus bringing Raf to the membrane, which causes Raf to be activated, probably because it is phosphorylated by a kinase associated with the membrane. Raf phosphorylates MEK, which is a dual-specificity kinase that phosphorylates ERK MAP kinases on both tyrosine and threonine. ERK MAP kinases activate other kinases; ERK2 MAP kinase also translocates to the nucleus, where it phosphorylates transcription factors that trigger pathways required for cell growth (in mammalian cells) or differentiation (in fly retina, worm vulva, or yeast mating).

An alternative connection to the MAP kinase cascade exists from serpentine receptors. Activation of a trimeric G protein causes MEKK to be activated. One component in the pathway between G  $\beta \gamma$  and MEKK in *S. cerevisiae* is the kinase STE20. The MEKK (STE11), MEK (STE7), and MAPK (Fus3) form a complex with the scaffold protein STE5 that may be necessary for the kinases to function. The use of scaffolding proteins allows the same kinases to participate in different pathways, but to signal to the downstream components only of the pathway that activates them.

The cyclic AMP pathway for activating transcription proceeds by releasing the catalytic subunit of PKA in the cytosol. It diffuses to the nucleus, where it phosphorylates the transcription factor CREB. The activity of this factor is responsible for activating cAMP-inducible genes. The response is down regulated by phosphatases that dephosphorylate CREB and by an inhibitor that exports the C subunit back to the cytosol.

JAK-STAT pathways are activated by cytokine receptors. The activated receptor associates with a JAK kinase and activates it. The target for the kinase is a STAT(s); STATs associate with a receptor-JAK kinase complex, are phosphorylated by the JAK kinase, dimerize, translocate to the nucleus, and form a DNA-binding complex that activates transcription at a set of target genes. In an analogous manner, TGF  $\beta$  ligands activate type II/type I receptor systems that phosphorylate Smad proteins, which then are imported into the nucleus to activate transcription.

## CELL CYCLE AND GROWTH REGULATION

### 6.29.1 Introduction

---

#### Key Terms

The **cell cycle** is the set of stages through which a cell progresses from one division to the next.

**Interphase** is the period between mitotic cell divisions; divided into G<sub>1</sub>, S, and G<sub>2</sub>.

**Mitosis (M phase)** is the process by which the cell nucleus divides, resulting in daughter cells that contain the same amount of genetic material as the parent cell.

The two cells that result from a cell division are referred to as **daughter cells**. In budding yeast only the cell derived from the bud is called the daughter cell.

**G<sub>1</sub>** is the period of the eukaryotic cell cycle between the last mitosis and the start of DNA replication.

**S phase** is the restricted part of the eukaryotic cell cycle during which synthesis of DNA occurs.

**G<sub>2</sub> phase** is the period of the cell cycle separating the replication of a cell's chromosomes (S phase) from the following mitosis (M phase).

The **spindle** guides the movement of chromosomes during cell division. The structure is made up of microtubules.

---

The act of division is the culmination of a series of events that have occurred since the last time a cell divided. The period between two mitotic divisions defines the somatic **cell cycle**. The time from the end of one mitosis to the start of the next is called **interphase**. The period of actual division, corresponding to the visible mitosis, is called **M phase**.

In order to divide, a eukaryotic somatic cell must double its mass and then apportion its components equally between the two **daughter cells**. Doubling of size is a continuous process, resulting from transcription and translation of the genes that code for the proteins constituting the particular cell phenotype. By contrast, reproduction of the genome occurs only during a specific period of DNA synthesis.

Mitosis of a somatic cell generates two identical daughter cells, each bearing a diploid complement of chromosomes. Interphase is divided into periods that are defined by reference to the timing of DNA synthesis, as summarized in **Figure 29.1**:

**Figure 29.1** Overview: interphase is divided into the G1, S, and G2 periods. One cell cycle is separated from the next by mitosis (M). Cells may withdraw from the cycle into G0 or reenter from it.

- Cells are released from mitosis into **G1** phase, when RNAs and proteins are synthesized, but there is no DNA replication.
- The initiation of DNA replication marks the transition from G1 phase to the period of **S phase**. S phase is defined as lasting until all of the DNA has been replicated. During S phase, the total content of DNA increases from the diploid value of  $2n$  to the fully replicated value of  $4n$ .
- The period from the end of S phase until mitosis is called **G2** phase; during this period, the cell has two complete diploid sets of chromosomes.

[S phase was so called as the synthetic period when DNA is replicated, G1 and G2 standing for the two "gaps" in the cell cycle when there is no DNA synthesis (823).]

The changes in cellular components are summarized in **Figure 29.2**. During interphase, there is little visible change in the appearance of the cell. The more or less continuous increase of RNA and protein contrasts with the discrete doubling of DNA. The nucleus increases in size predominantly during S phase, when proteins accumulate to match the production of DNA. Chromatin remains a compact mass in which no change of state is visible.

**Figure 29.2** Synthesis of RNA and proteins occurs continuously, but DNA synthesis occurs only in the discrete period of S phase. The units of mass are arbitrary.

Mitosis segregates one diploid set of chromosomes to each daughter cell. Individual chromosomes become visible only during this period, when the nuclear envelope dissolves, and the cell is reorganized on a **spindle**. The mechanism for specific segregation of material applies only to chromosomes, and other components are apportioned essentially by the flow of cytoplasm into the two daughter cells. Virtually all synthetic activities come to a halt during mitosis.

In a cycling somatic animal cell, this sequence of events is repeated every 18-24 hours. **Figure 29.1** shows that G1 phase usually occupies the bulk of this period, varying from ~6 h in a fairly rapidly growing animal cell to ~12 h in a more slowly growing cell. The duration of S phase is determined by the length of time required to replicate all the genome, and a period of 6-8 h is typical. G2 phase is usually the shortest part of interphase, essentially comprising the preparations for mitosis. M phase (mitosis) is a brief interlude in the cell cycle, usually <1 h in duration.

**CELL CYCLE AND GROWTH REGULATION****6.29.2 Cycle progression depends on discrete control points****Key Terms**

**START (restriction point)** is the point during G1 at which a cell becomes committed to division.

**G0** is a noncycling state in which a cell has ceased to divide.

**Key Concepts**

- **START** in yeast cells and the restriction point in animal cells define the time in G1 when a cell makes a commitment to divide.

There are two points at which a decision may be taken on whether to proceed through another cell cycle. These are superimposed on the cycle in **Figure 29.3**:

**Figure 29.3** Commitment to replication occurs in G1, and commitment to division occurs in G2.

- *Commitment to chromosome replication occurs in G1 phase.* If conditions to pass a "commitment point" are satisfied, there is a lag period and then a cell enters S phase. The commitment point has been defined most clearly in yeast cells, where it is called **START**. The comparable feature in animal cells is called the **restriction point**.
- *Commitment to mitotic division occurs at the end of G2.* If the cell does not divide at this point, it remains in the condition of having twice the normal complement of chromosomes.

How do cells use these two control points?

For animal cells growing in culture, G1 control is the major point of decision, and G2/M control is subsidiary. Cells spend the longest part of their cycle in G1, and it is the length of G1 that is adjusted in response to growth conditions. When a cell proceeds past G1, barring accidents it will complete S phase, proceed through G2, and divide. Cultured cells do not halt in G2. Control at G1 is probably typical of most diploid cells, in culture or *in vivo*.

Some cell phenotypes do not divide at all. These cells are often considered to have withdrawn from the cell cycle into another state, resembling G1 but distinct from it because they are unable to proceed into S phase. This noncycling state is called **G0**. Certain types of cells can be stimulated to leave G0 and reenter a cell cycle. Withdrawal from, or reentry into, the cell cycle can occur before the restriction point in G1 (see **Figure 29.1**).

Some cell types do halt in G2. In the diploid world, these are usually cells likely to be called upon to divide again; for example, nuclei at some stages of insect embryogenesis divide and rest in the tetraploid state. In the haploid world, it is more common for cells to rest in G2; this affords some protection against damage to DNA, since there are two copies of the genome instead of the single copy present in G1. Some yeasts can use either G1 or G2 as the primary control point, depending on the nutritional conditions. Some (haploid) mosses usually use G2 as the control point.

*This content is available online at <http://www.ergito.com/main.jsp?bcs=MBIO.6.29.2>*

**CELL CYCLE AND GROWTH REGULATION****6.29.3 Checkpoints occur throughout the cell cycle****Key Terms**

A **checkpoint** is an event in the cell cycle that can only proceed if some earlier event has been completed.

**Key Concepts**

- Orderly progress through the cell cycle is controlled by checkpoints, which prevent one stage from proceeding unless necessary earlier stages have been completed.

The upper part of **Figure 29.4** (in blue) identifies the critical points in the cell cycle:

**Figure 29.4** Checkpoints control the ability of the cell to progress through the cycle by determining whether earlier stages have been completed successfully. A horizontal red bar indicates the stage at which a checkpoint blocks the cycle.

- For a cell with a cycle determined through G1 control, START marks the point at which the cell takes the basic decision: do I divide? Various parameters influence the ability of a cell to take this decision, including the response to external stimuli (such as supply of nutrients), and an assessment of whether cell mass is sufficient to support a division cycle. (Generally a cell is permitted to divide at a mass that is not absolute but is determined by a control that itself responds to growth rate.)

- The beginning of S phase is marked by the point at which the replication apparatus begins to synthesize DNA.
- The start of mitosis is identified by the moment at which the cell begins to reorganize for division.

Each of these events represents a discrete moment at which a molecular change occurs in a regulatory molecule. Once a cell has taken the decision to proceed at START, the other events will follow in order as the result of the cell cycle pathway.

**Checkpoints** that assess the readiness of the cell to proceed are superimposed on the pathway. The lower part of **Figure 29.4** (in red) shows that *each checkpoint represents a control loop that makes the initiation of one event in the cell cycle dependent on the successful completion of an earlier event*. A checkpoint works by acting directly on the factors that control progression through the cell cycle.

**Figure 29.5** summarizes the events that trigger some important checkpoints (for review see 319). DNA damage is checked at every stage of the cycle. Checkpoints for specific events related to the individual stage occur at S phase and at mitosis.

**Figure 29.5** Checkpoints can arrest the cell cycle at many points in response to intrinsic or extrinsic conditions.

Checkpoints operate within S phase to prevent replication from continuing if there are problems with the integrity of the DNA (for example, because of breaks or other damage). One important checkpoint establishes that all the DNA has been replicated. This explains why a common feature in the cycle of probably all somatic eukaryotic cells is that completion of DNA replication is a prerequisite for cell division

Several checkpoints operate at mitosis, to ensure that the cell does not try to divide unless it has completed all of the necessary preceding events. There is a checkpoint that confirms that mitosis has been successfully completed before a cell can proceed through START to commit itself to another cycle.

Two types of cycle must be coordinated for a cell to divide:

- A cell must replicate every sequence of DNA once and only once. This is controlled by licensing factor (see *Molecular Biology 4.14.20 Licensing factor controls eukaryotic rereplication* ). Having begun replication, it must complete

it; *and it must not try to divide until replication has been completed.* This control is accomplished by the checkpoint at mitosis.

- The mass of the cell must double, so that there is sufficient material to apportion to the daughter cells. So *a cell must not try to start a replication cycle unless its mass will be sufficient to support division.* Cell mass influences ability to proceed through START and may also have a checkpoint at mitosis.

Some embryonic cycles bypass some of these controls and respond instead to a timer or oscillator. So the control of the cell cycle can be coupled as required to time, growth rate, mass, and the completion of replication.

## CELL CYCLE AND GROWTH REGULATION

### 6.29.4 Cell fusion experiments identify cell cycle inducers

---

#### Key Terms

A **heterokaryon** is a cell containing two (or more) nuclei in a common cytoplasm, generated by fusing somatic cells.

The **S phase activator** is the cdk-cyclin complex that is responsible for initiating S phase.

**M phase kinase (MPF)** was originally called the maturation promoting factor (or M phase-promoting factor). It is a dimeric kinase, containing the p34 catalytic subunit and a cyclin regulatory subunit, whose activation triggers the onset of mitosis.

**Cyclins** are proteins that accumulate continuously throughout the cell cycle and are then destroyed by proteolysis during mitosis. A cyclin is one of the two subunits of the M-phase kinase.

#### Key Concepts

- The S phase activator is responsible for the ability of an S phase nucleus to induce DNA replication in a G1 nucleus in a heterokaryon.
- The M phase inducer is responsible for the ability of a mitotic cell to induce pseudo-mitosis in an interphase nucleus upon fusion of two cells.
- The M phase inducer is produced by activating the M phase kinase, which consists of a catalytic subunit and a cyclin regulatory subunit.

---

The existence of different regulators at different stages of the cell cycle was revealed by early experiments that fused together cells in different stages of the cycle. As illustrated in **Figure 29.6**, cell fusion is performed by mixing the cells in the presence of either a chemical or viral agent that causes their plasma membranes to fuse, generating a hybrid cell (called a **heterokaryon**) that contains two (or more) nuclei in a common cytoplasm.

**Figure 29.6** Cell fusions generate heterokaryons whose nuclei behave in a manner determined by the states of the cells that were fused.

When a cell in S phase is fused with a cell in G1, both nuclei in the heterokaryon replicate DNA. This suggests that *the cytoplasm of the S phase cell contains an activator of DNA replication*. The *quantity* of the activator may be important, because in fusions involving multiple cells, an increase in the ratio of S phase to G1 phase nuclei increases the rate at which G1 nuclei enter replication. The regulator identified by these fusions is called the **S phase activator**.

When a mitotic cell is fused with a cell at any stage of interphase, it causes the interphase nucleus to enter a pseudo-mitosis, characterized by a premature condensation of its chromosomes. This suggests that *an M phase inducer is present in dividing cells*.

Both the S phase and M phase inducers are present only transiently, because fusions between G1 and G2 cells do not induce replication or mitosis in either nucleus of the heterokaryon.

**Figure 29.7** relates the cell cycle to the molecular basis for the regulatory cyclical events that control transitions between phases. Some of these events require the synthesis of new proteins or the degradation of existing proteins; other events occur by reversible activation or inactivation of pre-existing components. A minimum of three molecular activities must exist, and the striking thread that connects them is that all of these activities are controlled by phosphorylation:

**Figure 29.7** The phases of the cell cycle are controlled by discrete events that happen during G1, at S phase, and at mitosis.

- During G1, the cell passes **START** and becomes committed to a division cycle. The key event is a phosphorylation. The target protein is called **RB**, and its nonphosphorylated form represses transcription of genes that are needed for the cell cycle to advance. The repression is released when RB is phosphorylated.
- The period of S phase is marked by the presence of the **S phase activator**. This is a protein kinase. It is related to the kinase that activates mitosis (which was identified first and is better characterized).
- Mitosis depends upon the activation of a pre-existing protein, the **M phase kinase**, which has two subunits. One is a kinase catalytic subunit that is activated by modification at the start of M phase. The other subunit is a **cyclin**, so named because it accumulates by continuous synthesis during interphase, but is destroyed during mitosis. Its destruction is responsible for inactivating M phase kinase and releasing the daughter cells to leave mitosis.

*A striking feature of cell cycle regulation is that similar regulatory activities are employed in (probably) all eukaryotic systems. Some of these systems have cycles that superficially appear quite different from the normal somatic cycle. So very rapid divisions in which S phase alternates directly with mitosis characterize the development of the *Xenopus* egg, where entry into mitosis is controlled by M phase kinase, the very same factor that controls somatic mitosis. Yeast cells exist in a unicellular state, and certain species divide by an asymmetrical budding process; but control of entry into S phase and control of mitosis are determined by pathways that are related to those employed in the *Xenopus* egg. Homologous genes play related roles in organisms as distant as yeasts, insects, and mammals.*

*This content is available online at <http://www.ergito.com/main.jsp?bcs=MBIO.6.29.4>*

## CELL CYCLE AND GROWTH REGULATION

### 6.29.5 M phase kinase regulates entry into mitosis

---

#### Key Terms

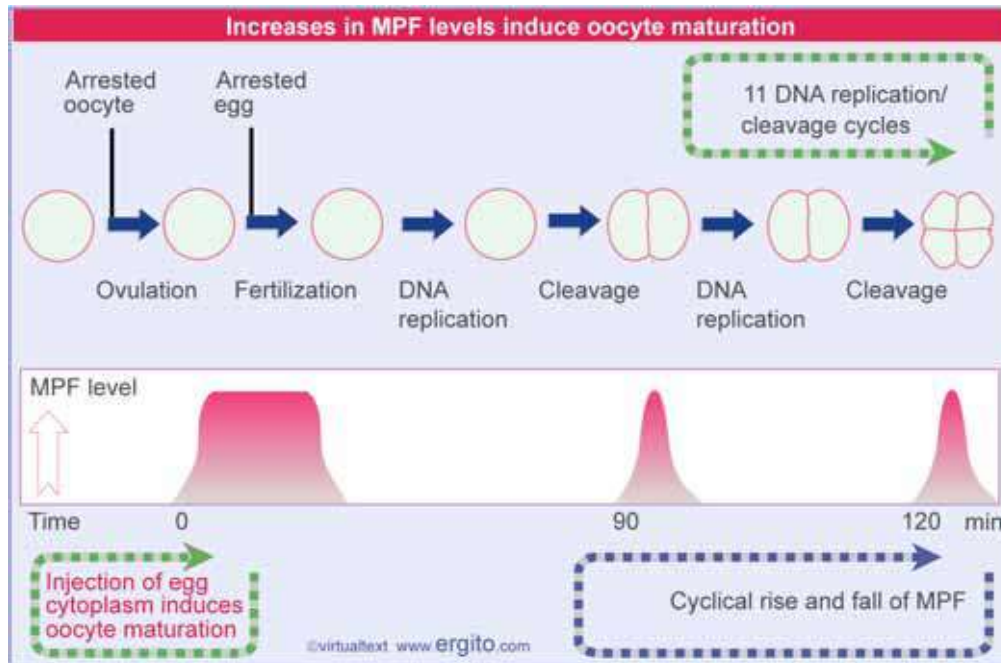

The fertilized eggs of some species are very large and initially undergo several rounds of cell division without any growth of the cells between successive mitoses. As a result each embryo is progressively divided into smaller and smaller cells. This process is the **cleavage stage** of embryogenesis.

**M phase kinase (MPF)** was originally called the maturation promoting factor (or M phase-promoting factor). It is a dimeric kinase, containing the p34 catalytic subunit and a cyclin regulatory subunit, whose activation triggers the onset of mitosis.

#### Key Concepts

- MPF was originally identified as a factor that can induce G2 stage oocytes to enter meiosis.
  - The same factor is responsible for inducing somatic cells to enter mitosis.
  - Maturation promoting factor and M phase promoting factor are both manifestations of the M phase kinase.
- 

The early development of eggs of the toad *X. laevis* has provided a particularly powerful system to analyze the features that drive a cell into mitosis. **Figure 29.8** summarizes the early divisions of *Xenopus* embryogenesis.

**Figure 29.8** MPF induces M phase in early *Xenopus* development.

In its immature form, the *Xenopus* oocyte is arrested in its first meiotic division cycle, just at the initial stage of chromosome condensation. The closest correspondence to a somatic cycle is to the G2 stage. Ovulation occurs when the hormone progesterone releases the arrest, and the egg proceeds into meiosis. When the egg is laid, it is arrested towards the end of the second meiosis in a condition that corresponds to a somatic M phase.

The egg is a large structure (~1 mm. diameter in the case of *X. laevis*), which contains a vast store of material needed for early divisions. Fertilization triggers a series of very rapid division cycles. The initial division takes ~90 minutes; then during the **cleavage stage**, another 11 divisions occur synchronously, each lasting ~30 minutes. These divisions in effect represent an alternation of S phase and mitosis; the major synthetic activity of the cleavage egg is the replication of DNA, all the required proteins having been previously synthesized and stored in the oocyte.

The size of the egg allows material to be purified from it. It is particularly useful that arrested oocytes (equivalent to G2 somatic cells) and arrested eggs (equivalent to M phase somatic cells) can be readily obtained. After eggs have been treated with progesterone, a factor can be obtained from their cytoplasm that, when injected into arrested oocytes, causes them to enter meiosis. (The original work is reviewed in *Great Experiments 8.1 The discovery of MPF*.) The active component of the extract was called *maturation promoting factor (MPF)*. The same factor can induce mitosis in somatic cells.

Because MPF turns out to have a general responsibility for causing somatic cells to enter M phase, MPF is now understood to stand for *M phase promoting factor*. The importance of MPF in inducing mitosis can be seen from its cyclical increase and decrease at the next stage of development, in the cleaving egg. As a synchronous wave of mitoses occurs in the cleaving egg, the level of MPF activity rises; as the

mitoses are completed and S phase occurs, the MPF activity disappears.

MPF causes germinal vesicle (nuclear envelope) breakdown when injected into *Xenopus* oocytes, and induces several mitotic events in a cell-free system, including nuclear envelope disaggregation, chromosome condensation, and spindle formation. MPF is a kinase that can phosphorylate a variety of protein substrates. This immediately suggests a mode for its action: *by phosphorylating target proteins at a specific point in the cell cycle, MPF controls their ability to function.* In fact, the activity of the enzyme is most often assayed by its ability to phosphorylate target proteins (rather than by the induction of mitosis), and so the name *M phase kinase* provides a better description.

*This content is available online at <http://www.ergito.com/main.jsp?bcs=MBIO.6.29.5>*

---

## CELL CYCLE AND GROWTH REGULATION

### 6.29.6 M phase kinase is a dimer of a catalytic subunit and a regulatory cyclin

---

#### Key Concepts

- Cdc2 is the catalytic subunit of M phase kinase and phosphorylates target proteins on Ser or Thr.
- The regulatory subunit is cyclin A or cyclin B.
- Activation results from covalent modification of the Cdc2 subunit.
- Inactivation results from degradation of the cyclin subunit.

---

M phase kinase consists of two types of subunit with different functions:

- Cdc2 is the *catalytic subunit* which phosphorylates serine and threonine residues in target proteins. It is named for the homologous protein in *S. pombe*.
- Its partner is a cyclin; this is a *regulatory subunit* which is necessary for the kinase to function with appropriate substrates.

The crystal structure of a dimer shows that the cyclin induces a change in the conformation of its partner that is necessary to create the active kinase site. So a catalytic subunit by itself is inactive, and can be active only when joined by a cyclin partner.

An M phase kinase typically has a single type of catalytic subunit (Cdc2), but may have any one of several alternative cyclin partners. There are two general types of mitotic cyclins, A and B. They are characterized by the sequence of a stretch of ~150 amino acids (sometimes known as the cyclin box). In mammals and frogs, the B cyclins can be divided into the subtypes B1 and B2.

So there are (at least) two general forms of the M phase kinase: Cdc2-cyclin A and Cdc2-cyclin B. The common properties of the cyclins suggest that they have the same type of function: to influence the activity of the catalytic subunit of M phase kinase. Yet the two classes of cyclins have only weak similarity and follow a different temporal and spatial pattern of behavior. Although they are involved in the timing and localization of M phase kinase activity, we do not know how they function as regulatory subunits in determining the specificity of the catalytic subunit. We should like to know in particular whether Cdc2-cyclin A and Cdc2-cyclin B recognize different proteins as substrates.

The events that activate M phase kinase at G2/M and inactivate it during M phase identify crucial points in the cell cycle. Activation and inactivation are achieved by different types of action:

- *Activation requires modification of the catalytic subunit.* In most cells, the level of Cdc2 remains constant through the cycle, and is in excess compared to the cyclins. Cyclins are necessary to turn on the M phase specific kinase activity of Cdc2. However, they cannot provide the activating event because they accumulate to a maximum level before the kinase activity appears. The intact Cdc2-cyclin dimer accumulates in an inactive form; modification of Cdc2 is the critical event that triggers the G2/M transition (833; 836).
- *Inactivation is achieved by the physical destruction of the cyclin.* Cyclins were originally named for their property of accumulating continuously through the cell cycle; then they are destroyed abruptly by proteolysis during mitosis (see **Figure 29.7**). The timing of cyclin destruction is characteristic; typically A precedes B (by a few minutes in embryonic divisions, by rather longer in a cultured cell cycle), and this difference appears to be common to all cells (825; 830; 832).

What activates the catalytic activity of the M phase kinase? Cdc2 is itself a phosphoprotein, and its state of phosphorylation is a crucial determinant of activity. The events involved in the cycle of activation and inactivation of M phase kinase are summarized in **Figure 29.9**. For M phase kinase to be active, phosphate groups must be absent at some positions, but present at another position (826).

**Figure 29.9** The activity of M phase kinase is regulated by phosphorylation, dephosphorylation, and protein proteolysis. The 3 phosphorylated amino acids are: Thr-14, Tyr-15, Thr-161. The first two are in the ATP-binding site.

Two residues located within the ATP-binding site of Cdc2 must be *dephosphorylated* in order to activate the kinase (in mouse cells). The phosphates are located on Thr-14 and Tyr-15; both are removed by the same (dual specificity) phosphatase. M phase kinase is autocatalytic, that is, the activation of a small amount of the kinase is sufficient to trigger activation of the rest. This could be explained if M phase kinase itself activates the phosphatase.

Another phosphorylation occurs on Thr-161 of Cdc2. This phosphate group is added in G2 and removed at the end of mitosis. The phosphate is *required* for activity of Cdc2; mutations introducing an amino acid that cannot be phosphorylated at this site inactivate the kinase activity.

Association of the catalytic and cyclin subunits, and phosphorylation and dephosphorylation, occur in a specific order. Cyclin B associates specifically with the tyrosine-*dephosphorylated* form of Cdc2 *in vitro*. This generates a potentially active dimer. However, formation of the dimer causes Thr-14/Tyr-15 to be phosphorylated. So *association with cyclin induces the inactivating event*. The dimer is then maintained in its inactive form until the phosphates are removed.

Cyclins A and B both have a short motif near the N-terminus – the cyclin destruction box – which is required to make the cyclin a target for proteolysis. Cyclins are degraded by a common proteolytic system, the proteasome (a complex containing proteolytic activities that recognizes its targets when ubiquitin is added to them; see *Molecular Biology Supplement 8.32 The proteasome is a large machine that degrades ubiquitinated proteins*).

Destruction of the cyclin subunits is responsible for inactivating M phase kinase during mitosis, and is necessary for cells to exit mitosis. A truncated cyclin B that lacks the N-terminal region is resistant to proteolysis. When this protein is synthesized in *Xenopus* eggs, or in a cell-free extract that undertakes some of the typical cycling reactions, it causes anaphase arrest. This is the basis for concluding that *loss of kinase activity is a prerequisite for completing mitosis*.

An important question is how the roles of cyclin A and cyclin B differ in mitosis. A hint that their functions are different is provided by differences in the timing of their synthesis and destruction, but there is as yet no direct evidence to show whether both cyclins are required for passage through mitosis in an animal cell or whether they are redundant with one another.

**CELL CYCLE AND GROWTH REGULATION****6.29.7 Protein phosphorylation and dephosphorylation control the cell cycle**

---

**Key Concepts**

- M phase kinase triggers mitosis by phosphorylating a wide variety of substrates.
  - Mitosis is terminated by dephosphorylating the substrates.
  - One of the best substrates for M phase kinase, which is often used to assay its activity, is histone H1.
- 

Phosphorylation (catalyzed by kinases) and dephosphorylation (catalyzed by phosphatases) are the critical events that regulate the cell cycle. *They are used both to control the activities of the regulatory circuit itself and to control the activities of the substrates that execute the decisions of the regulatory circuit.*

The cell cycle regulatory circuit consists of a series of kinases and phosphatases that respond to external signals and checkpoints by phosphorylating or dephosphorylating the next member of the pathway. The ultimate readout of the circuit is to determine the activity of M phase kinase (or the S phase kinase) by controlling its state of phosphorylation.

Activation of M phase kinase is the event that triggers onset of M phase. Inactivation is necessary to exit M phase. This suggests that the events regulated by M phase kinase are reversible: *phosphorylation of substrates is required for the reorganization of the cell into a mitotic spindle, and dephosphorylation of the same substrates is required to return to an interphase organization.*

What are the targets for M phase kinase? A major reorganization of the cell occurs at mitosis, and the ability of MPF to induce mitosis implies that the M phase kinase triggers these activities. Does M phase kinase act directly or indirectly upon the various potential substrates? Two general models could be proposed for its role:

- It may be a "master regulator" that phosphorylates target proteins that in turn act to regulate other necessary functions – a classic cascade.
- Or it may directly phosphorylate the proteins that are needed to execute the regulatory events or cell reorganization involved in the cycle.

The only common feature in substrates that are phosphorylated by M phase kinase is the presence of the duo Ser-Pro, flanked by basic residues (most often in the form Ser-Pro-X-Lys). Potential substrates, based upon the ability of M phase kinase preparations to phosphorylate targets *in vitro*, include H1 histone (perhaps required to condense chromosomes), lamins (possibly required for nuclear envelope breakdown), nucleolin (potentially involved in the arrest of ribosome synthesis), and

other structural and enzymatic activities. The strength of the evidence varies as to which of these targets is phosphorylated *in vivo* in a cyclic manner and whether M phase kinase is in fact the active enzyme. From the variety of substrates, however, it seems likely that M phase kinase acts directly upon many of the proteins that are directly involved in the change in cell structure at mitosis.

How can we determine whether a potential substrate is an authentic target for Cdc2 in the cell cycle? The same sites should be phosphorylated by Cdc2 *in vitro* that are cyclically phosphorylated *in vivo* at time(s) when Cdc2 is known to be active. Ideally it should be possible to show that a mutation in Cdc2 kinase activity blocks the phosphorylation *in vivo*, but this is at present practical only in yeast. To conclude that the phosphorylation is a significant event in the cycle, some function of the protein must be altered by the presence of phosphate. This can be tested by making mutations at the amino acid that is phosphorylated to determine whether the absence of phosphorylation blocks a mitotic function.

The best characterized substrate for Cdc2 kinase is the H1 histone (one of the 5 histones that are the major protein constituents of chromatin; see *Molecular Biology 5.20 Nucleosomes*). It has been known for a long time that H1 is phosphorylated during the cell cycle, with 2 phosphate groups added during S phase, and 4 further phosphate groups added during mitosis. The major H1 kinase activity of the cell is provided by M phase kinase (827; 831).

What purpose the phosphorylation of H1 serves in the cell cycle remains a matter for speculation, since no effects upon chromatin structure have been directly demonstrated. It is reasonable to suppose that it might be connected with chromosome condensation at M phase. Not enough is known about the timing of modification at S phase to wonder whether it is concerned with preparations for replication (which might require uncoiling) or with the consequences of replication (when preparations for mitosis could begin). But H1 histone is an exceedingly good substrate for kinases based on the Cdc2 engine, with the result that H1 kinase activity has become the usual means by which this enzyme is assayed *in vitro*. An illustration of the appeal of this assay is its application to *S. cerevisiae*, where H1 kinase activity is routinely measured to assess the cyclic activity of M phase kinase, although this yeast in fact is unusual in containing no H1 histone!

## CELL CYCLE AND GROWTH REGULATION

### 6.29.8 Many cell cycle mutants have been found by screens in yeast

---

#### Key Terms

Some species of yeast, the most well known of which is *Saccharomyces cerevisiae*, reproduce by forming a **bud**. The bud is formed off the side of the mother cell and gradually enlarges over the course of the cell cycle. Its interior is initially continuous with the cytoplasm of the mother cell, but after a copy of the genome is segregated into the bud during mitosis a wall is constructed between the two and the bud breaks free to become a separate cell.

The **cell division cycle** is the entire sequence of events required to reliably replicate the cell's genetic material and separate the two copies into new cells. The term "cell division cycle" has been largely replaced by the term "cell cycle".

**cdc** is an abbreviation for "cell division cycle". It is most frequently used as part of the names of a large collection of yeast mutants isolated in the 1970s in which the cell cycle arrested at a specific point in each type of mutant.

#### Key Concepts

- Blocking the cell cycle is likely to kill a cell, so mutations in the cell cycle must be obtained as conditional lethals.
- Screens for conditional lethal cell cycle mutations identify ~80 genes in either *S. cerevisiae* or *S. pombe*.

---

To define the circuit for cell cycle control, we need to identify the genes that regulate progression through the cycle. We define a mutation in the cell cycle as one that *blocks the cell cycle at a specific stage*, a definition that excludes mutations in genes that control continuous processes of growth and metabolism. But the approach of characterizing mutants that are unable to proceed through the cycle has not been straightforward to develop. A mutation that prevents a cell from dividing will be lethal; and the reverse is also true, insofar as any lethal mutation will stop cells from dividing. It has therefore been difficult to devise procedures to isolate cell cycle mutants of animal cells, or, indeed, to demonstrate that potential mutants have specific blocks in the cell cycle.

Because of their nature, cell cycle mutants must be obtained as conditional lethals, so that although they are unable to grow under the conditions of isolation, they can be maintained by growth in other conditions. A series of such mutants has been isolated in two yeasts, in which the block to the cell cycle can be seen to affect the visible phenotype of the cell.

The mitotic cycles of fission yeast (*S. pombe*) and baker's yeast (*S. cerevisiae*) are summarized in **Figure 29.10**.

**Figure 29.10** *S. pombe* lengthens and then divides during a conventional cell cycle, while *S. cerevisiae* buds during a cycle in which G2 is absent or very brief, and M occupies the greatest part.

The cell cycle of *S. pombe* is divided into the usual phases (G1, S, G2, M). The cell grows longitudinally and then divides; progress through the cell cycle can be assessed (approximately) by the physical length of the cell (which doubles from 7-8  $\mu\text{m}$  to 14-16  $\mu\text{m}$ ).

The cycle of *S. cerevisiae* is unusual. Cells proceed almost directly from S phase into division, so there is effectively very little or no G2 phase. (A short G2 phase is shown in this and subsequent figures for the purpose of localizing the relative timing of events concerned with the transition into M phase.) And instead of an equal division of the cell, the daughter cell grows as a **bud** off the mother cell, eventually obtaining its independence when it is released as a small separate cell. Again the cell cycle can be followed visually in terms of the growth of the bud. Mitosis itself shares some unusual features in both types of yeast; the nuclear membrane does not break down, and segregation of chromosomes therefore is compelled to occur within the nucleus.

Extensive screens for **cell division cycle** or **cdc** mutants have been performed in both yeasts. Initial isolation relies upon the criterion that cells accumulate at a particular stage of the cell cycle at an elevated temperature (36°C), but continue normally through the cycle at 23°C. The mutant phenotype allows cells to continue growing larger while the cycle is blocked, causing an obvious aberration; in *S. pombe* the cells become highly elongated, and in *S. cerevisiae* they fail to bud. **Figure 29.11** compares cell cycle mutants with wild-type *S. pombe*. The left panel shows a group of normal cells; the center panel shows a *cdc* mutant that is blocked in the ability to divide, and has therefore become elongated, because it has continued to grow (824).

**Figure 29.11** *S. pombe* cells are stained with calcofluor to identify the cell wall (surrounding the yeast cell) and the septum (which forms a central division when a cell is dividing). Wild-type cells double in length and then divide in half, but *cdc* mutants grow much longer, and *wee* mutants divide at a much smaller size. Photograph kindly provided by Paul Nurse.

Because the mutants are temperature sensitive, the time at which a mutation takes effect can be determined by temperature shift protocols in which cells are shifted up in temperature at a specific point in the cycle. If this point is prior to the point at which the gene product acts, the cells halt at the execution point, but if the point is past the time when the protein function is needed, the cells continue their cycle.

Of the order of 80 *cdc* genes have been identified in each species, but not all of these loci are concerned with regulating the cell cycle. Many represent genes whose products are needed for metabolic purposes; for example, absence of enzymes that replicate DNA or synthesize the nucleotide precursors can block progression through S phase.

## CELL CYCLE AND GROWTH REGULATION

### 6.29.9 Cdc2 is the key regulator in yeasts

---

#### Key Terms

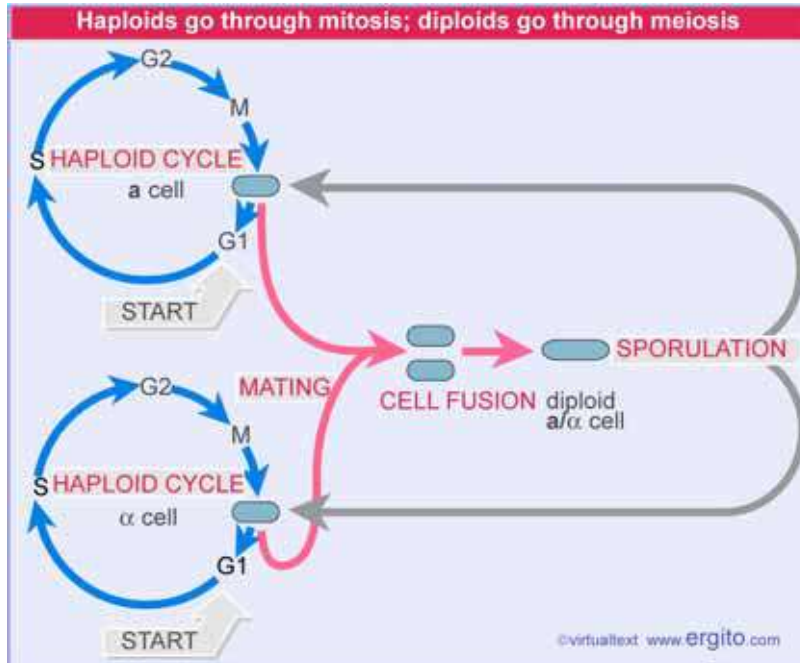

The **mating type** is a property of haploid yeast that makes it able to fuse to form a diploid only with a cell of the opposite mating type.

#### Key Concepts

- *cdc* mutants of *S. pombe* fall into two groups that block the cell cycle either at G2/M or at START in G1.
- Different *cdc2* mutant alleles may block the cycle at either of these stages.
- *CDC28* is the homologous gene in *S. cerevisiae*.
- Homologues of *cdc2* are found in all eukaryotic organisms.
- The active form of M phase kinase is phosphorylated on Thr-161; the inactive form is phosphorylated on Tyr-15 (and in animal cells also on Thr-14).

---

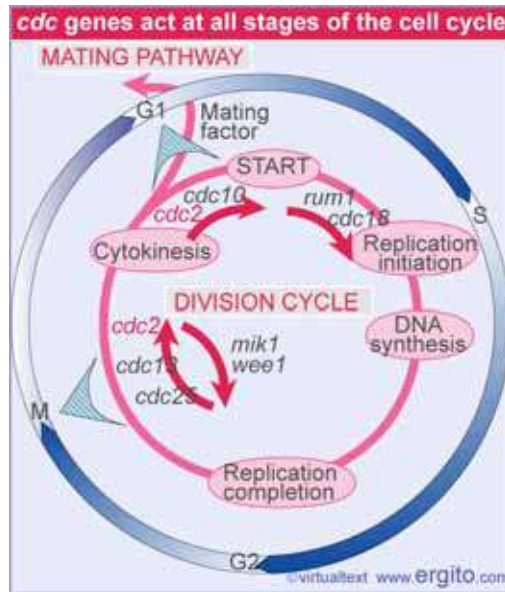

Yeast cells may exist in either haploid or diploid form. They have two forms of life cycle, as illustrated in **Figure 29.12**. Haploid cells double by mitosis. A haploid cell has a **mating type** of either *a* or  $\alpha$ . Haploids of opposite types enter the sexual mating pathway, in which they conjugate (fuse) to form diploid cells. The diploid cells in turn sporulate to form haploid cells by meiosis (see *Molecular Biology 4.18.2 The mating pathway is triggered by pheromone-receptor interactions*).

**Figure 29.12** Haploid yeast cells of either *a* or  $\alpha$  mating type may reproduce by a mitotic cycle. Cells of opposite type may mate to form an *a/α* diploid. The diploid may sporulate to generate haploid spores of both *a* and  $\alpha$  types.

A crucial point in the cell cycle is defined by the behavior of haploid cells. A haploid cell decides at a point early in G1 whether to proceed through a division cycle or to mate. The decision is influenced by environmental factors; for example, cells of opposite mating type must be present for conjugation to occur. In fact, a mating factor (a polypeptide hormone) secreted by a cell of one type causes a cell of the other type to arrest its cycle (see *Molecular Biology 4.18.2 The mating pathway is triggered by pheromone-receptor interactions*). But a mating factor can divert a cell into the mating pathway *only early in G1*; later in G1 the cell becomes committed to the division cycle and cannot be stimulated to enter the mating pathway. This assay was how the commitment point in G1 (START) was originally identified.

The events and genes involved in the cycle of *S. pombe* are summarized in **Figure 29.13**. Various *cdc* mutants of *S. pombe* block the cell cycle at one of two stages: at the boundary between G2 and M phase; or in G1 at START.

**Figure 29.13** The cell cycle in *S. pombe* requires *cdc* genes to pass specific stages, but may be retarded by genes that respond to cell size (*wee1*). Cells may be diverted into the mating pathway early in G1.

*cdc2* is identified as a crucial regulator by its involvement at *both* stages of cell cycle block: mutants of *cdc2* may be blocked prior to START or prior to M phase (depending on the point a cell had reached in the cycle when the mutation took effect).

The homologous gene in *S. cerevisiae* is called *CDC28*. A deficiency in the gene of either type of yeast can be corrected by the homologue from the other yeast. In both yeasts, proteins that resemble B-type cyclins associate with Cdc2 or *CDC28* at G2/M.

The crucial breakthrough in understanding the nature and function of M phase kinase was the observation that *Xenopus Cdc2* is the homologue of *cdc2* of *S. pombe* and *CDC28* of *S. cerevisiae*. [When this discovery was made, the *Xenopus* protein was called p34, after its size, but then it was renamed Cdc2 after its name in *S. pombe* (828; 829).]

The activity of the Cdc2 catalytic subunit in these dimers (and of the equivalent *CDC28* in *S. cerevisiae*) is controlled by phosphorylation in the same way as Cdc2 in animal cells. A difference is that in yeast there is no Thr-14, so there are only two relevant sites: Tyr-15 where phosphorylation is inhibitory; and Thr-161 where phosphorylation is required.

*The existence of a Cdc2 catalytic subunit, in organisms as diverse in evolution as yeasts, frogs, and mammals, identifies the key feature of cell cycle control. Conservation of function is indicated by the ability of the cloned human gene to complement the deficiency in cdc2 mutants of S. pombe. This was the crucial experiment that identified Cdc2 as the universal regulator (see Great Experiments 8.2 The discovery of cdc2 as the key regulator of the cell cycle).*

(Ability to compensate for the deficiency of a specific yeast mutant has been used with great effect to identify higher eukaryotic genes homologous to several cell cycle regulators of yeast. The assay introduces a cloned animal gene into a yeast mutant and then identifies cells that resume growth. It is quite remarkable that the control of the cell cycle has been so well conserved as to make this possible. However, it should be remembered that this assay does not impose very rigorous demands, and sometimes leads to the identification of a gene that is only loosely related to the mutant function.)

---

**CELL CYCLE AND GROWTH REGULATION****6.29.10 Cdc2 is the only catalytic subunit of the cell cycle activators in *S. pombe***

---

**Key Terms**

**G1** is the period of the eukaryotic cell cycle between the last mitosis and the start of DNA replication.

**Cyclins** are proteins that accumulate continuously throughout the cell cycle and are then destroyed by proteolysis during mitosis. A cyclin is one of the two subunits of the M-phase kinase.

A **mitotic cyclin (G2 cyclin)** is a regulatory subunit that partners a kinase subunit to form the M phase inducer.

**Key Concepts**

- During mitosis Cdc2 exists in a dimer with one of the mitotic cyclins (A or B).
- During G1 Cdc2 forms a dimer with a G1 cyclin.
- G1 cyclins are distantly related to mitotic cyclins but are not regulated by degradation.
- The Cdc2-G1 cyclin dimer must be activated in order to enter S phase.

---

One of the key concepts of cell cycle regulation is that each stage is controlled by a dimer consisting of a Cdc2-like catalytic subunit and a cyclin-like regulatory subunit. Either or both of these subunits may be changed between the regulatory stages, and in some cases there may in fact be several alternative versions of the dimer at one stage.

In yeast, there is only one type of catalytic subunit, and the differences between regulatory stages are determined by its partner. Thus Cdc2 in *S. pombe* has different partners at mitosis and during G1. At mitosis, its partner is the product of *cdc13*, generating an M phase kinase that resembles the Cdc2-B cyclin dimer of animal cells. During G1, the active form of Cdc2 is associated with a B-like cyclin, *cig2* (there is also a related cyclin, *cig1*).

**Figure 29.14** summarizes changes in phosphorylation of the alternative dimers during the cell cycle.

**Figure 29.14** The state of the cell cycle in *S. pombe* is defined by the forms of the Cdc2-cyclin complexes.

The upper part of the figure summarizes the condition of the M phase kinase. At mitosis, the Cdc2 subunit of the Cdc2/Cdc13 dimer is in the active state that lacks the phosphate at Tyr-15 and has the phosphate at Thr-161. At the end of mitosis, kinase activity is lost when Cdc13 is degraded. The state of phosphorylation of Cdc2 does not change at this point. As new Cdc13 is synthesized, it associates with Cdc2, but the dimeric complex is maintained in an inactive state by another protein (see **Figure 29.19**). After START, however, activity of the Cdc2/Cdc13 dimer is inhibited by addition of the phosphate to Tyr-15. Removal of the inhibitory phosphate is the trigger that activates mitosis.

The lower part of the figure shows that Cdc2 forms a dimer with cig2 during G1. This forms a kinase with the same general structure as the M phase kinase. This kinase is in effect a counterpart to the M phase kinase, and it controls progression through the earlier part of the cell cycle. cig2 resembles a B-type cyclin. The dimer is converted from the inactive state to the active state by dephosphorylation of the Tyr-15 residue of Cdc2 at or after START. We do not know what happens to the Cdc2-cig2 dimer at the transition from S phase into G2.

The existence of alternative dimers during the cell cycle suggests the concept that *cyclins can be classified according to their period of active partnership with cdc2 as G1cyclins or mitotic cyclins (also known as G2 cyclins)*. (Note that the cyclins defined in this way by their partnership with Cdc2 or a Cdc2-like protein do not necessarily have the property of cyclic degradation by which the original cyclins were defined. Cyclic degradation is a general property specifically for mitotic cyclins

in animal cells.)

We may take the concept of cyclin classification further and suggest that *the phase of the cell cycle is defined by the nature of the active cdc2-cyclin dimer*. The period of G1 and S phase is defined by the presence of an active Cdc2-G1 cyclin dimer. Progression through G1 into S is controlled by activation of the Cdc2-G1 cyclin. The period of G2 and mitosis is characterized by an active Cdc2-mitotic cyclin dimer. The transition from G2 into mitosis is controlled by activation of the Cdc2-mitotic cyclin.

The original model for the employment of Cdc2 proposed that the available form of the Cdc2-cyclin dimer was regulated simply by replacement of one cyclin with another. However, it seems now that the mitotic and G1 forms may coexist in the yeast cell, but that their activities are differently regulated at each stage of the cycle.

*This content is available online at <http://www.ergito.com/main.jsp?bcs=MBIO.6.29.10>*

---

**CELL CYCLE AND GROWTH REGULATION****6.29.11 CDC28 acts at both START and mitosis in *S. cerevisiae***

---

**Key Terms**

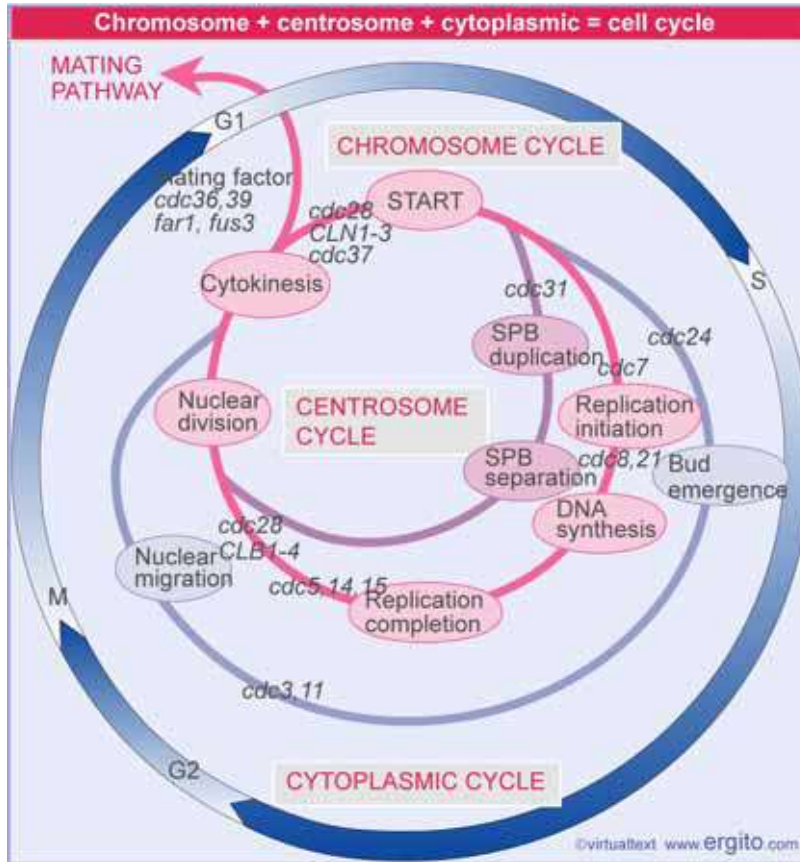

**Functionally redundant** genes fulfill the same function in the same time and place, so that mutation of every member of the set is necessary to show a deficient phenotype.

**Key Concepts**

- CDC28 forms dimers with each of 4 B-type cyclins at mitosis.
- It forms dimers with each of 3 G1 cyclins, any one of which is sufficient to activate START.

---

The analysis of *cdc* mutants in *S. cerevisiae* shows that more than one type of cycle is required to proceed from one division to the next, although the cycles are connected at crucial points. (Remember that mitosis in *S. cerevisiae* is unusual morphologically, and chromosome segregation occurs within the intact nucleus; see **Figure 29.10**.) **Figure 29.15** shows how the three cycles of *S. cerevisiae* relate to the conventional phases of the overall cell cycle:

**Figure 29.15** The cell cycle in *S. cerevisiae* consists of three cycles that separate after START and join before cytokinesis. Cells may be diverted into the mating pathway early in G1.

- The *chromosome cycle* comprises the events required to duplicate and separate the chromosomes, consisting of the initiation, continuation, and completion of S phase, and nuclear division. A mutation such as *cdc8* stops this cycle in S phase.
- Mutations in the chromosome cycle do not stop the *cytoplasmic cycle*, which consists of bud emergence and nuclear migration into the bud (visualized at the start of M phase in **Figure 29.10**). This cycle can be halted before bud emergence by *cdc24*, but the mutation does not prevent chromosome replication.
- The *centrosome cycle* consists of the events associated with the duplication and then separation of the spindle pole body (SPB), which in effect substitutes for the centrosome and organizes microtubules to allow chromosome segregation within the nucleus. Blocking this cycle, for example with *cdc31*, does not prevent S phase or bud emergence.

Completion of an entire cell cycle requires all three constituent cycles to be functional, since nuclear division requires both the chromosome and centrosome cycles, and cytokinesis requires these and the cytoplasmic cycle.

The decision on whether to initiate a division cycle is made before the point START.

The crucial gene in passing START is *CDC28* (the homologue of *cdc2* of *S. pombe*). Mutations in *CDC28* prevent all three cycles from proceeding. The ability to pass START is determined by environmental conditions, since stationary phase populations that are limited by nutrients are arrested at START. Morphologically, the cells of such a population are arrested at point after cell separation and prior to SPB duplication, bud emergence, and DNA replication, which is to say that when *S. cerevisiae* exhaust their nutrients, they complete the current cycle and arrest all three cycles before START. In terms of phases of the cell cycle, this corresponds to a point early in G1.

Most mutants in *CDC28* are blocked at START, which has therefore been characterized as the major point for *CDC28* action. This contrasts with the better characterized function of M phase kinase at M phase. However, one mutant in *CDC28* passes START normally, but is inhibited in mitosis, suggesting that *CDC28* is required to act at both points in the cycle. In fact, the function of *CDC28* is required at three stages: classically before START; then during S phase; and (of course) prior to M phase.

There is a difference in emphasis concerning control of the cell cycle in fission yeast and bakers' yeast, since in *S. pombe* we know most about control of mitosis, and in *S. cerevisiae* we know most about control of START. However, in both yeasts, the same principle applies that a single catalytic subunit (Cdc2/*CDC28*) is required for the G2/M and the G1/S transitions. It has different regulatory partners at each transition, using B-like (mitotic) cyclins at mitosis and G1 cyclins at the start of the cycle. A difference between these yeasts is found in the number of cyclin partners that are available at each stage (for review see 323).

A single regulatory partner for Cdc2 is used at mitosis in *S. pombe*, the product of *cdc13*. In *S. cerevisiae*, there are multiple alternative partners. These are coded by the *CLB1-4* genes, which code for products that resemble B cyclins and associate with *CDC28* at mitosis. Sequence relationships place the genes into pairs, *CLB1-2* and *CLB3-4*. Mutation in any one of these genes fails to block division, but loss of the *CLB1-2* pair of genes is lethal. Constitutive expression of *CLB1* prevents cells from exiting mitosis.

The state of *CDC28* in the *S. cerevisiae* cell cycle is summarized in **Figure 29.16**. The G1 cyclins were not immediately revealed by mutations that block the cell cycle in G1. The absence of such mutants has been explained by the discovery that three independent genes, *CLN1*, *CLN2*, *CLN3* all must be inactivated to block passage through START in *S. cerevisiae*. Mutations in any one or even any two of these genes fail to block the cell cycle; thus the *CLN* genes are **functionally redundant**. The *CLN* genes show a weak relationship to cyclins (resembling neither the A nor B class particularly well), although they are usually described as G1 cyclins.

**Figure 29.16** Cell cycle control in *S. cerevisiae* involves association of CDC28 with redundant cyclins at both START and G2/M.

Accumulation of the CLN proteins is the rate-limiting step for controlling the G1/S transition. Blockage of protein synthesis arrests the cycle by preventing the proteins from accumulating. The half-life of CLN2 protein is ~15 minutes; its accumulation to exceed a critical threshold level could be the event that triggers passage. This instability presents a different type of control from that shown by the abrupt destruction of the cyclin A and B types. Dominant mutations that truncate the protein by removing the C-terminal stretch (which contains sequences that target the protein for degradation) stabilize the protein, and as a result G1 phase is basically absent, with cells proceeding directly from M phase into S phase. Similar behavior is shown by the product of *CLN3*.

The redundancy of the *CLN* genes and the *CLB* genes is a feature found at several other stages of the cell cycle. In each case, the hallmark is that deletion of an individual gene produces a cell cycle mutant, but deletion of both or all members of the group is lethal. Members of a group may play overlapping rather than identical functions. This form of organization has the practical consequence of making it

difficult to identify mutants in the corresponding function.

**CELL CYCLE AND GROWTH REGULATION****6.29.12 Cdc2 activity is controlled by kinases and phosphatases**

---

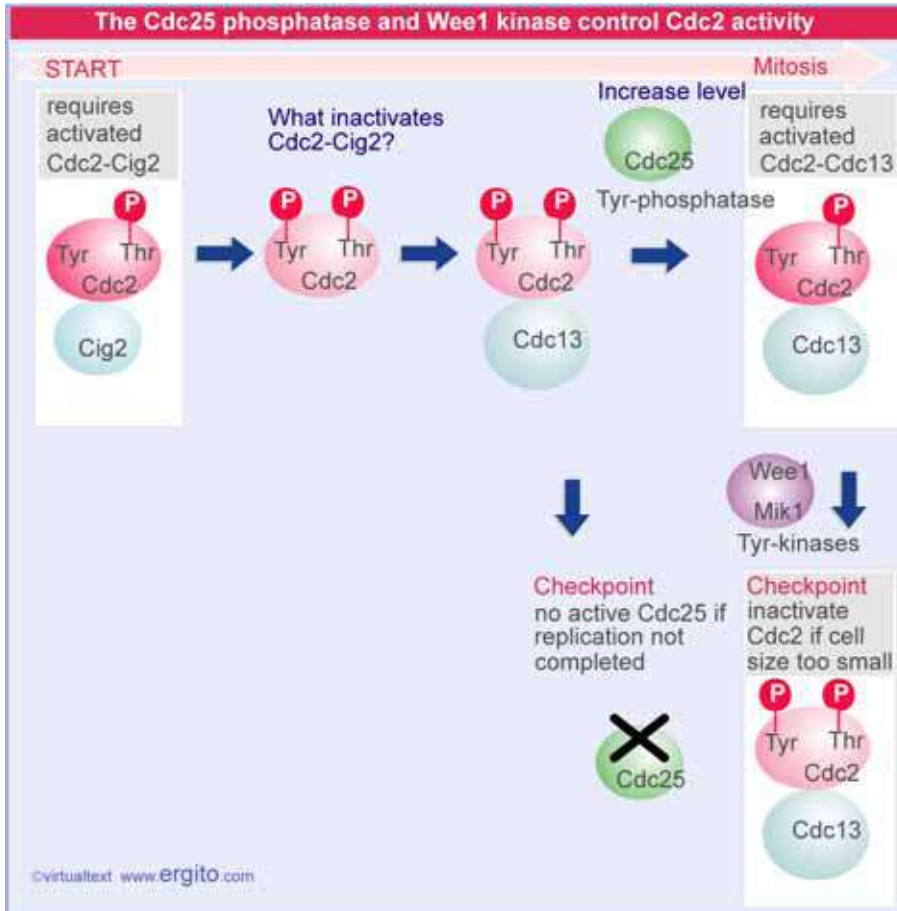

**Key Concepts**

- Cdc25 is a phosphatase that removes the inhibitory phosphate from Tyr-15 of Cdc2 in order to activate the M phase kinase.
- Wee1 is a kinase that antagonizes Cdc25 by phosphorylating Tyr-15 when the cell size is small.

---

We can divide *cdc* genes into two classes, defined by the stage of the cell cycle at which the effects of a mutation are manifested. We know most about the circuit that controls the state of the Cdc2/Cdc13 dimer at mitosis.

The states of Cdc2 complexes and the enzymes that act upon them during the *S. pombe* cell cycle are summarized in **Figure 29.17**. The Cdc2-cig2 dimer is phosphorylated during G1. By G2, the predominant form is the Cdc2/Cdc13 dimer whose activity is controlled by antagonism between kinases and phosphatases that respond to environmental signals or to checkpoints.

**Figure 29.17** Cell cycle control in *S. pombe* involves successive phosphorylations and dephosphorylations of Cdc2. Checkpoints operate by influencing the state of the Tyr and Thr residues.

*cdc25* codes for a tyrosine phosphatase that is required to dephosphorylate Cdc2 in the Cdc2/Cdc13 dimer. It is responsible for the key dephosphorylating event in activating the M phase kinase. It is not a very powerful phosphatase (its sequence is atypical), and the quantities of Cdc25 and Cdc2 proteins are comparable, so the reaction appears almost to be stoichiometric rather than catalytic.

The level of Cdc25 increases at mitosis, and its accumulation over a threshold level could be important. Cdc25 executes the checkpoint that ensures S phase is completed before M phase can be activated (837). In mutants of *cdc2* that do not require *cdc25*, or in strains that over-express *cdc25*, blocking DNA replication does not impede mitosis. (Wild-type cells arrest in the cell cycle if DNA synthesis is prevented, for example, by treatment with hydroxyurea. But these mutant cells attempt to divide in spite of the deficiency in replication, with lethal consequences.)

Under normal conditions, the cell division cycle is related to the size of the cell. In poor growth conditions, when the cells increase in size more slowly, G1 becomes longer, because START does not occur until the cells attain a critical size. This is a protection against starting a cell division cycle and risking division before the amount of material is adequate to support two daughter cells. *cdc* mutants typically

---

delay the onset of mitosis and lead either to cell cycle arrest or to division at increased size (as shown for *cdc25* in **Figure 29.11**).

Genes involved in cell size control are identified by mutations with the opposite property: they advance cells into mitosis and therefore divide at reduced size. The *wee1* gene takes its name from this phenotype (see the right panel of **Figure 29.11**). This behavior suggests that *wee1* usually inhibits cells from initiating mitosis until their size is adequate. This identifies a checkpoint that prevents the activation of Cdc2 until an adequate mass has been attained. *wee1* codes for a "dual specificity" kinase: it can phosphorylate serine/threonine and tyrosine. It inhibits Cdc2 by phosphorylating Tyr-15. Another gene, *mik1*, has similar effects. The deletion of both *wee1* and *mik1* is lethal, suggesting that either gene can fulfill the same function. Redundancy of this sort is a common theme in the yeast cell cycle.

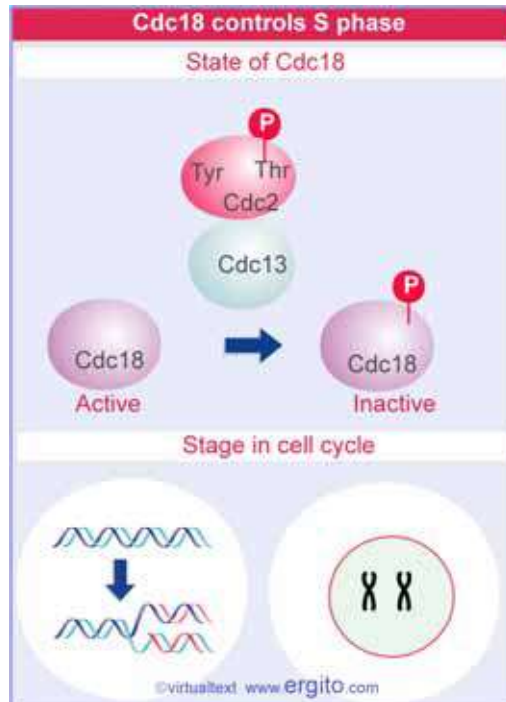

The products of *wee1* and *cdc25* play antagonistic roles, as shown in **Figure 29.17**. The kinase activity of *wee1* acts on Tyr-15 to inhibit Cdc2 function. The phosphatase activity of *cdc25* acts on the same site to activate Cdc2. Mutants that over-express *cdc25* have the same phenotype as mutants that lack *wee1*. Regulation of Cdc2 activity is therefore important for determining *when* the yeast cell is ready to commit itself to a division cycle; inhibition by *wee1* and activation by Cdc25 allow the cell to respond to environmental or other cues that control these regulators.

It is striking that all of the genes known to affect the G2/M boundary appear to have been widely conserved in evolution. Extending beyond the conservation of the components of the M phase kinase, *cdc25* has a counterpart in the *string* gene of *D. melanogaster*, and analogous proteins are found in amphibian and mammalian cells.

*The basic principle established by this work is that the activity of the key regulator, Cdc2, is controlled by kinase and phosphatase activities that themselves respond to other signals. Cdc2 is the means by which all of these various signals are ultimately integrated into a decision on whether to proceed through the cycle (for review see 321; 322).*

Activation of the G1/S form of the kinase (Cdc2/Cig2 in *S. pombe*) is required to enter S phase, but inactivity of the M phase form (Cdc2/Cdc13) is also required. Mutants in *cdc13* fail to enter mitosis (of course), but also undergo multiple cycles of DNA replication, suggesting that the M phase kinase usually inhibits S phase. This provides a checkpoint that ensures the alternation of S phase and mitosis. Activation of the M phase kinase during G2 prevents further rounds of DNA replication occurring before mitosis; and inactivation of the M phase kinase prevents another mitosis from occurring before the next S phase has occurred (835).

The target protein through which this circuit functions is probably Cdc18. Transcription of *cdc18* is activated as a consequence of passing START, and Cdc18 is required to enter S phase. Overexpression of *cdc18* allows multiple cycles of DNA replication to occur without mitosis. If Cdc18 is a target for Cdc2/Cdc13 M phase kinase, and is inactivated by phosphorylation, the circuit will take the form shown in **Figure 29.18**. For Cdc18 to be active, Cdc2/Cdc13 must be inactive. When the M phase kinase is activated, it causes Cdc18 to be inactive (possibly by phosphorylating it), and thereby prevents initiation of another S phase.

**Figure 29.18** Cdc18 is required to initiate S phase and is part of a checkpoint for ordering S phase and mitosis. Active M phase kinase inactivates Cdc18, generating a reciprocal relationship between mitosis and S phase.

Activity of the Cdc2/Cdc13 M phase kinase is itself influenced by the factor Rum1, which controls entry into S phase. When *rum1* is over-expressed, multiple rounds of replication occur, and cells fail to enter mitosis. When *rum1* is deleted, cells enter mitosis prematurely. These properties suggest that *rum1* is an inhibitor of the M phase kinase. It is expressed between G1 and G2 and keeps any M phase kinase in an inactive state. (This is important during G1, before the inhibitory phosphate is added to Tyr-15; see **Figure 29.14**.) It also represses the level of Cdc13 protein. The overall effect is to minimize M phase kinase activity, which is necessary to allow S phase to proceed. The consequences of the production of Rum1 on the state of M phase kinase, and consequently on the state of *cdc18*, are illustrated in **Figure 29.19**, which suggests a model for the overall circuit to control S phase.

**Figure 29.19** Rum1 inactivates the M phase kinase, preventing it from blocking the initiation of S phase.

A general theme emerges from these results: the circuits that control the cell cycle have interlocking feedback loops to ensure orderly progression. And giving dual roles to a single component in which its activity is necessary to promote one event but to block another creates an intrinsic alternation of events. So an active M phase kinase simultaneously promotes mitosis as a legitimate event and inhibits S phase as an illegitimate event. This creates an intrinsic checkpoint: one event cannot be initiated until the state of the component responsible for the prior event has been reversed. By contrast, the pathway of **Figure 29.23** is an example of an extrinsic checkpoint: in response to specific conditions, a pathway is activated whose end result is to alter the state of regulatory components in the cell cycle pathway.

A checkpoint is most often executed by controlling the state of phosphorylation of Cdc2. This may be achieved by activating or inhibiting the phosphatases and kinase that act on the activating or inhibitory tyrosines. Similar circuitry controls progress through meiosis as well as mitosis. For example, failure in recombination or in formation of synaptonemal complexes activates the pachytene checkpoint, which halts the cell during meiotic prophase. In *S. cerevisiae*, this is accomplished by activating the kinase Swe1 that phosphorylates the inhibitory tyrosine on Cdc28.

**CELL CYCLE AND GROWTH REGULATION****6.29.13 DNA damage triggers a checkpoint**

---

**Key Concepts**

- Damage to DNA triggers a checkpoint that blocks the cell cycle until the damage has been repaired.
  - The protein kinase ATM is a key component of the checkpoint pathway; it phosphorylates Chk2, which phosphorylates Cdc25, which is inactive in this form.
  - The response pathway also activates genes that code for some repair proteins and directly activates other repair proteins.
- 

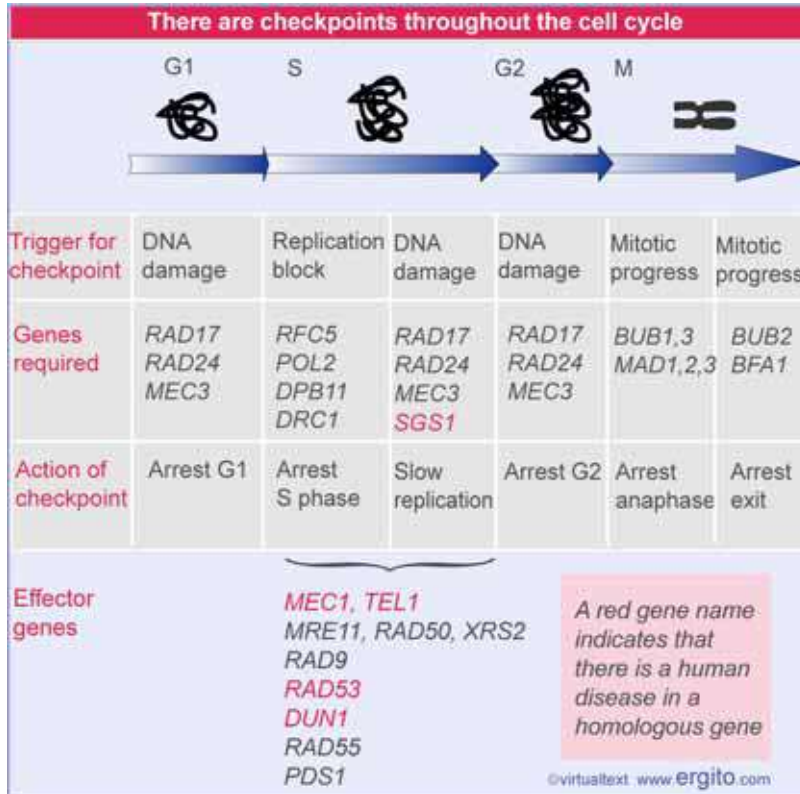

Some of the most important cell cycle checkpoints are triggered by DNA damage. Cells contain many pathways to respond to DNA damage. A key aspect of the response is the control of the cell cycle. Cells are extremely sensitive to double-strand breaks in DNA—even a single break in the genome of *S. cerevisiae* can trigger a checkpoint (2858).

**Figure 29.20** illustrates the basic principle of the response to DNA damage. A complex of proteins binds to damaged DNA, and then triggers signaling pathways. The best characterized signaling pathways lead to a block in the cell cycle, which allows time for response genes to be activated and then for the damage to be repaired (1402). An alternative response is to trigger death of the cell (thus preventing the sites of damage from inducing mutations) by apoptosis (see *Molecular Biology* 6.29.25 *Apoptosis is a property of many or all cells*).

**Figure 29.20** Damage to DNA triggers a response system that blocks the cell cycle, transcribes response genes, and repairs the damage, or that causes the cell to die.

Checkpoints respond to DNA damage at every stage of the cell cycle. There are also checkpoints to detect whether appropriate progress has been made through specific stages of the cycle. For example, replication must be completed before division is allowed to occur. All kinetochores must be paired before metaphase can give way to anaphase (see *Molecular Biology 6.29.19 Cohesins hold sister chromatids together*). **Figure 29.21** summarizes the checkpoints in *S. cerevisiae*. Note the distortion when the cycle is plotted in terms of checkpoints instead of real time. Although G1 is the longest part of the cycle, the checkpoints are concentrated in the later phases. This is because once a cell has left G1, it is committed to proceeding, but cannot be allowed to do so if the result will be to produce daughter cells with damaged DNA or other problems. So there are many checkpoints to ensure quality control.

**Figure 29.21** Checkpoints function at each stage of the cell cycle in *S. cerevisiae*. When damage to DNA is detected, the cycle is halted. The products of *RAD17*, *RAD24*, *MEC3* are involved in detecting the damage. During S phase, there is a checkpoint for the completion of replication. During mitosis, there are checkpoints for progress, for example, for kinetochore pairing.

A checkpoint pathway typically involves three groups of proteins:

- Sensor proteins recognize the event that triggers the pathway. In the case of a checkpoint that responds to DNA damage, they bind to the damaged structure in DNA, typically to a double-strand break or to single-stranded DNA.
- Transducer proteins are activated by the sensor proteins. They are usually kinases that amplify the signal by phosphorylating the next group of proteins in the pathway.
- Effector proteins are activated by the transducer kinases. They execute the actions that are required by the particular pathway. They often include kinases whose targets are the final proteins in the pathway.

The three genes *RAD17*, *RAD24*, and *MEC3* code for a group of sensor proteins that are important in detecting DNA damage at each stage of the cell cycle in *S. cerevisiae* (for review see 3243). At replication, there is a second checkpoint, which also includes *SGS1*, that activates the same effector pathway. The least well

characterized stage of the process is in fact the initial binding to DNA, but we believe that many of the early events in the pathway occur at a complex that assembles at the site of damage (for review see 2855). **Figure 29.22** shows that this complex includes the three proteins RAD17, RAD24, and MEC3. They are joined by two transducer kinases, MEC1 and TEL1, that play partially redundant roles. These kinases phosphorylate and thereby activate the effector kinases RAD53 (called Chk2 in Man) and CHK1, which then phosphorylate proteins required to execute the pathway. The importance of this pathway is emphasized by the fact that many of its genes have human homologues that are implicated in genetic diseases.

**Figure 29.22** A complex assembles at a damaged DNA site. It includes the proteins required to detect damage, trigger the checkpoint, and execute the early stages of the effector pathway.

One of the effectors of the response pathway in mammalian cells is the protein kinase ATM (the homologue of yeast TEL1). This is a central component of the DNA damage response. Loss of ATM function is responsible for the human disease ataxia telangiectasia. Patients with this disease are not only abnormally sensitive to agents that damage DNA, but also have many cellular defects that result from errors that occur during normal cell division, but which fail to be repaired because they did not induce the checkpoint. The protein kinase ATR (homologue of yeast MEC1) is related to ATM and also triggers this response.

ATM exists in unirradiated cells as a dimer in which its enzymatic activity is suppressed. DNA damage causes phosphorylation of a serine, which causes the dimer to dissociate (3602). The monomer is an active kinase. The activation event may be the consequence of changes in chromatin structure that result from breaks in DNA caused by irradiation.

The ATR kinase exists in a complex with the another protein (ATRIP).ATRIP is recruited to single-stranded DNA by the RPA protein complex (a component of the replication fork that binds to free single-stranded DNA). This localizes ATR at the single-stranded DNA, where it acts on Chk enzymes to trigger the damage response (3995).

**Figure 29.23** shows that DNA damage triggers a G2 checkpoint that involves both kinases and phosphatases. ATM activates (directly or indirectly) the kinase Chk2. Chk2 (and also the related kinase Chk1) phosphorylates Cdc25 on the residue Ser216. This causes Cdc25 to bind to the protein 14-3-3s, which maintains it in an inactive state. As a result, Cdc25 cannot dephosphorylate Cdc2, so M phase cannot be activated. A similar pathway is found in animal cells and in *S. pombe*, but in *S. cerevisiae* it is different.

**Figure 29.23** DNA damage triggers the G2 checkpoint.

**Figure 29.24** shows that repair of the damaged DNA requires a combination of products of genes that are activated in response to damage and proteins that are activated by phosphorylation. Response genes that are transcribed as the result of DNA damage produce proteins that are involved directly in repairing DNA (such as the excision repair protein p48) and proteins that are needed in an ancillary capacity (such as the enzymes required for dNTP synthesis). Direct targets for phosphorylation by ATM include proteins involved in homologous recombination and the protein Nbs1 which is required for nonhomologous end-joining.

**Figure 29.24** Proteins required to repair damaged DNA are provided by transcribing response genes to synthesize new proteins and by phosphorylating existing proteins.

The *RAD9* mutant of *S. cerevisiae* reveals another connection between DNA and the cell cycle. Wild-type yeast cells cannot progress from G2 into M if they have damaged DNA. This can be caused by X-irradiation or by the result of replication in a mutant such as *cdc9* (DNA ligase). Mutation of *RAD9* allows these cells to divide in spite of the damage. *RAD9* therefore exercises a checkpoint that inhibits mitosis in response to the presence of damaged DNA. The reaction may be triggered by the existence of double-strand breaks. *RAD9*-dependent arrest and recovery from arrest can occur in the presence of cycloheximide, suggesting that the *RAD9* pathway functions at the post-translational level. At least 6 other genes are involved in this pathway; its ultimate regulatory target remains to be found (843).

## CELL CYCLE AND GROWTH REGULATION

### 6.29.14 The animal cell cycle is controlled by many cdk-cyclin complexes

---

#### Key Terms

A **cyclin-dependent kinase (cdk)** is one of a family of kinases which are inactive unless bound to a cyclin molecule. Most cyclin-dependent kinases participate in some aspect of cell cycle control.

#### Key Concepts

- Many dimeric kinases with a Cdc2-like catalytic subunit (cdk) are found in animal cells.
  - cdk2 and cdk4 are the catalytic subunits that are usually bound to G1 cyclins.
- 

Control of the cell cycle uses the same types of components in animal cells and in yeasts, although there is more diversity in each component in animal cells. The unifying theme is that progression to the next stage of the cell cycle is controlled by a kinase that consists of a catalytic subunit and a regulatory (cyclin) partner.

The components of the regulatory kinases for both G1/S and G2/M in yeasts and animal cells are summarized in **Figure 29.25**. The major difference is that animal cells have more variation in the subunits of the kinases. Instead of using the same catalytic subunit at both START and G2/M, animal cells use different catalytic subunits at each stage. They also have a larger number of cyclins (for review see 325).

**Figure 29.25** Similar or overlapping components are used to construct M phase kinase and a G1 counterpart.

At mitosis in animal cells, the Cdc2 catalytic subunit is provided by a single gene. The regulatory partner at mitosis usually is not unique, but is provided by a family of B-type cyclins, and sometimes also A-type cyclins.

During G1, animal cells have multiple kinases involved in cell cycle control, and they vary in *both* the catalytic subunit and the regulatory (cyclin) subunit. This contrasts with the retention of a common catalytic subunit in yeasts.

Just as families of cyclins can be defined by ability to interact with Cdc2, so may families of catalytic subunits be defined by the ability to interact with cyclins. Catalytic subunits that associate with cyclins are called **cyclin-dependent kinases (cdks)**. Higher eukaryotes possess a large number of genes (~10) related to the true *cdc2* homologue. It is not entirely clear how many of these gene products are involved with the cell cycle and how many code for kinases with other functions. The cdk/cyclin dimers have the same general type of kinase activity as the Cdc2-cyclin dimers, and are often assayed in the same way, by H1 histone kinase activity. The involvement of the Cdc2/cdk kinase engines (and/or others related to them) at two regulatory points *in vivo* is consistent with an increase in H1 kinase activity at S phase as well as at M phase.

The pairwise associations between the catalytic and regulatory subunits are not exclusive, and a particular cyclin may associate with several potential catalytic subunits, while a catalytic subunit may associate with several potential cyclins. The trick is to determine which of these pairwise combinations form in the cell and are concerned with regulating the cell cycle.

Two of the *cdk* genes, *cdk2* and *cdk4*, code for proteins that form pairwise combinations with potential G1 cyclins. The first and best characterized is *cdk2*; it has 66% similarity to the *cdc2* homologue in the same organism.

G1 cyclins were originally identified as genes that could overcome the deficiency of *CLN* mutants in *S. cerevisiae*. Several new types of cyclins (including D and E) were identified by this means. They are distantly related to one another and to other cyclins. Cyclin E accumulates in a periodic manner through the cycle, but is not regulated by periodic destruction of protein. There are 3 D-type cyclins; they form dimers with *cdk4* and *cdk6*.

Proteins described as "cyclins" are therefore now significantly more diverse than the A and B classes encompassed by the original definition. For working purposes, we class as cyclins various proteins that have some sequence relationship to the original class, and which can participate in formation of a kinase by pairing with a Cdc2 or *cdk2* or related catalytic subunit.

## CELL CYCLE AND GROWTH REGULATION

### 6.29.15 Dimers are controlled by phosphorylation of cdk subunits and by availability of cyclin subunits

The timing of activity of the various forms of cdk- and Cdc2-cyclins during the animal cell cycle suggests a model in which cdk2-G1 cyclin dimers function to regulate progression through G1 and S phase, while Cdc2-cyclinA,B dimers regulate passage through mitosis. We know most about the details of controlling the G2/M transition, but the principles are likely to be similar for G1/S, since the Cdc2 and cdk catalytic subunits conserve the residues that are involved in regulation (for review see 328; 329).

**Figure 29.26** shows that the regulatory events in an animal cell mitosis are similar to those in yeast cells (compare with **Figure 29.17**). The lower part of the figure shows the changes in M phase kinase; the upper part shows the enzymes that catalyze these changes. A cell leaves mitosis with Cdc2 monomers and no mitotic cyclins (because cyclins A and B were degraded during mitosis). Cyclins are then resynthesized. After a lag period, their level reaches a threshold at which they form dimers with Cdc2. But this does not activate the kinase activity; as we saw previously in **Figure 29.9**, the activity of the dimer is controlled by the state of certain Tyr and Thr residues:

**Figure 29.26** Control of mitosis in animal cells requires phosphorylations and dephosphorylations of M phase kinase by enzymes that themselves are under similar control or respond to M phase kinase.

- The phosphate that is necessary at Thr-161 is added by CAK (the Cdc2-activating kinase). CAK activity is probably constitutive (839; 840).
- The Wee1 kinase is a counterpart to the enzyme of *S. pombe* and phosphorylates Tyr-15 to maintain the M phase kinase in inactive form.
- The Cdc25 phosphatase is a counterpart to the yeast enzyme and removes the phosphate from Tyr-15. Cdc25 is itself activated by phosphorylation; and M phase kinase can perform this phosphorylation, creating a positive feedback loop. Removal of the phosphate from Tyr-15 is the event that triggers the start of mitosis. Cdc25 is itself regulated by several pathways, including phosphatases that inactivate it, but these pathways are not yet well defined.
- Separate kinases and phosphatases that act on Thr-14 have not been identified; in some cases, the same enzyme may act on Thr-14 and Tyr-15.

This means of control is common, but not universal, since in some cells tyrosine phosphorylation does not seem to be critical, and in these cases other events must be used to control the activity of M phase kinase.

Various cdk-cyclin dimers regulate entry into S and progression through S in animal cells. Some may be concerned with entering the cycle from G<sub>0</sub> or exiting to it. The pairwise combinations of dimers that form during G<sub>1</sub> and S are summarized in **Figure 29.27**. All of these dimers require phosphorylation on Thr-161 by CAK to generate the active form (834; for review see 326; 327).

**Figure 29.27** Several cdk-cyclin complexes are active during G1 and S phase. The shaded arrows show the duration of activity.

The synthesis of D cyclins is activated when growth factors stimulate cells to reenter the cycle from G<sub>0</sub>. The D cyclins have short half-lives, and their levels decline rapidly when the growth stimulus is removed. They may be involved with triggering reentry of quiescent cells into the cycle. Loss of D cyclins could be a trigger for a cell to leave the cell cycle for the G<sub>0</sub> state.

The activity of D cyclins is required during the latter part of G<sub>1</sub>, but not close to the G<sub>1</sub>/S boundary. Their functions may be partly redundant, but there are some differences between the D cyclins in their susceptibilities to inhibitors of the cell cycle. The significance of the ability of each D cyclin to associate with 3 different cdk subunits is not clear.

Activity of the cdk2-cyclin E complex is necessary to enter S phase. Cyclin E is synthesized during a period that spans the G<sub>1</sub>/S transition, but we do not yet know how and when it is inactivated or at what point it becomes dispensable. Cyclin E clearly has a unique role.

Progression through S phase requires the cdk2-cyclin A complex. Cyclin A is also required to associate with Cdc2 for entry into mitosis. The dual use of cyclin A in animal cells appears to be the only case in which a cyclin is used for both G<sub>1</sub>/S and

G2/M transitions.

The states of cyclin-cdk complexes may influence the licensing system that prevents reinitiation of replication (see **Figure 14.39**). Cyclin B-cdk complexes prevent Cdc6 from loading on to the origin. This results in an orderly succession of events, because the degradation of cyclin B in mitosis releases the block and allows the procedure to start for forming a prereplication complex at the origin.

Both the beginning and end of S phase are important points in the cell cycle. Just as a cell must know when it is ready to initiate replication, so it must have some means of recognizing the successful completion of replication. This may be accomplished by examining the state of DNA.

Inhibitors of DNA replication can block the cell cycle. The effect may depend on the presence of replication complexes on DNA. We do not know exactly how they trigger the checkpoint that blocks the activation of M phase kinase.

Controls that ensure an orderly progression through the cell cycle and that can be visualized in the context of checkpoints include monitoring the completion of DNA replication and checking cell size. It may be necessary to bypass some of these checkpoints in early embryogenesis; for example, early divisions in *Drosophila* in effect are nuclear only (because there are no cellular compartments: see *Molecular Biology 6.31 Gradients, cascades, and signaling pathways*). It may be significant that the product of *string* (the counterpart of *S. pombe cdc25* which exercises a size-dependent control) is present at high levels in these early cycles. After the 14th cycle, division becomes dependent on *string* expression. It is at this point that cellular compartments develop, and it becomes appropriate for there to be a checkpoint for cell size. *string* may provide this checkpoint.

## CELL CYCLE AND GROWTH REGULATION

### 6.29.16 RB is a major substrate for cdk-cyclin complexes

---

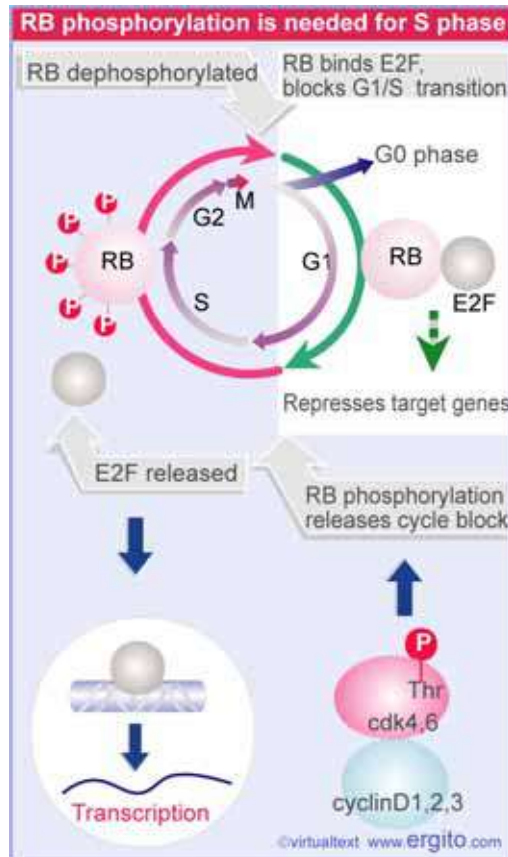

#### Key Concepts

- RB is an important target for cdk-G1 cyclin complexes; its phosphorylation is required for initiation of S phase.

---

An important insight into control of the cell cycle at G1 has been provided by the identification of tumor suppressor genes that code for products that interact with cdk-cyclin complexes or with the downstream circuitry. Tumor suppressors are generally identified as genes in which loss of function causes tumor formation, either as seen by transformation of cells in culture, or by association of loss-of-function mutations with tumors in animals (see *Molecular Biology 6.30.3 Oncogenes and tumor suppressors have opposite effects*). The tumor suppressor RB is a key component in controlling the cell cycle (see also *Molecular Biology 6.30.19 RB is a tumor suppressor that controls the cell cycle*).

RB is a substrate for cdk-cyclin D complexes, and exerts its effects during the part of G1 that precedes the restriction point. **Figure 29.28** shows the basic circuit. In quiescent cells, or during the first part of G1, RB is bound to the transcription factor E2F. This has two effects. First, some genes whose products are essential for S phase depend upon the activity of E2F. By sequestering E2F, RB ensures that S phase cannot initiate. Second, the E2F-RB complex represses transcription of other genes. This may be the major effect in RB's ability to arrest cells in G1 phase (for review see 333).

**Figure 29.28** A block to the cell cycle is released when RB is phosphorylated by cdk-cyclin.

RB may exert its repressive effects by interacting with chromatin (for review see 1863). It binds histone deacetylases, which raises the possibility that it functions by causing them to remove acetyl groups from the histones at target promoters, thus inactivating the promoters (see *Molecular Biology 5.23.8 Deacetylases are associated with repressors*). It also interacts with components of a chromatin remodeling complex.

The nonphosphorylated form of RB forms a complex with cdk-cyclins. The complex with cdk4,6-cyclin D1,2,3 is the most prominent, but RB is also a substrate for cdk2-cyclin E. At or close to the restriction point, RB is phosphorylated by cdk4,6-cyclin D kinases. The phosphorylation causes RB to release E2F, which then activates transcription of the genes whose functions are required for S phase, and also releases repression of genes by the E2F-RB complex. The importance of E2F is seen by the result that expression of E2F in quiescent cells enables them to synthesize DNA.

There is an especially close relationship between RB and cyclin D1. Overexpression of D1 causes cells to enter S phase early. Inhibition of expression of D1 arrests cells before S phase. The sole role of cyclin D1 could be to inactivate RB and permit entry into S phase.

There are several related transcription factors in the E2F family, sharing the property

that all recognize genes with the same consensus element. RB binds three of these factors. Two further proteins, p107 and p130, which are related to RB, behave in a similar way, and bind the other members of the E2F group. So together RB and p107 may control the activity of the E2F group of factors.

**CELL CYCLE AND GROWTH REGULATION****6.29.17 G0/G1 and G1/S transitions involve cdk inhibitors**

---

**Key Terms**

**Cyclin-dependent kinase inhibitors (cki)** are a class of proteins which inhibit cyclin-dependent kinases by binding to them. Inhibition lasts until the cki is inactivated, often in response to a signal for the cell cycle to progress.

**Key Concepts**

- CKI proteins are inhibitors of cdk-cyclin dimers.
  - Different CKI proteins have specificities for different cdk-cyclin complexes.
- 

RB is a target for several pathways that inhibit growth, and may be the means by which growth inhibitory signals maintain cells in G1 (or G0). Several of these signals, including the growth inhibitory factor TGF  $\beta$ , act through inhibitors of cdk-cyclin kinases. The inhibitors are called **CKIs**. They are found as proteins bound to cdk-cyclin dimers in inactive complexes, for example, in quiescent cells. By maintaining the cdk-cyclin complexes in inactive form, they prevent the phosphorylation of RB, making it impossible to release cells to enter S phase.

The CKI proteins fall into two classes. The INK4 family is specific for cdk4 and cdk6, and has four members: p16<sup>INK4A</sup>, p15<sup>INK4B</sup>, p18<sup>INK4C</sup>, and p19<sup>INK4D</sup>. The Kip family inhibit all G1 and S phase cdk enzymes, and have three members: p21<sup>Cip1/WAF1</sup>, p27<sup>Kip1</sup>, and p57<sup>Kip2</sup>. [Each protein is identified by its size, with the casual name used as a superscript; for review see 332].

INK4 protein binds specifically to cdk4 and cdk6. This suggests a connection with the G0/G1 transition. p16 cannot inhibit proliferation of cells that lack RB, which suggests that it functions by preventing cdk-cyclin kinase activity from using RB as a substrate, as illustrated in **Figure 29.29**. By binding to the cdk subunits, INK4 proteins inhibit both cdk4-cyclin D and cdk6-cyclin D activities. As exemplified by p16 and p19, they bind next to the ATP binding site of cdk6. This both inhibits catalytic activity and triggers a conformational change that prevents cyclin from binding (the conformational change is propagated to the cyclin-binding site).

**Figure 29.29** p16 binds to cdk4 and cdk6 and to cdk4,6-cyclin dimers. By inhibiting cdk-cyclin D activity, p16 prevents phosphorylation of RB and keeps E2F sequestered so that it is unable to initiate S phase.

p21 is a universal cdk inhibitor, binding to all complexes of cdk2, 4, 6. This suggests that it is likely to block progression through all stages of G1/S. In primary cultured cells (taken directly from the animal), cdk-cyclin dimers are usually found in the form of quaternary complexes that contain two further components. One is PCNA, a component of DNA polymerase  $\delta$ , which may provide a connection with DNA replication. The other is the inhibitor p21. It may seem paradoxical that an inhibitor is consistently associated with the cdk-cyclin dimer, but it turns out that at a stoichiometry of 1:1 the p21 is not inhibitory. An increase in the number of p21 subunits associated with the cdk-cyclin dimer inhibits kinase function. In transformed cells (from lines that have been successfully perpetuated in culture), cdk-cyclin complexes lack p21 and PCNA. This suggests the possibility that p21 is involved in G1/S control, and that relaxation of this control is necessary for cells to be perpetuated in culture.

p27 has a sequence that is partly related to p21, and also binds promiscuously to cdk-cyclin complexes. Overexpression of p27 blocks progression through S phase, and levels of p27 are increased when cells are sent into a quiescent state by treatment with TGF  $\beta$ . p21 and p27 block the catalytic subunit of cdk-cyclin dimers from being a substrate for activation by phosphorylation by CAK. They also prevent catalytic activity of the cdk-cyclin complex. The stages at which they function are illustrated in the summary of inhibitory pathways in **Figure 29.30**.

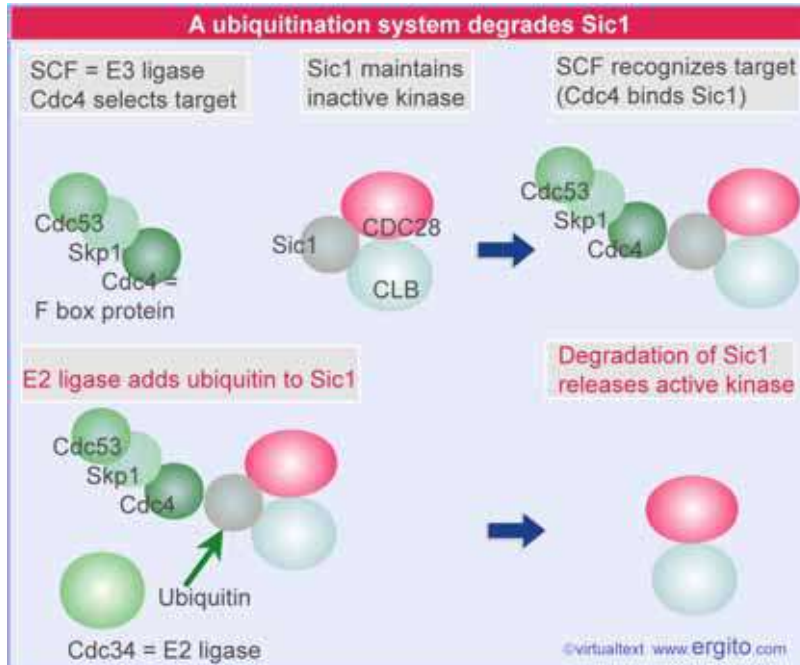

**Figure 29.30** p21 and p27 inhibit assembly and activity of cdk4,6-cyclin D and cdk2-cyclin E by CAK. They also inhibit cycle progression independent of RB activity. p16 inhibits both assembly and activity of cdk4,6-cyclin D.

p21 and p27 are probably partially redundant in their functions. The pathway by which they inhibit the cell cycle is not entirely clear, but we know that it does not depend on controlling RB, because they can inhibit proliferation of cells that lack RB. This may mean that their inhibition of cdk2-cyclin E dimers is critical. Since both are present in proliferating cells, the normal progress of the cell cycle may require the levels of the cdk-cyclin dimers to increase to overcome an inhibitory threshold. p27 appears to be the major connection between extracellular mitogens and the cell cycle, with an inverse correlation between p27 activity and ability to proliferate.

The importance of the pathway from CKI proteins to RB is emphasized by the fact that tumor suppressors are found at every stage, including CKI proteins, cyclins D1,2, and RB. The implication is that the CKI proteins are needed to suppress unrestrained growth of cells. In terms of controlling the cell cycle, this pathway is clearly central. It may be the key pathway by which cells are enabled to undertake a division cycle (by passing the restriction point in G1 if they are already cycling, or by reentering G1 if they are quiescent in G0; for review see 331).

The CKI proteins are also involved in another level of control. In *S. cerevisiae*, the CKI Sic1 is bound to CDC28-CLB during G1, and this maintains the kinase in an inactive state. Entry into S phase requires degradation of Sic1 to release the kinase. **Figure 29.31** shows how Sic1 is targeted for degradation by a ubiquitinating system (see **Figure 8.68** for a general description). The Sic1 target is recognized by a complex called the SCF, which functions as an E3 ligase (the component that selects the target). The SCF complex includes Cdc53, Skp1, and Cdc4. Cdc4 is the targeting component, which, together with Skp1, binds to Sic1. For this reason, the complex is described as SCF<sup>Cdc4</sup>. Skp1 is the connection to Cdc53, which interacts with the E2 ligase (Cdc34). The E2 ligase adds ubiquitin to Sic1, causing it to be degraded.

**Figure 29.31** The SCF is an E3 ligase that targets the inhibitor Sic1.

Cdc4 is a member of a class of proteins called F-box proteins. It uses the F-box motif to bind to Skp1. This is a general paradigm for the construction of SCF complexes (for review see 1006). Other SCF complexes exist in which the targeting subunit is a different F-box protein, but the Cdc53 and Skp1 components remain the same. An example relevant to the cell cycle is SCF<sup>Grr1</sup> in which the F-box protein Grr1 provides the targeting subunit, and causes the degradation of G1 cyclins (850).

There are further layers of control in this system. The substrates for the SCF must be phosphorylated to be recognized. The kinases that perform the phosphorylation are the cdk-cyclin complexes that are active at the appropriate stage of the cell cycle. The abundance of the SCF complexes is itself controlled by degrading the F-box subunits. SCF<sup>Cdc4</sup> targets Cdc4, thus creating an autoregulatory limitation on its activity. The consequence of such feedbacks is to maintain a supply of the Cdc53-Skp1 cores that can be recruited as appropriate by the F-box subunits.

## CELL CYCLE AND GROWTH REGULATION

### 6.29.18 Protein degradation is important in mitosis

---

#### Key Terms

The **anaphase promoting complex (APC)** is a set of proteins that triggers proteolysis or targets required to allow chromosomes to separate.

The **cyclosome** is a multisubunit complex which initiates anaphase and the exit of cells from mitosis by promoting the ubiquitination and proteolysis of a variety of proteins. These include the mitotic cyclins, several proteins required to hold sister chromatids together, and other proteins which control the dynamics of the mitotic spindle.

#### Key Concepts

- Cyclins are degraded at two points during mitosis, cyclin A during metaphase, and B cyclins to terminate mitosis.
- The APC (anaphase promoting complex) is an E3 ubiquitin ligase that targets a substrate for degradation.

---

The timing of the events that regulate mitosis is summarized in **Figure 29.32**. Mitosis is initiated by the activation of M phase kinase. Progress through mitosis requires degradation of cyclins, and also of other proteins (845). Several degradation events play different roles in mitotic progression:

**Figure 29.32** Progress through mitosis requires destruction of cyclins and other targets.

- The first event to occur is the degradation of cyclin A at metaphase.
- The separation of chromosomes at anaphase requires the activity of the proteasomal system for protein degradation (but does not require cyclin degradation). The target for this event is the protein Pds1p, whose degradation triggers the pathway that enables sister chromatids to separate.
- Later during anaphase, B cyclins must be degraded in order to inactivate M phase kinase. This is necessary to allow the phosphorylations of substrate proteins that were catalyzed by M phase kinase to be reversed at the end of mitosis.

A large complex of 8 subunits is responsible for selecting the substrates that are degraded in anaphase. It is called the **anaphase promoting complex (APC)**

(sometimes also known as the **cyclosome**). Similar complexes are found in both yeasts and vertebrates (for review see 3026). The APC becomes active specifically during mitosis (846; for review see 1438). It functions as an E3 ubiquitin ligase (see **Figure 8.68**), which is responsible for binding to the substrate protein so that ubiquitin is transferred to it. The ubiquitinated substrate is then degraded by the proteasome.

There are two separate routes to activating the APC, and each causes it to target a particular substrate. **Figure 29.33** shows that the regulatory factors CDC20 and Cdh1 bind to the APC and activate its ubiquitination activity. CDC20 is necessary for the APC to degrade Pds1p, which controls the transition from metaphase to anaphase. Cdh1 is necessary for the APC to degrade Clb2 (yeast cyclin B), which is necessary to exit mitosis. The timing of activation and persistence of each type of complex is different (847; 849).

**Figure 29.33** Two versions of the APC are required to pass through anaphase.

## CELL CYCLE AND GROWTH REGULATION

### 6.29.19 Cohesins hold sister chromatids together

---

#### Key Terms

**Cohesin** proteins form a complex that holds sister chromatids together. They include some SMC proteins.

**Separins** are proteins which play a direct role in initiating anaphase by cleaving and inactivating a component (a cohesin) that holds sister chromatids together.

**Securins** are a class of proteins that prevent the initiation of anaphase by binding to and inhibiting separin, a protease which cleaves the structural component required for holding sister chromatids together. Inhibition of separin by securin ends when securin is itself proteolyzed as a result of activation of the anaphase promoting complex (APC).

#### Key Concepts

- Cohesins associate with chromatin at S phase and hold sister chromatids together.
- A securin is a protein that sequesters a separin and keeps it in an inactive state.
- Anaphase in yeast is triggered when CDC20 causes the APC to degrade the securin Pds1p.
- Degradation of the securin releases the separin (Esp1 in yeast) which is a protease that cleaves the cohesin Scc1p.
- Cleavage of Scc1p releases the sister chromatids.

---

After replication occurs at S phase, the products of each chromosome (sister chromatids) remain associated with one another, although this becomes evident only later at the beginning of mitosis. This is a crucial aspect of segregating the sister chromatids to different daughter cells, as shown in **Figure 19.22**. The sister chromatids are held together by a complex of **cohesin** proteins, which functions as a sort of "glue". The cohesins are the key players in assuring chromatid association at the start of mitosis, and dissociation during mitosis (for review see 2859).

**Figure 29.34** shows that cohesins are located at various sites along a pair of sister chromatids, with the appearance of being centrally localized between the chromatids. At metaphase, each sister chromatid pair is in equilibrium on the spindle, being connected to both poles by microtubules. When the connecting glue dissolves, the sister chromatids are released from one another and pulled toward opposite poles. This marks the transition from metaphase to anaphase.

**Figure 29.34** Cohesins are located sporadically along a pair of sister chromatids early in mitosis. DNA is in red; cohesins are in yellow. Photograph kindly provided by Ana Losada and Tatsuya Hirano.

At the metaphase-anaphase transition, the route to releasing sister chromatids so that they may segregate to opposite poles is indirect, as illustrated in **Figure 29.35**. There are three components in the system (for review see 2297). The cohesins connect the sister chromatids. A **separin** releases the cohesins. And the separin is controlled by a **securin**.

**Figure 29.35** Anaphase progression requires the APC to degrade Pds1p to allow Esp1p to remove Scc1 from sister chromatids.

Prior to anaphase in yeast, the securin Pds1p binds to the separin Esp1p. When the APC degrades Pds1p (securin), Esp1p (separin) is released. The separin is a protease. It cleaves the protein Scc1p, which is a component of the cohesin complex (848; 1430). When Scc1p is released by the action of Esp1p, the cohesin complex can no longer hold the chromatids together, and they therefore become free to segregate on the spindle.

If securin simply sequesters separin, we would expect the loss of securin to cause premature chromosome separation. However, the opposite happens. If the securin gene is inactivated, the chromosomes have difficulty in separating, and the delay causes abnormalities in chromosome segregation (1958). This suggests that securin plays two roles. Suppose that the separin is in an inactive state before it binds to

securin. The securin activates it, but keeps it sequestered. When securin is degraded, the separin is released in the active state. If securin is absent altogether, the separin never becomes activated, so that the cohesins are not destroyed.

Sccl1p is only one component of the cohesin complex. The core of the complex is a heterodimer of SMC proteins. (SMC stands for structural maintenance of chromosome; other SMC proteins form the condensins, which are involved in controlling chromosome condensation; see *Molecular Biology 5.23.18 Chromosome condensation is caused by condensins*). The cohesin complex contains Sccl1p, Sccl3p, and a heterodimer of the two SMC proteins Smc1p and Smc3p (2483). However, loss of Sccl1p is sufficient to abolish the ability to hold sister chromatids together. The cohesins may function by cross-linking DNAs as shown in **Figure 23.30** (for review see 2323; 2262).

Smc3p is involved in meiosis as well as mitosis. It is required for sister chromatid cohesion, together with a protein (Rec8p) that is related to Sccl1p. This suggests that a cohesin complex, related to that of mitosis, may form at meiosis. Both of these components are required for synaptonemal complexes to form (see *Molecular Biology 4.15.5 Recombining chromosomes are connected by the synaptonemal complex*). The metaphase-anaphase transition at the first meiotic division in yeast is triggered in the same way as at mitosis, when the cohesin Rec8 is cleaved by separin to allow disjunction of homologous chromosomes (1431).

The situation in higher eukaryotic cells is more complex. The cohesin Sccl1p is mostly released from the chromosomes during prophase, although it is left in the centromeric regions. It is degraded at the start of anaphase, and its loss from the centromeric regions may be the trigger for chromosome separation (1432).

The major target of the APC<sup>Cdh1</sup> complex is the mitotic cyclin component of the cdk-cyclin kinase. Its destruction makes it possible to reverse the phosphorylations that triggered mitosis, which is necessary to exit mitosis. However, there is some overlap in the actions of the two APC complexes, and APC<sup>CDC20</sup> may also act on mitotic targets. The relative timing of activation of the two APC complexes may be determined by a circuit in which a target of APC<sup>CDC20</sup> is needed to activate APC<sup>Cdh1</sup>.

Formation of the cohesin complex (or possibly its association with the chromosomes) occurs during S phase. Mutants in the locus *ctf7* have sister chromatids that never associate. The gene acts during the period of DNA replication, but does not code for a component of the cohesin complex (2485). It is possible that the establishment of cohesion is triggered by replication in some way. So far as we can tell from examining individual sequences, the replicated copies remain tightly associated from replication until cell division (2484).

The cohesion system is the target for a checkpoint. Progression through mitosis requires all kinetochores to be paired with their homologues. **Figure 29.36** shows that the checkpoint consists of a surveillance system that is triggered by the presence of an unattached kinetochore. Mutations in the *Mad* and *Bub* genes allow mitosis to continue (aberrantly) in the presence of unpaired kinetochores. The Mad proteins control the system for chromatid segregation. They bind to CDC20 and prevent it from activating the APC. When the kinetochores are all attached, some (unidentified) signal causes Mad proteins to be released from CDC20, which now activates the

APC, allowing anaphase to continue. A similar role is played by Bub proteins in controlling the ability of Cdh1 to activate the APC.

**Figure 29.36** An unattached kinetochore causes the Mad pathway to inhibit CDC20 activity

## CELL CYCLE AND GROWTH REGULATION

### 6.29.20 Exit from mitosis is controlled by the location of Cdc14

---

#### Key Concepts

- During interphase the phosphatase Cdc14 is held in the nucleolus.
- When a spindle pole body migrates into the bud of *S. cerevisiae*, it carries the protein Tem1.
- Tem1 is a monomeric G protein that is activated by the local concentration of the exchange factor Lte1 in the bud.
- Activation of Tem1 triggers release of Cdc14.
- The action of Cdc14 triggers exit from mitosis.

---

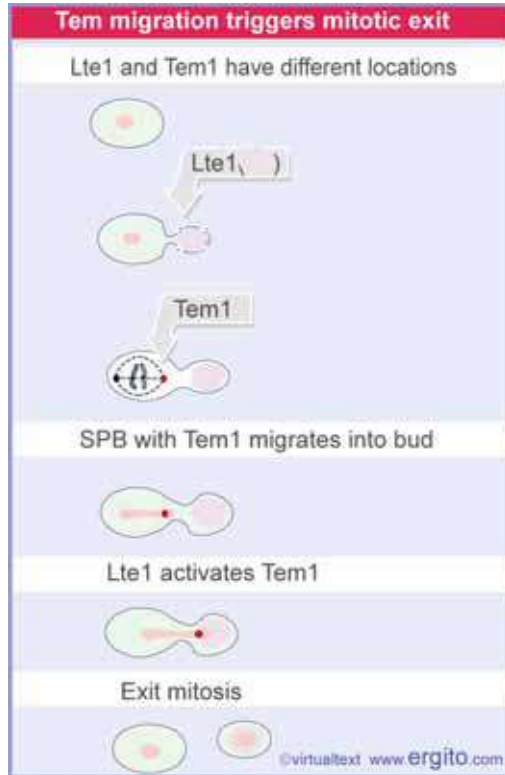

The key event in leaving mitosis is the activation of the phosphatase Cdc14 (908). **Figure 29.37** shows that during interphase, Cdc14 is sequestered in the nucleolus (because it binds to a nucleolar protein variously called RENT/Cfi1/Net1) (1202; 1203). When it is localized in the nucleolus, it cannot find any of its substrates, and therefore is inactive. When it is released from the nucleolus, it acts on (at least) two substrates. Dephosphorylation of Cdh1 is necessary to activate the APC<sub>Cdh1</sub> complex. And dephosphorylation of Sic1 enables it to inactivate mitotic cyclins. This is another example of belts and braces in cell cycle control, where parallel pathways lead to the same outcome.

**Figure 29.37** Cdc14 dephosphorylates both Cdh1 and Sic1. The first action leads to activation of the APC that degrades mitotic cyclins. The second action enables Sic1 to reversibly inactivate mitotic cyclins.

What triggers the release of Cdc14 from the nucleolus? The pathway for leaving mitosis has many genes, and genetic relationships suggest that two key components are the GTP-binding protein Tem1 and the exchange factor Lte1. Like other monomeric G proteins, Tem1 is active when bound to GTP, and inactive when bound to GDP. The exchange factor activates it by causing bound GDP to be replaced with GTP (see *Molecular Biology Supplement 32.10 G proteins*). The ability of Lte1 to activate Tem1 is controlled in an interesting way by the locations of the two components in the yeast cell.

Recall that *S. cerevisiae* has an asymmetrical division in which the daughter cell forms as a bud of the mother cell (see **Figure 29.10**). Lte1 protein is present throughout the cell cycle, and when the bud forms at the beginning of S phase, the Lte1 is localized in it. By contrast, Tem1 is synthesized only at late S phase. At mitosis, the Tem1 is localized with one of the spindle pole bodies (the structures identifying the ends of the spindle where microtubules are nucleated). **Figure 29.38** shows that this is the spindle pole body that migrates into the bud! When Tem1 arrives in the concentration of Lte1 in the bud, it is activated (1204). This triggers the release of Cdc14 from the nucleolus, which in turn triggers exit from mitosis.

**Figure 29.38** Exit from mitosis is triggered when the Tem1 that is localized on a spindle pole body migrates into the bud where Lte1 is localized.

## CELL CYCLE AND GROWTH REGULATION

### 6.29.21 The cell forms a spindle at mitosis

---

#### Key Terms

The **spindle** guides the movement of chromosomes during cell division. The structure is made up of microtubules.

A **microtubule** is a filament consisting of dimers of tubulin. It serves as a track for the movement of chromosomes during cell division and for the movements of vesicles and organelles in nondividing cells. It is also a dynamic component of cilia and flagella.

#### Key Concepts

- The activity of M phase kinase is responsible for condensation of chromatin into chromosomes, dissolution of the nuclear lamina and envelope breakdown, reorganization of actin filaments, and (by unknown means) reorganization of microtubules into the spindle.

---

The culmination of the cell cycle is the act of division, when the chromosomes segregate into two diploid sets and the other components of the cell are partitioned between the two daughter cells. The change in cell structure is dramatic, as summarized in **Figure 29.39**. The division between nucleus and cytoplasm is abolished, and the cytoskeleton is entirely reorganized. The relevant events include:

**Figure 29.39** Major changes in the cell at mitosis involve the chromosomes, nuclear envelope, nuclear lamina, and microtubules.

- Condensation of chromatin to give recognizable chromosomes.
- Dissolution of the nuclear lamina and breakdown of the nuclear envelope. The lamina dissociates into individual lamin subunits, and the nuclear envelope, endoplasmic reticulum, and Golgi apparatus break down into small membrane vesicles. (Nuclear dissolution is typical of animal cells but does not occur in some lower eukaryotes, including yeasts, where mitosis involves nuclear division.)
- Dissociation and reconstruction of microtubules into a **spindle**. **Microtubules**

dissociate into tubulin dimers, which reassemble into microtubules extended from the mitotic microtubule organizing centers.

- Reorganization of actin filaments to replace the usual network by the contractile ring that pinches the daughter cells apart at cytokinesis.

All of these changes are reversible; following the separation of daughter cells, the actin filaments resume their normal form, the microtubular spindle is dissolved, the nuclear envelope reforms, and chromosomes take a more dispersed structure in the form of interphase chromatin. Modification of appropriate substrate proteins (which could be either the structural subunits themselves or proteins associated with them) provides a plausible means to control the passage of mitosis. The question then becomes how the mitotic changes and their reversal depend upon the activation and inactivation of M phase kinase (for review see 320; 330).

The best characterized substrate for M phase kinase is histone H1. As noted previously, we do not know what role the phosphorylation of H1 plays at either G1/S or M phase transitions. It is a reasonable assumption, however, that M phase kinase acts directly on chromatin by phosphorylating H1 and other target proteins, and that this is the cause of chromosomal condensation.

Two types of event have been implicated in nuclear envelope breakdown (sometimes abbreviated to NEBD). They affect the two components of the envelope: the membrane and the underlying lamina.

Mechanical effects are caused by the growth of microtubules into the envelope. This occurs when the centrosomes (the microtubule nucleating centers) move into the envelope at the start of mitosis. The motor dynein pulls the envelope along the microtubules. The stress causes the envelope to tear, and may also disrupt the structure of the lamina (2401; 2402).

Nuclear integrity is abandoned when the lamina dissociates into its constituent lamins. The lamina is a dense network of fibers just underneath the inner nuclear membrane. It is responsible for maintaining the shape of the nucleus (for review see 2425). The components of the lamina are three types of lamins, each of which has a domain structure similar to that of the protein subunits of the intermediate filaments that are found in the cytoplasm. The importance of lamins is emphasized by the existence of human diseases resulting from mutations in lamin genes, although we cannot yet relate the phenotypes of the diseases to the molecular functions of the lamins.

Lamins are phosphorylated at the start of mitosis, and the presence of phosphate groups on only two serine residues per lamin is sufficient to cause dissociation of the lamina. Mutations that change these serines into alanines prevent the lamina from dissociating at mitosis. So the reversible phosphorylation of these two serine residues induces a structural change in the individual lamin subunits that controls their ability to associate into the lamina (841; 842).

The combined effects of tearing the membrane and dissociating the lamina generate a series of vesicles containing the membranes. The process is reversed at the end of

mitosis, when lamins are closely involved in reassembly of the nuclear membrane.

Nuclear pore complexes dissociate from the envelope during mitosis. Nuclear pore components are phosphorylated, and as a result are released from the pores and dispersed in the cell (2403).

These phosphorylation events are the direct responsibility of the M phase kinase, which can cause the nuclear lamina to dissociate *in vitro*. The reorganization of the endoplasmic reticulum and Golgi is not well defined.

## CELL CYCLE AND GROWTH REGULATION

### 6.29.22 The spindle is oriented by centrosomes

---

#### Key Terms

**Centrosomes** are the regions from which microtubules are organized at the poles of a mitotic cell. In animal cells, each centrosome contains a pair of centrioles surrounded by a dense amorphous region to which the microtubules attach.

The **kinetochore** is the structural feature of the chromosome to which microtubules of the mitotic spindle attach. Its location determines the centromeric region.

A **centriole** is a small hollow cylinder consisting of microtubules. It occurs in the centrosome (a type of microtubule organizing center) and is thought to play a role in organizing the microtubules.

The **procentriole** is an immature centriole, formed in the vicinity of a mature centriole.

#### Key Concepts

- Microtubule assembly is nucleated by complexes located within the centrosomes that contain  $\gamma$ -tubulin.
- The centrioles duplicate by a mechanism involving orientation of the daughter relative to the parent.

---

The reorganization of microtubules into the spindle has been extensively described, but cannot yet be connected to the action of M phase kinase. Some microtubules extend from pole to pole, others connect the chromosomes to the poles. The ends of each microtubules are attached to MTOCs – microtubule organizing centers. The MTOCs at the poles lie in the regions of the **centrosomes**. The MTOC on a chromosome is located at the **kinetochore**.

The structure of centrosomes is not well defined, but in animal cells a centrosome contains a pair of **centrioles**, surrounded by a dense amorphous region. The centriole is a small hollow cylinder whose wall consists of a series of triplet fused microtubules. A centriole is shown in cross-section in **Figure 29.40**.

**Figure 29.40** The centriole consists of nine microtubule triplets, apparent in cross-section as the wall of a hollow cylinder. Photograph kindly provided by A. Ross.

The function of the centriole in mitosis is not clear. Originally it was thought that it might provide the structure to which microtubules are anchored at the pole, but the fibers seem instead to terminate in the amorphous region (the pericentriolar material) around the centrioles. It is possible that the centriole is concerned with orienting the spindle; it may also have a role in establishing directionality for cell movement. However, there are cell types in which centrosomes do not appear to contain centrioles.

Centrioles have their own cycle of duplication. When born at mitosis, a cell inherits two centrioles. During interphase they reproduce, so that at the start of mitosis there are four centrioles, two at each pole. Probably only the parental centriole is functional.

The centriole cycle is illustrated in **Figure 29.41**. Soon after mitosis, a **procentriole** is elaborated perpendicular to the parental centriole. It has the same structure as the mature parental centriole, but is only about half its length. Later during interphase, it is extended to full length. It plays no role in the next mitosis, but becomes a parental centriole when it is distributed to one of the daughter cells. The orientation of the parental centriole at the mitotic pole is responsible for establishing the direction of the spindle.

**Figure 29.41** A centriole reproduces by forming a procentriole on a perpendicular axis; the procentriole is subsequently extended into a mature centriole. Photograph kindly provided by J. B. Rattner and S. G. Phillips.

How are centrioles reproduced? The precise elaboration of the procentriole adjacent to the parental centriole suggests that some sort of template function is involved. The parental centriole cannot itself be seen to reproduce or divide, but it could provide some nucleating structure onto which tubulin dimers assemble to extend the procentriole. Could a centriole be assembled in the absence of a pre-existing centriole?

Microtubules consist of hollow filaments made of 13 protofilaments that are constructed from dimers of  $\alpha$ -tubulin and  $\beta$ -tubulin. Within the centrosome there is a related protein,  $\gamma$ -tubulin, which is part of a complex that provides the actual nucleating source for the microtubules (for review see 317; 318). The complex is large, sedimenting at  $\sim 25S$ , and contains several other proteins in addition to  $\gamma$ -tubulin. The complex can nucleate the formation of microtubules from  $\alpha$ -tubulin and  $\beta$ -tubulin *in vitro*. The complex takes the form of a ring, and probably the  $\gamma$ -tubulin-containing complex nucleates microtubules through some sort of end-binding mechanism (1591).

The spindle is generally nucleated by the centrosomes, although cells can in fact generate spindles by other pathways in the absence of centrosomes. In addition to its mechanical role in cell reorganization, a centrosome is a regulatory target. Centrosome duplication is regulated during the cell cycle, and there is a checkpoint to stop the cycle proceeding until centrosome duplication has occurred. The components of the centrosome involved in nucleating microtubules are beginning to be defined, but the components involved in regulation mostly remain to be described (for review see 3424).

## CELL CYCLE AND GROWTH REGULATION

### 6.29.23 A monomeric G protein controls spindle assembly

---

#### Key Concepts

- The active form of the G protein Ran (Ran-GTP) causes importin dimers to release proteins that trigger microtubule nucleation.
  - The Ran-activating protein RCC is localized on chromosomes, generating a high local concentration of Ran-GTP.
  - The proteins released by the importins have several different functions that assist microtubule nucleation.
- 

The trigger for the reorganization of microtubules from the interphase network into the spindle may be the breakdown of the nuclear envelope, which exposes nuclear components to cytoplasmic components. Indirect evidence has been available for some time to indicate a connection, but only recently has a molecular mechanism been suggested. The important point here is that the ability of an MTOC to nucleate microtubules must be *controlled*, so that it happens only in the right time and place.

The critical component is a monomeric G protein called Ran, which controls the direction of protein transport through the nuclear envelope. Like all members of its class, Ran is active when bound to GTP, and inactive when bound to GDP (see *Molecular Biology Supplement 32.10 G proteins*). Conditions in the nucleus and cytosol differ so that typically there is Ran-GTP in the nucleus, but there is Ran-GDP in the cytosol. Protein export complexes are stable in the presence of Ran-GTP, whereas import complexes are stable in the presence of Ran-GDP. So export complexes are driven to form in the nucleus and dissociate in the cytosol, whereas the reverse is true of import complexes (see *Molecular Biology 2.8.28 Transport receptors carry cargo proteins through the pore*).

Mutations in some proteins that bind to Ran cause the spindle to malfunction, and overexpression of the protein RanBPM (another Ran-binding protein) causes the formation of ectopic asters – arrays of microtubules emanating from centrosomes. The usual assay for these experiments is to inject demembrated sperm into *Xenopus* eggs. The sperm centrioles assemble into centrosomes that nucleate microtubule asters. Using this assay identifies proteins that can stimulate nucleation. These include a mutant of Ran and the protein RCC that maintains Ran in the GTP-bound active state (1592; 1593). The most likely explanation is that the breakdown of the nuclear envelope releases Ran-GTP, which then triggers microtubule nucleation by centrosomes.

Does Ran act directly or indirectly? One of the targets for Ran in the nuclear transport process is the import receptor importin-  $\beta$ , which (in combination with importin-  $\alpha$ ) transports cargo proteins from the cytoplasm to the nucleus. It turns out that the importin dimer binds to proteins that affect microtubules. One of these

proteins is Xklp2, which connects a motor (a protein that moves other proteins) to microtubules at the poles; another is NuMA which cross links microtubules at the poles during mitosis. When the complex of importins with either of these proteins is exposed to Ran-GTP, it dissociates, releasing the cargo protein, which can then act to trigger microtubule nucleation (1594; 1595).

How does the exposure of the importins to Ran-GTP change at mitosis? **Figure 29.42** shows that the situation in the cytoplasm of the interphase cell, and then correspondingly in the spindle, is that Ran is predominantly in the form of Ran-GDP, and therefore does not affect the importin complex. But there are localized areas where Ran-GTP is formed. The Ran-activating protein RCC is located on chromatin, so Ran-GTP forms in the vicinity of the chromosomes. This releases the proteins that are bound to the importin dimer, which activate the kinetochores to connect to microtubules.

**Figure 29.42** The Ran-activating protein RCC is localized on chromosomes. Ran-GTP is high in the nucleus in the interphase cell. When the nuclear envelope breaks down, RCC maintains a high level of Ran-GTP in the vicinity of the chromosomes. This causes importin dimers to release the proteins bound to them. These proteins cause microtubule nucleation.

## CELL CYCLE AND GROWTH REGULATION

## 6.29.24 Daughter cells are separated by cytokinesis

## Key Terms

**Cytokinesis** is the process involved in separation and movement apart of daughter cells. Cytokinesis occurs at the end of mitosis.

The constriction in the cell cortex that separates newly reformed nuclei after mitosis and results in the formation of two cells is the **cleavage furrow**.

The **contractile ring** is a ring of actin filaments that forms around the equator at the end of mitosis and is responsible for pinching the daughter cells apart.

The **midbody** is the last connection between two cells as they separate at the end of cytokinesis. A parallel array of microtubules derived from the mitotic spindle enters the midbody from each cell, and the two arrays interdigitate across its whole width.

Once the two sets of daughter chromosomes have been separated at the poles, the cell must complete its division by physically separating into two parts. This process is called **cytokinesis**, and it passes through the stages illustrated in **Figure 29.43** (for review see 2303).

**Figure 29.43** The spindle specifies the cleavage plane where the contractile ring assembles, the midbody forms in the center, and then the daughter cells separate.

The plane for division forms in the center of the spindle. We do not know exactly how its position is defined, but it seems to depend on the microtubules arrays that run to the poles. A local event that may be needed is the activation of the RhoA monomeric G protein. (This is one of the monomeric G proteins that controls actin filament behavior in the interphase cell; see **Figure 28.35** in *Molecular Biology 6.28.15 The activation of Ras is controlled by GTP*).

An invagination called the **cleavage furrow** appears in the plasma membrane soon after the start of anaphase. This is caused by the formation of the **contractile ring**, which forms from actomyosin fibers. It extends around the equator of the dividing cell and then pinches inward until it contacts a group of microtubules that run between the poles. This forms a structure connecting the future daughter cells that is called the **midbody**.

The final step in cytokinesis is to cut the cytoplasmic connection between the two cells by "resolving" the midbody. This requires changes in the organization of the plasma membrane, but we cannot yet account for these events at the molecular level.

## CELL CYCLE AND GROWTH REGULATION

### 6.29.25 Apoptosis is a property of many or all cells

#### Key Terms

**Apoptosis (Programmed cell death)** is the capacity of a cell to respond to a stimulus by initiating a pathway that leads to its death by a characteristic set of reactions.

#### Key Concepts

- All cells possess the pathways that can cause death by apoptosis, which requires RNA and protein synthesis by the dying cell, but the pathway is activated only by appropriate stimuli.

During development of a multicellular eukaryotic organism, *some cells must die*. Unwanted cells are eliminated during embryogenesis, metamorphosis, and tissue turnover. This process is called **programmed cell death** or **apoptosis**. It provides a crucial control over the total cell number. In the worm *C. elegans* (in which somatic cell lineages have been completely defined), 131 of the 1090 adult somatic cells undergo programmed cell death – cells die predictably at a defined time and place in each animal. Similar, although less precisely defined, cell deaths occur during vertebrate development, most prominently in the immune system and nervous system. The proper control of apoptosis is crucial in probably all higher eukaryotes.

Apoptosis involves the activation of a pathway that leads to suicide of the cell by a characteristic process in which the cell becomes more compact, blebbing occurs at the membranes, chromatin becomes condensed, and DNA is fragmented (see **Figure 29.44**). *The pathway is an active process that depends on RNA and protein synthesis by the dying cell.* The typical features of a cell as it becomes heteropycnotic (condensed with a small, fragmented nucleus) are shown in **Figure 29.45**, and the course of fragmentation of DNA is shown in **Figure 29.46**. Ultimately the dead cells become fragmented into membrane-bound pieces, and may be engulfed by surrounding cells (for review see 324).

**Figure 29.44** The nucleus becomes heteropycnotic and the cytoplasm blebs when a cell apoptoses.

**Figure 29.45** Cell structure changes during apoptosis. The top panel shows a normal cell. The lower panel shows an apoptosing cell; arrows indicate condensed nuclear fragments. Photographs kindly provided by Shigekazu Nagata.

**Figure 29.46** Fragmentation of DNA occurs ~2 hours after apoptosis is initiated in cells in culture. Photograph kindly provided by Shigekazu Nagata.

Apoptosis can be triggered by a variety of stimuli, including withdrawal of essential growth factors, treatment with glucocorticoids,  $\gamma$ -irradiation, and activation of certain receptors, as summarized in **Figure 29.47**. These all involve a molecular insult to the cell. Another means of initiating apoptosis is used in the immune system, where cytotoxic T lymphocytes attack target cells. Apoptosis is also an important mechanism for removing tumorigenic cells; the ability of the tumor suppressor p53 to trigger apoptosis is a key defense against cancer (see *Molecular Biology 6.30.20 Tumor suppressor p53 suppresses growth or triggers apoptosis*). Apoptosis is important, therefore, not only in tissue development, but in the immune defense and in the elimination of cancerous cells. Also, inappropriate activation of apoptosis is involved in neurodegenerative diseases.

**Figure 29.47** Apoptosis is triggered by a variety of pathways.

**CELL CYCLE AND GROWTH REGULATION****6.29.26 The Fas receptor is a major trigger for apoptosis****Key Terms**

The **death domain** is a protein-protein interaction motif found in certain proteins of the apoptotic pathway.

**Key Concepts**

- The Fas receptor on a target cell is activated by interaction with the FasL protein on an activating cell plasma membrane.
- Fas is related to TNF receptor, and FasL is related to TNF.
- Fas is a trimer that aggregates upon interaction with FasL.
- Fas has a cytoplasmic domain called the "death domain" which is involved in protein-protein interactions.

The Fas receptor (called Fas or FasR) and Fas ligand (FasL) are a pair of plasma membrane proteins whose interaction triggers one of the major pathways for apoptosis. **Figure 29.48** shows that the cell bearing the Fas receptor apoptoses when it interacts with the cell carrying the Fas ligand (for review see 969).

**Figure 29.48** The Fas receptor and ligand are both membrane proteins. A target cell bearing Fas receptor apoptoses when it interacts with a cell bearing the Fas ligand.

Activation of Fas resembles other receptors in involving an aggregation step. However, **Figure 29.49** shows that there are some interesting differences from the growth receptor model. First, Fas forms a homomeric trimer. Second, the trimer assembles *before* the interaction with ligand. The effect of ligand may be to cause the trimers to cluster into large aggregates (1067; 1068). At all events, when FasL interacts with Fas, there is an aggregation event that enables Fas to activate the next stage in the pathway.

**Figure 29.49** Fas forms trimers that are activated when binding to FasL causes aggregation.

The names of the two proteins (Fas receptor and Fas ligand) reflect the way the system was discovered. An antibody directed against Fas protein kills cells that express Fas on their surface. The reason is that the antibody-Fas reaction activates Fas, which triggers a pathway for apoptosis. This defines Fas as a receptor that activates a cellular pathway.

Fas is a cell surface receptor related to the TNF (tumor necrosis factor) receptor. The FasL ligand is a transmembrane protein related to TNF. A family of related receptors includes two TNF receptors, Fas, and several receptors found on T lymphocytes. A corresponding family of ligands comprises a series of transmembrane proteins. This suggests that there are several pathways, each of which can be triggered by a cell-cell interaction, in which the "ligand" on one cell surface interacts with the receptor on the surface of the other cell. Both the Fas- and TNF-receptors can activate apoptosis.

Both of the Fas and TNF ligands are initially produced as membrane-bound forms, but can also be cleaved to generate soluble proteins, which function as diffusible factors. The soluble form of TNF is largely produced by macrophages, and is a pleiotropic factor that signals many cellular responses, including cytotoxicity. Most of its responses are triggered by interaction with one of the TNF receptors, TNF-R1. FasL is cleaved to generate a soluble form, but the soluble form is much less active than the membrane-bound form, so the reaction probably is used to reduce the activity of the cell bearing the ligand.

An assay for the capacity of the ligand-receptor interaction to trigger apoptosis is to introduce the receptor into cultured cells that do not usually express it. On treatment with the ligand, the transfected cells die by apoptosis, but the parental cells do not. Using this assay, similar results are obtained with FasL/Fas receptor and with TNF/TNF-R1. Mutant versions of the receptor show that the apoptotic response is triggered by an ~80 amino acid intracellular domain near the C-terminus. This region is loosely conserved (~28%) between Fas and TNF-R1, and is called the **death domain** (854).

An assay for components of the apoptotic pathway in the cell is to see whether their overexpression causes apoptosis. This is done by transfecting the gene for the protein into the cell (which results in overexpression of the protein). This assay identifies several proteins that interact specifically with the Fas and/or TNF receptors. All of

these proteins themselves have death domains, and it is possible that a homomeric interaction between two death domains provides the means by which the signal is passed from the receptor to the next component of the pathway.

The validity of this pathway *in vivo* was demonstrated by the discovery of the mouse mutation *lpr*. This is a recessive mutation in the gene for Fas. It causes proliferation of lymphocytes, resulting in a complex immune disorder affecting both B cells and T cells. Another mutation with similar effects is *gld* (generalized lymphoproliferative disease). This turns out to lie in the gene that codes the FasL ligand. The related properties of these two loci suggest that this apoptotic pathway is triggered by an interaction between the FasL ligand (*gld* product) and Fas (*lpr* product). The pathway is required for limiting the numbers of mature lymphocytes (851; 852; 853).

## CELL CYCLE AND GROWTH REGULATION

### 6.29.27 A common pathway for apoptosis functions via caspases

---

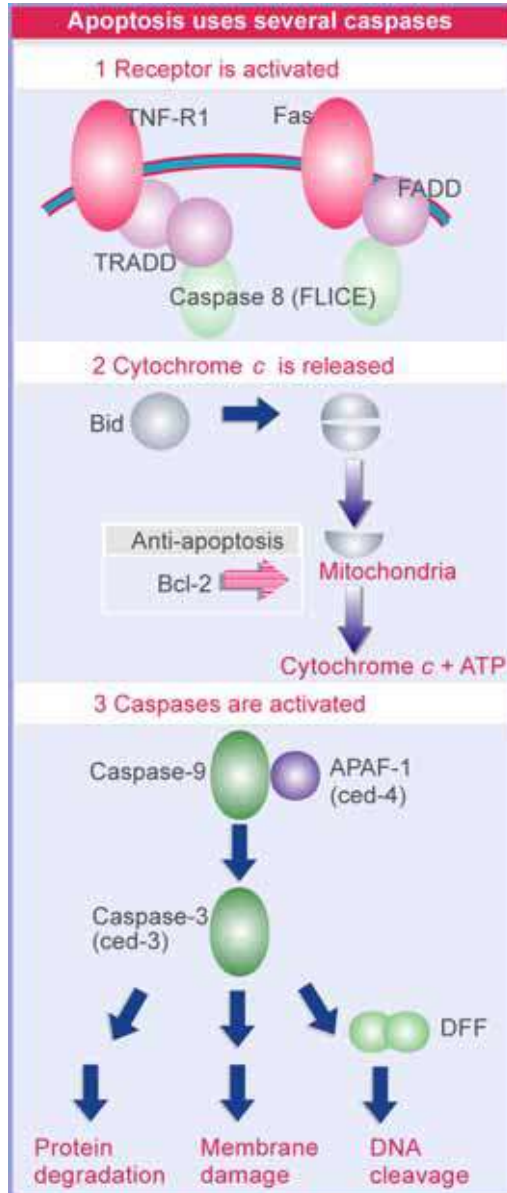

#### Key Terms

**Caspases** comprise a family of protease some of whose members are involved in apoptosis (programmed cell death).

#### Key Concepts

- Caspases are proteases that are involved in multiple stages of the apoptotic pathway.
  - Caspases are synthesized as inactive procaspases that are activated by autocleavage to form the active dimer.
  - A complex forms at the Fas or TNF receptor that activates caspase-8 to initiate the intracellular pathway.
- 

The "classical" pathway for apoptosis is summarized in **Figure 29.50**. A ligand-receptor interaction triggers the activation of a protease. This leads to the release of cytochrome *c* from mitochondria. This in turn activates a series of proteases, whose actions culminate in the destruction of cell structures (for review see 1003).

**Figure 29.50** Apoptosis can be triggered by activating surface receptors. Caspase proteases are activated at two stages in the pathway. Caspase-8 is activated by the receptor. This leads to release of cytochrome *c* from mitochondria. Apoptosis can be blocked at this stage by Bcl-2. Cytochrome *c* activates a pathway involving more caspases.

A complex containing several components forms at the receptor. The exact components of the complex depends on the receptor (for review see 2264). TNF receptor binds a protein called TRADD, which in turn binds a protein called FADD. Fas receptor binds FADD directly. **Figure 29.51** shows that, in either case, FADD binds the protein caspase-8 (also known as FLICE), which has a death domain as well as protease catalytic activity. The activation of caspase-8 activates a common pathway for apoptosis. The trigger for the activation event is the oligomerization of the receptor. In the case of the Fas system, the interaction of FasL with Fas causes

the Fas trimers to interact, activating the pathway.

**Figure 29.51** The TNF-R1 and Fas receptors bind FADD (directly or indirectly). FADD binds caspase-8. Activation of the receptor causes oligomerization of caspase-8, which activates the caspase.

Members of the **caspase** family (cysteine aspartate proteases) are important downstream components of the pathway. Caspases have a catalytic cysteine, and cleave their targets at an aspartate. Individual enzymes have related, but not identical targets. For example, caspase-3 and ICE both cleave at tetrapeptide sequences in their substrates, but caspase-3 recognizes YVAD and ICE recognizes DEVD. There are ~14 mammalian members of the caspase family.

Caspases fall into two groups. The caspase-1 subfamily is involved in the response to inflammation. The caspase-3 subfamily (consisting of caspase 3 and caspases 6-10) is involved in apoptosis. All caspases are synthesized in the form of inactive procaspases, which have additional sequences at the N-terminus. **Figure 29.52** shows that the activation reaction involves cleavage of the prodomain followed by cleavage of the caspase sequence itself into a small subunit and large subunit. All procaspases except procaspase-9 probably exist as dimers.

**Figure 29.52** Caspase activation requires dimerization and two cleavages.

Caspases with large prodomains are involved in initiating apoptosis. Dimerization causes an autocatalytic cleavage that activates the caspase (for review see 992). The prodomain of caspase-8 has two death domain motifs that are responsible for its association with the receptor complex. Cleavage to the active form occurs as soon as procaspase-8 is recruited to the receptor complex (1007; 1008).

Caspases with small prodomains function later in the pathway. The first in the series is activated by an autocleavage when it forms an oligomer. Others later in the pathway typically are activated when another caspase cleaves them .

The first caspase to be discovered (ICE=caspase-1) was the IL-1  $\beta$ -converting enzyme, which cleaves the pro-IL-1  $\beta$  precursor into its active form. Although this caspase is usually involved with the inflammatory response, transfection of ICE into cultured cells causes apoptosis. The process is inhibited by CrmA (a product of cowpox virus). All caspases are inhibited by CrmA, although each caspase has a characteristic sensitivity. CrmA inhibits apoptosis triggered in several different ways, which demonstrates that the caspases play an essential role in the pathway,

irrespective of how it is initiated. However, it turns out that ICE is not itself the protease commonly involved in apoptosis, because inactivation of the gene for ICE does not block general apoptosis in the mouse. [The ability of ICE to cause apoptosis demonstrates a danger of the transfection assay: overexpression may allow it to trigger apoptosis, although usually it does not do so. But ICE may be needed specifically for apoptosis of one pathway in lymphocytes (855).]

**CELL CYCLE AND GROWTH REGULATION****6.29.28 Apoptosis involves changes at the mitochondrial envelope**

---

**Key Concepts**

- Caspase-8 cleaves Bid to release a C-terminal domain that translocates to the mitochondrion.
- Bid is a member of the Bcl2 family and acts together with other members of the family to cause mitochondria to release cytochrome *c*.
- Some members of the family, including Bcl2, inhibit the release of cytochrome *c*.

---

Changes in mitochondria occur during apoptosis (and also during other forms of cell death). These are typically detected by changes in permeability. The breakthrough in understanding the role of mitochondria was the discovery that cytochrome *c* is released into the cytosol (see *Great Experiments 7.1 The role of cytochrome c in apoptosis*) (1009). **Figure 29.53** summarizes the central role of the mitochondrion (for review see 2431). In addition to releasing cytochrome *c*, it also releases other proteins from its intermembrane space that may either promote or inhibit apoptosis.

**Figure 29.53** The mitochondrion plays a central role in apoptosis by releasing cytochrome *c*. This is activated by BID. It is inactivated by Bcl-2. Cytochrome *c* binds to Apaf-1 and (pro)-Caspase-9 to form the apoptosome. The proteolytic activity of caspase-9 (and other caspases) can be inhibited by IAP proteins. Proteins that antagonize IAPs may be released from the mitochondrion.

The pathway moves from the plasma membrane to the mitochondrion when caspase-8 cleaves a protein called Bid. The cleavage releases the C-terminal domain, which then translocates to the mitochondrial membrane. The action of Bid causes cytochrome *c* to be released (1011; 1012).

Bid is a member of the important Bcl2 family. Some members of this family are required for apoptosis, while others counteract apoptosis. The eponymous Bcl2 inhibits apoptosis in many cells. It has a C-terminal membrane anchor, and is found on the outer mitochondrial, nuclear, and ER membranes. It prevents the release of cytochrome *c*, which suggests that in some way it counteracts the action of Bid.

*bcl2* was originally discovered as a proto-oncogene that is activated in lymphomas by translocations resulting in its overexpression. (As discussed in more detail in *Molecular Biology 6.30 Oncogenes and cancer*, this means that Bcl2 is a member of a class of proteins that causes proliferation or tumorigenesis when inappropriately expressed.) Its role as an inhibitor of apoptosis was discovered when it was shown that its addition protects cultured lymphoid and myeloid cells from dying when the essential factor IL-3 is withdrawn.

Mammalian cells that are triggered into apoptosis by a wide variety of stimuli, including activation of the Fas/TNF-R1 pathways, can be rescued by expression of Bcl2. This suggests that these pathways converge on a single mechanism of cell killing, and that Bcl2 functions at a late, common stage of cell death. There are some systems in which Bcl2 cannot block apoptosis, so the pathway that it blocks may be common, but is not the only one.

Bcl2 belongs to a family whose members can homodimerize and heterodimerize. Two other members are bcl-x (characterized in chicken) and Bax (characterized in man). bcl-x is produced in alternatively spliced forms that have different properties. When transfected into recipient cells, bcl-x<sub>L</sub> mimics Bcl2, and inhibits apoptosis. But bcl-x<sub>S</sub> counteracts the ability of Bcl2 to protect against apoptosis. Bax behaves in the same way as bcl-x<sub>S</sub>. This suggests that the formation of Bcl2 homodimers may be needed to provide the protective form, and that Bcl2/Bax or Bcl2/bcl-x<sub>S</sub> heterodimers may fail to protect. Whether Bax or bcl-x<sub>S</sub> homodimers actively assist apoptosis, or are merely permissive, remains to be seen. The general conclusion suggested by these results is that combinatorial associations between members of the family may produce dimers with different effects on apoptosis, and the relative proportions of the family members that are expressed may be important. The susceptibility of a cell to undergo apoptosis may be proportional to the ratio of Bax to Bcl2 (for review see 334).

The mitochondrion is a crucial control point in the induction of apoptosis (for review see 4520). The release of cytochrome *c* is preceded by changes in the permeability of the mitochondrial membrane (1013). Bcl2 family members act at the mitochondrial membrane, and although their mode of action is not known, one possibility is that they form channels in the membrane. Apoptosis involves localization (or perhaps increased concentration) of Bcl2 family members at the mitochondrial membrane, including Bid (required to release cytochrome *c*) and Bax (perhaps involved in membrane permeability changes).

## CELL CYCLE AND GROWTH REGULATION

### 6.29.29 Cytochrome *c* activates the next stage of apoptosis

---

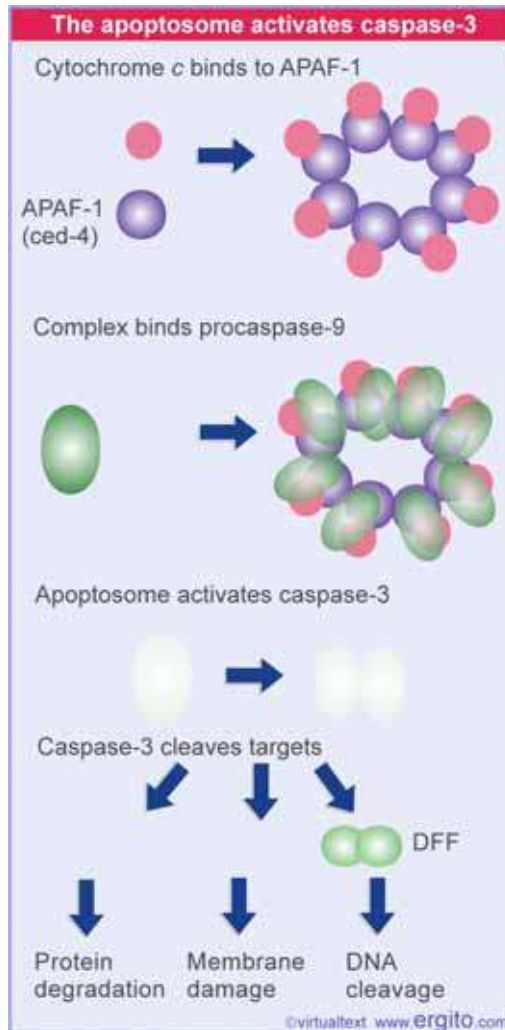

#### Key Terms

**IAPs** are inhibitors of apoptosis. They function by antagonizing the actions of caspases.

#### Key Concepts

- Cytochrome *c* causes Apaf-1 to aggregate with procaspase-9 to form the apoptosome, which then activates caspase-9 by autocleavage.
  - Caspase-9 cleaves caspase-3 and other caspases to trigger the effector phase of apoptosis, when cellular structures are destroyed.
- 

The release of cytochrome *c* is a crucial control point in the pathway (for review see 2431). The basic role of cytochrome *c* is to trigger the activation of caspase-9 (858). **Figure 29.54** shows the stages between cytochrome *c* release and caspase-9 activation. Cytochrome *c* triggers the interaction of the cytosolic protein Apaf-1 with caspase-9 in a complex called the apoptosome. The reaction takes place in several stages. Cytochrome *c* binds to Apaf-1. This enables Apaf-1 to bind ATP. This in turn enables it to oligomerize, which causes a change of conformation that exposes the caspase-binding domain; then Apaf-1 binds procaspase-9. The incorporation of procaspase-9 into the apoptosome triggers the auto-activating cleavage (1010).

**Figure 29.54** Cytochrome *c* causes Apaf-1 to interact with caspase-9, which activates caspase-3, which cleaves targets that cause apoptosis of the cell.

The properties of mice lacking Apaf-1 or caspase-9 throw some light upon the generality of apoptotic pathways. Lack of caspase-9 is lethal, because the mice have a malformed cerebrum as the result of the failure of apoptosis. Apoptosis is also reduced in thymocytes (immune precursors to lymphocytes). Apaf-1 deficient mice have less severe defects in brain development, implying that there are alternative means for activating caspase-9. Both types of deficient mice continue to show Fas-mediated apoptosis, implying that Fas has alternative means of triggering apoptosis.

Caspase-9 in turn cleaves procaspase-3 to generate caspase-3 (which is in fact the best characterized component of the downstream pathway. Caspase-3 is the homologue of the *C. elegans* protein ced-3; see below). Caspase-9 also activates caspases-6 and 7.

Caspase-3 acts at what might be called the effector stage of the pathway. We have not identified all of the targets of the protease activity that are essential for apoptosis.

One known target is the enzyme PARP (poly[ADP-ribose] polymerase). Its degradation is not essential, but is a useful diagnostic for apoptosis.

One pathway that leads to DNA fragmentation has been identified. Caspase-3 cleaves one subunit of a dimer called DFF (DNA fragmentation factor). The other subunit then activates a nuclease that degrades DNA (856). However, the degradation of DNA by this pathway does not appear to be necessary for cell death, which continues in mice that lack the enzyme (1926).

Another pathway for DNA degradation is triggered directly by release of an enzyme from the mitochondrion. The normal function of endonuclease G within the mitochondrion is concerned with DNA replication. However, in apoptosing cells it is released from the mitochondrion, and then degrades nuclear DNA (1925). Interference with the function of the corresponding gene in *C. elegans* reduces DNA degradation and delays the appearance of cell corpses (1924). This enzyme therefore appears to be important at least for the time course of apoptosis, even if it is not necessary for the eventual death of the cell.

The control of apoptosis involves components that inhibit the pathway as well as those that activate it. This first became clear from the genetic analysis of cell death in *C. elegans*, when mutants were found that either activate or inactivate cell death. Mutations in *ced-3* and *ced-4* cause the survival of cells that usually die, demonstrating that these genes are essential for cell death. *ced-3* codes for the protease activity (and was in fact the means by which caspases were first implicated in apoptosis). It is the only protease of this type in *C. elegans*. *ced-4* codes for the homologue to Apaf-1.

*ced-9* inhibits apoptosis. It codes for the counterpart of Bcl2. A mutation that inactivates *ced-9* is lethal, because it causes the death of cells that should survive. This process requires *ced-3* and *ced-4*, and this was the original basis for the idea that *ced-9* blocks the apoptotic pathway(s) in which *ced-3* and *ced-4* participate. This relationship makes an important point: *ced-3* and *ced-4* are not expressed solely in cells that are destined to die, but are expressed also in other cells, where normally their action is prevented by *ced-9*. The proper control of apoptosis may therefore involve a balance between activation and inhibition of this pathway.

The apoptotic pathway can also be inhibited at the stages catalyzed by the later caspases. Proteins called **IAP** (inhibitor of apoptosis) can bind to procaspases and activated caspases to block their activities (see **Figure 29.53**). The blocking activities of the AIPs need to be antagonized in order for apoptosis to proceed (for review see 3435). Vertebrate cells contain a protein called Diablo/Smac, which is released from mitochondria at the same time as cytochrome c, and acts by binding to IAPs (1060; 1061).

The existence of mechanisms to inhibit as well as to activate apoptosis suggests that many (possibly even all) cells possess the intrinsic capacity to apoptose. If the components of the pathway are ubiquitous, the critical determinant of whether a cell lives or dies may depend on the regulatory mechanisms that determine whether the pathway is activated or repressed.

---

**CELL CYCLE AND GROWTH REGULATION****6.29.30 There are multiple apoptotic pathways**

---

**Key Concepts**

- Fas activates apoptosis via the caspase pathway and also via the activation of the JNK kinase.

---

The pathway shown in **Figure 29.50** is the prototypical pathway for activation of apoptosis via a protease cascade. However, Fas can also activate apoptosis by a pathway that involves the kinase JNK, whose most prominent substrate is the transcription factor c-Jun (see **Figure 28.43**). This leads by undefined means to the activation of proteases. **Figure 29.55** shows that this pathway is mediated by the protein Daxx (which does not have a death domain). Binding of FADD and Daxx to Fas is independent: each adaptor recognizes a different site on Fas. The two pathways function independently after Fas has engaged the adaptor. The TNF receptor also can activate JNK by means of distinct adaptor proteins (857).

**Figure 29.55** Fas can activate apoptosis by a JNK-mediated pathway.

In the normal course of events, activation of Fas probably activates both pathways. Overexpression experiments show that either pathway can cause apoptosis. The relative importance of the two pathways may vary with the individual cell type, in response to other signals that affect each pathway. For example, JNK is activated by several forms of stress independently of the Fas-activated pathway. This pathway is not inhibited by Bcl2, which may explain the variable ability of cells to resist apoptosis in response to Bcl2.

Another apoptotic pathway is triggered by cytotoxic T lymphocytes, which kill target cells by a process that involves the release of granules containing serine proteases and other lytic components. One such component is perforin, which can make holes in the target cell membrane, and under some conditions can kill target cells. The serine proteases in the granules are called granzymes. In the presence of perforin, granzyme B can induce many of the features of apoptosis, including fragmentation of DNA. It activates a caspase called Ich-3, which is necessary for apoptosis in this pathway.

## CELL CYCLE AND GROWTH REGULATION

### 6.29.31 Summary

---

The cell cycle consists of transitions from one regulatory state to another. The change in regulatory state is separated by a lag period from the subsequent changes in cell phenotype. The transitions take the form of activating or inactivating a kinase(s), which modifies substrates that determine the physical state of the cell. Checkpoints can retard a transition until some intrinsic or extrinsic condition has been satisfied.

The two key control points in the cell cycle are in G1 and at the end of G2. During G1, a commitment is made to enter a replication cycle; the decision is identified by the restriction point in animal cells, and by START in yeast cells. After this decision has been taken, cells are committed to beginning an S phase, although there is a lag period before DNA replication initiates. The end of G2 is marked by a decision that is executed immediately to enter mitosis.

A unifying feature in the cell cycles of yeasts and animals is the existence of an M phase kinase, consisting of two subunits: Cdc2, with serine/threonine protein kinase catalytic activity; and a mitotic cyclin of either the A or B class. Homologous subunits exist in all eukaryotic cells. The genes that code for the catalytic subunit in yeasts are *cdc2* in *S. pombe* and *CDC28* in *S. cerevisiae*. Animal cells usually contain multiple mitotic cyclins (A, B1, B2); in *S. pombe*, there is only a single cyclin at M phase, a B class coded by *cdc13*, although *S. pombe* has several CLB proteins.

The activity of the M phase kinase is controlled by the state of phosphorylation of the catalytic subunit. The active form requires dephosphorylation on Tyr-15 (in yeasts) or Thr-14/Tyr-15 (in animal cells) and phosphorylation on Thr-161. The cyclins are also phosphorylated, but the significance of this modification is not known. In animal cells, the kinase is inactivated by degradation of the cyclin component, which occurs abruptly during mitosis. Cyclins of the A type are typically degraded before cyclins of the B type. Destruction of at least the B cyclins, and probably of both classes of cyclin, is required for cells to exit mitosis.

A comprehensive analysis of genes that affect the cell cycle has identified *cdc* mutants in both *S. pombe* and *S. cerevisiae*. The best characterized mutations are those that affect the components or activity of M phase kinase. Mutations *cdc25* and *wee1* in *S. pombe* have opposing effects in regulating M phase kinase in response to cell size (and other signals). Wee1 is a kinase that acts on Tyr-15 and maintains Cdc2 in an inactive state; Cdc25 is a phosphatase that acts on Tyr-15 and activates Cdc2. The existence of *wee1* and *cdc25* homologues in higher eukaryotes suggests that the apparatus for cell cycle control is widely conserved in evolution.

By phosphorylating appropriate substrates, the kinase provides MPF activity, which stimulates mitosis or meiosis (as originally defined in *Xenopus* oocytes). A prominent substrate is histone H1, and H1 kinase activity is now used as a routine assay for M phase kinase. Phosphorylation of H1 could be concerned with the need to condense chromatin at mitosis. Another class of substrates comprises the lamins, whose phosphorylation causes the dissolution of the nuclear lamina. A general

principle governing these (and presumably other) events is that the state of the substrates is controlled reversibly in response to phosphorylation, so that the phosphorylated form of the protein is required for mitotic organization, while the dephosphorylated form is required for interphase organization. Phosphatases are required to reverse the modifications introduced by M phase kinase.

Transition from G1 into S phase requires a kinase related to the M phase kinase. In yeasts, the catalytic subunit is identical with that of the M phase kinase, but the cyclins are different (the combinations being CDC28-cig1,2 in *S. cerevisiae*, Cdc2-CLN1,2,3 in *S. pombe*). Activity of the G1/S phase kinase and inactivity of the M phase kinase are both required to proceed through G1. Initiation of S phase in *S. pombe* requires rum1 to inactivate cdc2/cdc13 in order to allow the activation of Cdc18, which may be the S phase activator.

In mammalian cells, a family of catalytic subunits is provided by the *cdk* genes, named because they code for the catalytic subunits of cyclin-dependent kinases. There are ~10 *cdk* genes in an animal genome. Aside from the classic Cdc2, the best characterized product is cdk2 (which is well related to Cdc2). In a normal cell cycle, cdk2 is partnered by cyclin E during the G1/S transition and by cyclin A during the progression of S phase. cdk2 and cdk4 both partner the D cyclins to form kinases that are involved with the transition from G0 to G1. These cdk-cyclin complexes phosphorylate RB, causing it to release the transcription factor E2F, which then activates genes whose products are required for S phase. A group of CKI (inhibitor) proteins that are activated by treatments that inhibit growth can bind to cdk-cyclin complexes, and maintain them in an inactive form.

Checkpoints control progression of the cell cycle. One checkpoint responds to the presence of unreplicated or damaged DNA by blocking mitosis. Others control progress through mitosis, for example, detecting unpaired kinetochores.

Apoptosis is achieved by an active pathway that executes a program for cell death. The components of the pathway may be present in many or all higher eukaryotic cells. Apoptosis may be triggered by various stimuli. A common pathway involves activation of caspase-8 by oligomerization at an activated surface receptor. Caspase-8 cleaves Bid, which triggers release of cytochrome *c* from mitochondria. The cytochrome *c* causes Apaf-1 to oligomerize with caspase-9. The activated caspase-9 cleaves procaspase-3, whose two subunits then form the active protease. This cleaves various targets that lead to cell death. The pathway is inhibited by Bcl2 at the stage of release of cytochrome *c*. An alternative pathway for triggering apoptosis that does not pass through Apaf-1 and caspase-9, and which is not inhibited by Bcl2, involves the activation of JNK. Different cells use these pathways to differing extents. Apoptosis was first shown to be necessary for normal development in *C. elegans*, and knockout mutations in mice show that this is also true of vertebrates. Every cell may contain the components of the apoptotic pathway and be subject to regulation of the balance between activation and repression of cell death.

## ONCOGENES AND CANCER

### 6.30.1 Introduction

#### Key Terms

A **mutator** is a mutation or a mutated gene that increases the basal level of mutation. Such genes often code for proteins that are involved in repairing damaged DNA.

A major feature of all higher eukaryotes is the defined life span of the organism, a property that extends to the individual somatic cells, whose growth and division are highly regulated. A notable exception is provided by cancer cells, which arise as variants that have lost their usual growth control. Their ability to grow in inappropriate locations or to propagate indefinitely may be lethal for the individual organism in which they occur.

**Figure 30.1** shows that the incidence of cancer increases exponentially with age in a human population from the age of ~40 to ~80, when it plateaus. Immediately this suggests that cancer is the result of the occurrence of a series of independent events. From the trend of the curve we can estimate that a range of 4-10 stochastic events are required to generate a cancer (for review see 2252).

**Figure 30.1** The frequency of newly diagnosed cancers increases sharply with age. Each point on the graph gives the incidence over a one year period for the preceding age group (the first point is for 0-20 years of age, etc.). The incidence rate plateaus above age 80.

The basic model for the occurrence of cancer is that cancer is a multistage process in which initiation of a tumor requires several steps, which may then be followed by further changes to strengthen the tumorigenic state. Tumor progression is then driven by selection among the tumor cells for those that can grow more aggressively. Many different types of events contribute to this process at the molecular level (for review

see 2251).

The two major types of change in the genome are the accumulation of somatic mutations and the development of genetic instability. There is still much debate about the relative importance of their contributions to the cancerous state.

Most cancer cells have an increased number of mutations compared to normal cells (2253). As the cancer progresses, the number of mutations increases. However, the rate of somatic mutation is not sufficient to account for the accumulation of mutations that is observed in the cancer cells. **Figure 30.2** illustrates the view that some of the early mutations occur in **mutator** genes (2849). The inactivation of these genes decreases the repair of damaged DNA, and thereby increases the rate at which mutations occur (for review see 2848).

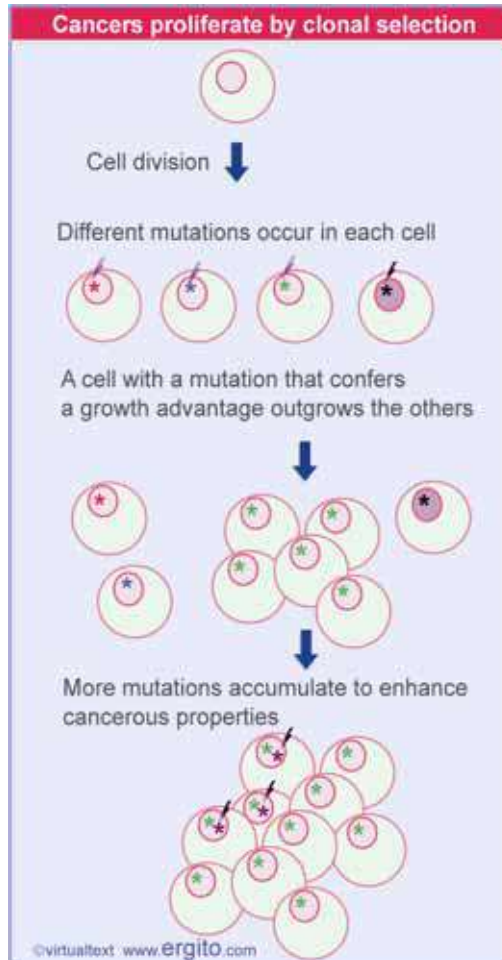

**Figure 30.2** Cancer cells accumulate mutations at an increased rate as a result of the mutation of a mutator gene and also undergo changes in the chromosomal constitution.

Genetic instability is reflected in changes in the numbers of genes in cancer cells. This can be the result of small duplications or deletions, translocations of material from one chromosome to another, or even changes that affect entire chromosomes. Instability at the level of chromosome can be caused by systems that act on partitioning at mitosis.

The occurrence of different mutations creates an opportunity to select among the population for cells with particular properties (2850). In the case of cancer, a mutation that increases the growth potential of a cell will give it a selective advantage. **Figure 30.3** illustrates the result that a cell that divides more often,

perhaps because it does not respect the usual constraints on growth, will generate more descendants. At each stage during the progression of a cancer, the cell population is selected for those cells that can grow more aggressively (this meaning initially that they can grow more rapidly and later that they can migrate to start colonies in new locations).

**Figure 30.3** When a mutation occurs to confer a growth advantage, the descendent cells will dominate the population. A cancer advances by clonal selection for more malignant cells at each stage.

Our current view of cancer is that it is driven by twin features: an increased rate of mutation is responsible for generating cells with altered growth properties; and the population of cells is then selected for those with an increased rate of proliferation. A cancer progresses by multiple cycles of mutation and selection.

By comparing cancer cells with normal cells, we can identify genes that have been changed by mutation. Those that have direct effects on the generation of a cancer can be divided into oncogenes (where a mutation has activated a gene whose function contributes to the tumorigenic state) and tumor suppressors (where a mutation has inactivated a gene whose function antagonizes the tumorigenic state). In most cases, a cancer arises because a series of mutations have accumulated in a somatic cell,

activating oncogenes and/or inactivating tumor suppressors.

Genetic diversity in the population means that each individual may have a different set of alleles at these loci. Natural selection acts to eliminate alleles in the germline that contribute to cancer formation. However, there are some rare hereditary diseases that are caused by such alleles. In these cases, the affected individuals have a high probability of suffering from a cancer. In addition, susceptibility to cancer is influenced by many other loci, generally known as tumor modifiers. The products of these loci affect the functions of oncogenes or tumor suppressors, either directly or indirectly, but do not themselves have any direct effects (for review see 2404).

## ONCOGENES AND CANCER

### 6.30.2 Tumor cells are immortalized and transformed

---

#### Key Terms

**Immortalization** describes the acquisition by a eukaryotic cell line of the ability to grow through an indefinite number of divisions in culture.

**Transformation (Oncogenesis)** of eukaryotic cells refers to their conversion to a state of unrestrained growth in culture, resembling or identical with the tumorigenic condition.

**Metastasis** describes the ability of tumor cells to leave their site of origin and migrate to other locations in the body, where a new colony is established.

**Crisis** is a state reached when primary cells placed into culture are unable to replicate their DNA because their telomeres have become too short. Most cells die, but a few emerge by a process of immortalization that usually involves changes to bypass the limitations of telomeric length.

**Primary cells** are eukaryotic cells taken into culture directly from the animal.

An **established** cell line consists of cells that can be grown indefinitely in culture (they are said to be immortalized).. The cells usually have had chromosomal changes in order to adapt to culture conditions.

**Anchorage dependence** describes the need of normal eukaryotic cells for a surface to attach to in order to grow in culture.

**Serum dependence** describes the need of eukaryotic cells for factors contained in serum in order to grow in culture.

**Density-dependent inhibition** describes the limitation that eukaryotic cells in culture grow only to a limited density, because growth is inhibited, by processes involving cell-cell contacts.

A **monolayer** describes the growth of eukaryotic cells in culture as a layer only one cell deep.

An **aneuploid** set of chromosomes differs from the usual set by loss or duplication of one or more chromosomes.

**Transformed** cells are cultured cells that have acquired many of the properties of cancer cells.

Transformed cells grow as a compact mass of rounded-up cells that grows in dense clusters, piled up on one another. They appear as a distinct **focus** on a culture plate, contrasted with normal cells that grow as a spread-out monolayer attached to the substratum.

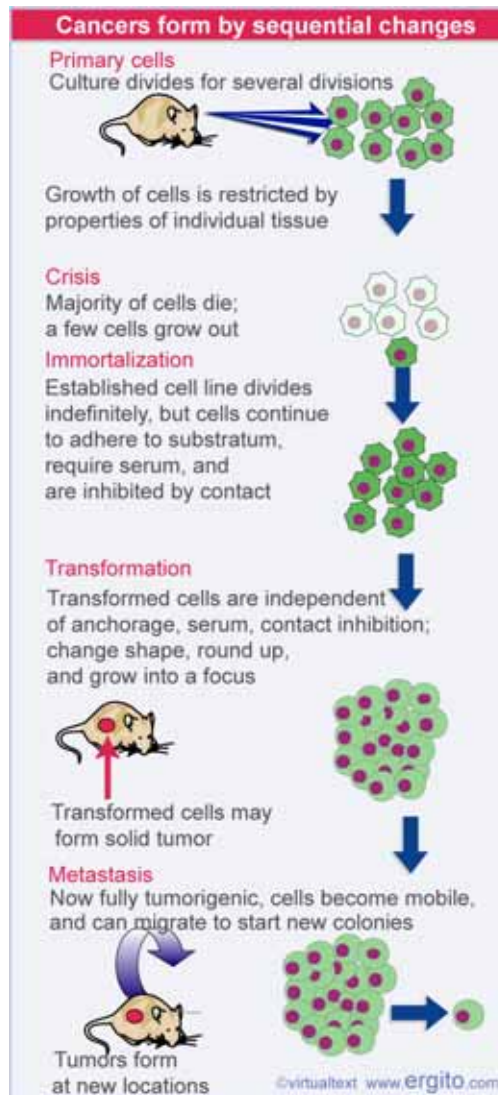

A **carcinogen** is a chemical that increases the frequency with which cells are converted to a cancerous condition.

#### Key Concepts

- Immortalization enables cells to overcome a limit on the number of cell divisions.
- Cultured cell lines have been immortalized.

- Transformation consists of a series of changes that release growth constraints on the immortalized cell.

Three types of changes that occur when a cell becomes tumorigenic are summarized in **Figure 30.4**:

**Figure 30.4** Three types of properties distinguish a cancer cell from a normal cell. Sequential changes in cultured cells can be correlated with changes in tumorigenicity.

- **Immortalization** describes the property of indefinite cell growth (without any other changes in the phenotype necessarily occurring).
- **Transformation** describes the failure to observe the normal constraints of

growth; for example, transformed cells become independent of factors usually needed for cell growth and survival.

- **Metastasis** describes the stage at which the cancer cell gains the ability to invade normal tissue, so that it can move away from the tissue of origin and establish a new colony elsewhere in the body.

To characterize the aberrant events that enable cells to bypass normal control and generate tumors, we need to compare the growth characteristics of normal and transformed cells *in vitro*. Transformed cells can be grown readily, but it is much more difficult to grow their normal counterparts.

When cells are taken from a vertebrate organism and placed in culture, they grow for several divisions, but then enter a senescent stage, in which growth ceases. This is followed by a **crisis**, in which most of the cells die. The number of divisions that occur before this happens is sometimes called the Hayflick limit, after the author who discovered the phenomenon (1977).

The survivors that emerge from crisis are capable of dividing indefinitely, but their properties have changed in the act of emerging from crisis. This comprises the process of immortalization. (The features of crisis depend on both the species and tissue. Typically mouse cells pass through crisis at ~12 generations. Human cells enter crisis at ~40 generations, although it is rare for human cells to emerge from it, and only some types of human cells in fact can do so.)

The limitation of the life span of most cells by crisis restricts us to two options in studying nontransformed cells, neither entirely satisfactory:

- **Primary cells** are the immediate descendants of cells taken directly from the organism. They faithfully mimic the *in vivo* phenotype, but in most cases survive for only a relatively short period, because the culture dies out at crisis.
- Cells that have passed through crisis become **established** to form a (nontumorigenic) cell line. They can be perpetuated indefinitely, but their properties have changed in passing through crisis, and may indeed continue to change during adaptation to culture. These changes may partly resemble those involved in tumor formation, which reduces the usefulness of the cells.

An established cell line by definition has become immortalized, but usually is not tumorigenic. Nontumorigenic established cell lines display characteristic features similar to those of primary cultures, often including:

- **Anchorage dependence** – a solid or firm surface is needed for the cells to attach to.
- **Serum dependence** (also known as growth factor dependence) – serum is needed to provide essential growth factors.
- **Density-dependent inhibition** – cells grow only to a limited density, because

growth is inhibited, perhaps by processes involving cell-cell contacts.

- *Cytoskeletal organization* – cells are flat and extended on the surface on which they are growing, and have an elongated network of stress fibers (consisting of actin filaments).

The consequence of these properties is that the cells grow as a **monolayer** (that is, a layer one cell thick) on a substratum.

These properties provide parameters by which the normality of the cell may be judged. Of course, any established cell line provides only an approximation of *in vivo* control. The need for caution in analyzing the genetic basis for growth control in such lines is emphasized by the fact that almost always they suffer changes in the chromosome complement and are not true diploids. A cell whose chromosomal constitution has changed from the true diploid is said to be **aneuploid**.

Cells cultured from tumors instead of from normal tissues show changes in some or all of these properties. They are said to be **transformed**. A transformed cell grows in a much less restricted manner. It has reduced serum-dependence, does not need to attach to a solid surface (so that individual cells "round-up" instead of spreading out) and the cells pile up into a thick mass of cells (called a **focus**) instead of growing as a surface monolayer. Furthermore, the cells may form tumors when injected into appropriate test animals. **Figure 30.5** compares views obtained by conventional microscopy of "normal" fibroblasts growing in culture with "transformed" variants. The difference can be seen more dramatically in the scanning electron microscope views of **Figure 30.6**.

**Figure 30.5** Normal fibroblasts grow as a layer of flat, spread-out cells, whereas transformed fibroblasts are rounded up and grow in cell masses. Photographs kindly provided by Hidesaburo Hanafusa.

**Figure 30.6** Scanning electron microscopy shows that normal cells spread out and form long processes, whereas tumor cells round up into tightly balled masses. Photographs kindly provided by J. Michael Bishop.

The joint changes of immortalization and transformation of cells in culture provide a paradigm for the formation of animal tumors. By comparing transformed cell lines with normal cells, we hope to identify the genetic basis for tumor formation and also to understand the phenotypic processes that are involved in the conversion.

Certain events convert normal cells into transformed cells, and provide models for the processes involved in tumor formation. Usually multiple genetic changes are necessary to create a cancer; and sometimes tumors gain increased virulence as the result of a progressive series of changes.

A variety of agents increase the frequency with which cells (or animals) are converted to the transformed condition; they are said to be *carcinogenic*. Sometimes these **carcinogens** are divided into those that "initiate" and those that "promote" tumor formation, implying the existence of different stages in cancer development. Carcinogens may cause epigenetic changes or (more often) may act, directly or indirectly, to change the genotype of the cell.

## ONCOGENES AND CANCER

### 6.30.3 Oncogenes and tumor suppressors have opposite effects

---

#### Key Terms

**Oncogenes** are genes whose products have the ability to transform eukaryotic cells so that they grow in a manner analogous to tumor cells. Oncogenes carried by retroviruses have names of the form *v-onc*.

**Proto-oncogenes** are the normal counterparts in the eukaryotic genome to the (*v-onc*) oncogenes carried by some retroviruses. They are given names of the form *c-onc*.

A **tumor suppressor** is identified by a loss-of-function mutation that contributes to cancer formation. They usually function to prevent cell division or to cause death of abnormal cells. The two most important are p53 and RB.

#### Key Concepts

- An oncogene results from a gain-of-function mutation of a proto-oncogene that generates a tumorigenic product.
- Mutation of a tumor suppressor causes a loss-of-function in the ability to restrain cell growth.

---

There are two classes of genes in which mutations cause transformation.

**Oncogenes** were initially identified as genes carried by viruses that cause transformation of their target cells. A major class of the viral oncogenes have cellular counterparts that are involved in normal cell functions. The cellular genes are called **proto-oncogenes**, and in certain cases their mutation or aberrant activation in the cell to form an oncogene is associated with tumor formation. About 100 oncogenes have been identified. The oncogenes fall into several groups, representing different types of activities ranging from transmembrane proteins to transcription factors, and the definition of these functions may therefore lead to an understanding of the types of changes that are involved in tumor formation.

The generation of an oncogene represents a gain-of-function in which a cellular proto-oncogene is inappropriately activated. This can involve a mutational change in the protein, or constitutive activation, overexpression, or failure to turn off expression at the appropriate time. The simple case of a somatic mutation is illustrated in **Figure 30.7**.

**Figure 30.7** Somatic mutation generates a transformed cell by converting a proto-oncogene to an oncogene.

**Tumor suppressors** are detected by deletions (or other inactivating mutations) that are tumorigenic. The mutations represent loss-of-function in genes that usually impose some constraint on the cell cycle or cell growth; the release of the constraint is tumorigenic. It is necessary for both copies of the gene to be inactivated.

The most compelling evidence for the nature of tumor suppressors is provided by certain hereditary cancers, in which patients with the disease develop tumors that have lost both alleles, and therefore lack an active gene. There is also now evidence that changes in these genes may be associated with the progression of a wide range of cancers. About 10 tumor suppressors are known at present.

*This content is available online at <http://www.ergito.com/main.jsp?bcs=MBIO.6.30.3>*

## ONCOGENES AND CANCER

### 6.30.4 Transforming viruses carry oncogenes

#### Key Terms

A **tumor virus** has the ability to transform an animal cell into a cancerous state.

#### Key Concepts

- A transforming virus usually carries a specific gene(s) that is responsible for transforming the target cell by changing its growth properties.

Transformation may occur spontaneously, may be caused by certain chemical agents, and, most notably, may result from infection with **tumor viruses**. There are many classes of tumor viruses, including both DNA and RNA viruses, and they occur widely in the avian and animal kingdoms.

The transforming activity of a tumor virus resides in a particular gene or genes carried in the viral genome. Oncogenes were given their name by virtue of their ability to convert cells to a tumorigenic (or oncogenic) state. An oncogene initiates a series of events that is executed by cellular proteins. In effect, the virus throws a regulatory switch that changes the growth properties of its target cell.

**Figure 30.8** summarizes the general properties of the major classes of transforming viruses. The oncogenes carried by the DNA viruses specify proteins that inactivate tumor suppressors, so their action in part mimics loss-of-function of the tumor suppressors. The oncogenes carried by retroviruses are derived from cellular genes and therefore may mimic the behavior of gain-of-function mutations in animal proto-oncogenes.

DNA and RNA oncogenic viruses carry different types of oncogenes					
Viral Class	Genome	Size	Oncogenes	Origin of Oncogene	Action of Oncogene
Polyoma	dsDNA	5-6 kb	T antigens	Early viral gene	inactivates tumor suppressor
HPV	dsDNA	~8 kb	E6 & E7	Early viral gene	inactivates tumor suppressor
Adeno	dsDNA	~37 kb	E1A & E1B	Early viral gene	inactivates tumor suppressor
Retrovirus (acute)	ssRNA	6-9 kb	Individual	Cellular	activates oncogenic pathway

## ONCOGENES AND CANCER

### 6.30.5 Early genes of DNA transforming viruses have multifunctional oncogenes

---

#### Key Terms

A protein that plays a **permissive** role in development is one that sets up a situation where a certain activity can occur, but does not cause the occurrence itself.

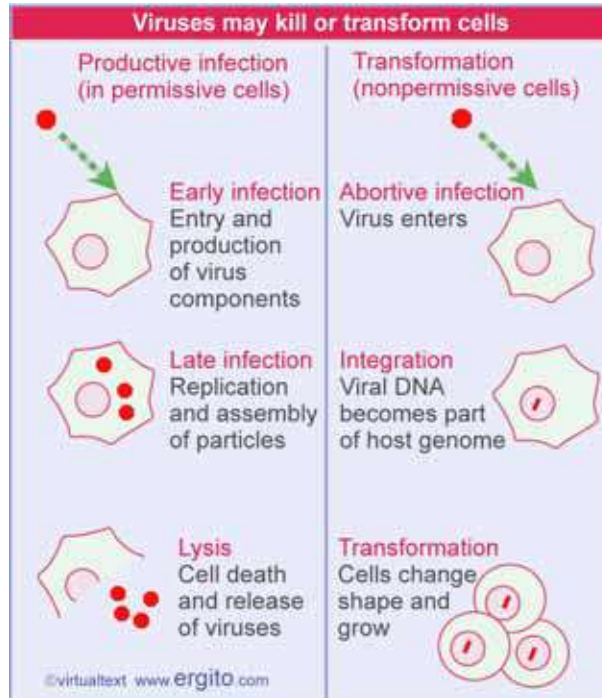

**Nonpermissive** conditions do not allow conditional lethal mutants to survive.

#### Key Concepts

- The oncogenes of DNA transforming viruses are early viral functions.
- The oncogene becomes integrated into the host cell genome and is expressed constitutively.
- The oncogenes of polyomaviruses are T antigens, which are expressed by alternative splicing from a single locus.
- Adenoviruses express several E1A and E1B proteins from two genes.

---

Polyomaviruses and adenoviruses have been isolated from a variety of mammals. Although perpetuated in the wild in a single host species, a virus may be able to grow in culture on a variety of cells from different species. The response of a cell to infection depends on its species and phenotype and falls into one of two classes, as illustrated in **Figure 30.9**:

**Figure 30.9** Permissive cells are productively infected by a DNA tumor virus that enters the lytic cycle, while nonpermissive cells are transformed to change their phenotype.

- **Permissive** cells are productively infected. The virus proceeds through a lytic cycle that is divided into the usual early and late stages. The cycle ends with release of progeny viruses and (ultimately) cell death.
- **Nonpermissive** cells cannot be productively infected, and viral replication is abortive. Some of the infected cells are transformed; in this case, the phenotype of the individual cell changes and the culture is perpetuated in an unrestrained manner.

A common mechanism underlies transformation by DNA tumor viruses. *Oncogenic potential resides in a single function or group of related functions that are active early in the viral lytic cycle. When transformation occurs, the relevant gene(s) are integrated into the genomes of transformed cells and expressed constitutively.* This suggests the general model for transformation by these viruses illustrated in **Figure 30.10**, in which the constitutive expression of the oncogene generates transforming protein(s) (oncoproteins).

**Figure 30.10** Cells transformed by polyomaviruses or adenoviruses have viral sequences that include the early region integrated into the cellular genome. Sites of integration are random.

Polyomaviruses are small. Polyomavirus itself is common in mice, the analogous virus SV40 (simian virus 40) was isolated from rhesus monkey cells, and more recently the human viruses BK and JC have been characterized. All of the polyomaviruses can cause tumors when injected into newborn rodents.

During a productive infection, the early region of each virus uses alternative splicing to synthesize overlapping proteins called T antigens. (The name reflects their isolation originally as the proteins found in tumor cells.) The various T antigens have a variety of functions in the lytic cycle. They are required for expression of the late region and for DNA replication of the virus.

Cells transformed by polyomaviruses contain integrated copies of part or all of the viral genome. The integrated sequences always include the early region. The T antigens have transforming activity, which rests upon their ability to interact with cellular proteins. This is independent of their ability to interact directly with the viral genome. SV40 requires "big T" and "little t" antigens, and polyoma requires "T" and "middle T" antigens for transformation.

Papillomaviruses are small DNA viruses that cause epithelial tumors; there are ~75 human papillomaviruses (HPVs); most are associated with benign growths (such as warts), but some are associated with cancers, in particular cervical cancers. Two

virus-associated products are expressed in cervical cancers; these are the E6 and E7 proteins, which can immortalize target cells.

Adenoviruses were originally isolated from human adenoids; similar viruses have since been isolated from other mammals. They comprise a large group of related viruses, with >80 individual members. Human adenoviruses remain the best characterized, and are associated with respiratory diseases. They can infect a range of cells from different species.

Human cells are permissive and are therefore productively infected by adenoviruses, which replicate within the infected cell. But cells of some rodents are nonpermissive. All adenoviruses can transform nonpermissive cultured cells, but the oncogenic potential of the viruses varies; the most effective can cause tumors when they are injected into newborn rodents. The genomes of cells transformed by adenoviruses have gained a part of the early viral region that contains the E1A and E1B genes, which code for several nuclear proteins.

Epstein-Barr is a human herpes virus associated with a variety of diseases, including infectious mononucleosis, nasopharyngeal carcinoma, African Burkitt lymphoma, and other lymphoproliferative disorders. EBV has a limited host range for both species and cell phenotype. Human B lymphocytes that are infected *in vitro* become immortalized, and some rodent cell lines can be transformed. Viral DNA is found in transformed cells, although it has been controversial whether it is integrated. It remains unclear exactly which viral genes are required for transformation.

*This content is available online at <http://www.ergito.com/main.jsp?bcs=MBIO.6.30.5>*

---

## ONCOGENES AND CANCER

### 6.30.6 Retroviruses activate or incorporate cellular genes

---

#### Key Terms

A **nondefective virus** describes a transforming retrovirus that has all the normal capabilities in replication etc. Its ability to transform depends on its effects on expression of host genes at its site of insertion into the cellular genome.

An **acute transforming virus** carries a gene(s) that originated in a cellular genome. Its transforming capacity is the result of expression of that gene. Because the gene replaced viral sequences, the virus does not have the capacity to replicate independently.

#### Key Concepts

- Acute transforming retroviruses have oncogenes that are derived from cellular genes.
- Nondefective transforming viruses do not have oncogenes, but activate an equivalent gene(s) in the host genome.

---

Retroviruses present a different situation from the DNA tumor viruses. They can transfer genetic information both horizontally and vertically, as illustrated in **Figure 30.11**. Horizontal transfer is accomplished by the normal process of viral infection, in which increasing numbers of cells become infected in the same host. Vertical transfer results whenever a virus becomes integrated in the germline of an organism as an endogenous provirus; like a lysogenic bacteriophage, it is inherited as a Mendelian locus by the progeny (see *Molecular Biology 3.12 Phage strategies*).

**Figure 30.11** Retroviruses transfer genetic information horizontally by infecting new hosts; information is inherited vertically if a virus integrates in the genome of the germline.

The retroviral life cycle propagates genetic information through both RNA and DNA templates. A retroviral infection proceeds through the stages illustrated previously in **Figure 17.2**, in which the RNA is reverse-transcribed into single-stranded DNA, then converted into double-stranded DNA, and finally integrated into the genome, where it may be transcribed again into infectious RNA. Integration into the genome leads to vertical transmission of the provirus. Expression of the provirus may generate retroviral particles that are horizontally transmitted. Integration is a normal part of the life cycle of every retrovirus, whether it is nontransforming or transforming.

The tumor retroviruses fall into two general groups with regard to the origin of their tumorigenicity:

- **Nondefective viruses** follow the usual retroviral life cycle. They provide infectious agents that have a long latent period, and often are associated with the induction of leukemias. Two classic models are FeLV (feline leukemia virus) and MMTV (mouse mammary tumor virus). *Tumorigenicity does not rely upon an individual viral oncogene, but upon the ability of the virus to activate a cellular proto-oncogene(s).*
- **Acute transforming viruses** have gained new genetic information in the form of an *oncogene*. This gene is not present in the ancestral (nontransforming virus); it originated as a cellular gene that was captured by the virus by means of a

transduction event during an infective cycle. These viruses usually induce tumor formation *in vivo* rather rapidly, and they can transform cultured cells *in vitro*. Reflecting the fact that each acute transforming virus has specificity toward a particular type of target cell, these viruses are divided into classes according to the type of tumor that is caused in the animal: leukemia, sarcoma, carcinoma, etc.

When a retrovirus captures a cellular gene by exchanging part of its own sequence for a cellular sequence (see *Molecular Biology 4.17.6 Retroviruses may transduce cellular sequences*), it generates the structure summarized in **Figure 30.12**. Some of the original retroviral sequences (which are usually organized into the genes *gag-pol-env*, coding for coat proteins, reverse transcriptase, and other enzyme activities) are replaced by a sequence derived by reverse transcription of a cellular mRNA. This type of event is rare, but creates a transducing virus that has two important properties:

**Figure 30.12** A transforming retrovirus carries a copy of a cellular sequence in place of some of its own gene(s).

- Usually it cannot replicate by itself, because viral genes needed for reproduction have been lost by the exchange with cellular sequences. So almost all of these viruses are replication-defective. But they can propagate in a simultaneous infection with a wild-type "helper" virus that provides the functions that were lost in the recombination event. (RSV is an exceptional transducing virus that retains the ability to replicate.)
- During an infection, the transducing virus carries with it the cellular gene(s) that were obtained in the recombination event, and their expression may alter the phenotype of the infected cell. Any transducing virus whose cellular genetic information assists the growth of its target cells could have an advantage in future infective cycles. If a virus gains a gene whose product stimulates cell growth, the acquisition may enable the virus to spread by stimulating the growth of the particular cells that it infects. This is important also because a retrovirus

can replicate only in a proliferating cell. After a virus has incorporated a cellular gene, the gene may gain mutations that enhance its ability to influence cell phenotype.

Of course, transformation is not the only mechanism by which retroviruses affect their hosts. A notable example is the HIV-1 retrovirus, which belongs to the retroviral group of lentiviruses. The virus infects and kills T lymphocytes carrying the CD4 receptor, devastating the immune system of the host, and inducing the disease of AIDS. The virus carries the usual *gag-pol-env* regions, and also has an additional series of reading frames, which overlap with one another, to which its lethal actions are attributed.

---

## ONCOGENES AND CANCER

### 6.30.7 Retroviral oncogenes have cellular counterparts

---

#### Key Terms

**Proto-oncogenes** are the normal counterparts in the eukaryotic genome to the (*v-onc*) oncogenes carried by some retroviruses. They are given names of the form *c-onc*.

#### Key Concepts

- A retroviral oncogene is derived by capturing a proto-oncogene from a host genome.
- 

New sequences that are present in an acute transforming retrovirus can be delineated by comparing the sequence of the virus with that of the parental (nontumorigenic) virus. Usually the new region is closely related to a sequence in the cellular genome. The normal cellular sequence itself is not oncogenic – if it were, the organism could scarcely have survived – but it defines a **proto-oncogene**.

The general model for retroviral transformation is illustrated in **Figure 30.13**. The virus gains a copy of a proto-oncogene from a cellular genome. Sometimes the copy is different from the cellular sequence, typically because it has been truncated. In some cases, the difference is sufficient to convert the proto-oncogene into an oncogene. In other cases, mutations occur in the viral sequence that convert the copy into an oncogene.

**Figure 30.13** A retrovirus may incorporate a cellular proto-oncogene during an infection. Subsequent mutation or other changes in the proto-oncogene make it oncogenic when the virus transfers it to a new cell in another infectious cycle.

The viral oncogenes and their cellular counterparts are described by using prefixes *v* for viral and *c* for cellular. So the oncogene carried by Rous sarcoma virus is called *v-src*, and the proto-oncogene related to it in cellular genomes is called *c-src*. Comparisons between *v-onc* and *c-onc* genes can be used to identify the features that confer oncogenicity (for review see 335; 336).

Oncogenes of some retroviruses are summarized in **Figure 30.14**. The type of tumor results from the combination of the particular oncogene with the time and place in which it is expressed. It is striking that usually the oncogenic activity resides in a single gene. AEV is one of a very few exceptions in which a retrovirus carries more

than one oncogene.

Transforming properties of retroviruses are determined by their v-onc genes				
Virus	Name	Species	Tumor	Oncogene
Rous sarcoma	RSV	chicken	sarcoma	<i>src</i>
Harvey murine sarcoma	Ha-MuSV	rat	sarcoma & erythroleukemia	<i>H-ras</i>
Kirsten murine sarcoma	Ki-MuSV	rat	sarcoma & erythroleukemia	<i>K-ras</i>
Moloney murine sarcoma	Mo-MuSV	mouse	sarcoma	<i>mos</i>
FBJ murine osteosarcoma	FBJ-MuSV	mouse	chondrosarcoma	<i>fos</i>
Simian sarcoma	SSV	monkey	sarcoma	<i>sis</i>
Feline sarcoma	PI-FeSV	cat	sarcoma	<i>sis</i>
Feline sarcoma	SM-FeSV	cat	fibrosarcoma	<i>fms</i>
Feline sarcoma	ST-FeSV	cat	fibrosarcoma	<i>fes</i>
Avian sarcoma	ASV-17	chicken	fibrosarcoma	<i>jun</i>
Fujinami sarcoma	FuSV	chicken	sarcoma	<i>fps</i>
Avian myelocytomatosis	MC29	chicken	carcinoma, sarcoma, & myelocytoma	<i>myc</i>
Abelson leukemia	MuLV	mouse	B cell lymphoma	<i>abl</i>
Reticuloendotheliosis	REV-T	turkey	lymphatic leukemia	<i>rel</i>
Avian erythroblastosis	AEV	chicken	erythroleukemia & fibrosarcoma	<i>erbB,A</i>
Avian myeloblastosis	AMV	chicken	myeloblastic leukemia	<i>myb</i>

**Figure 30.14** Each transforming retrovirus carries an oncogene derived from a cellular gene. Viruses have names and abbreviations reflecting the history of their isolation and the types of tumor they cause. This list shows some representative examples of the retroviral oncogenes.

More than 30 *c-onc* genes have been identified so far by their representation in retroviruses. Sometimes the same *c-onc* gene is represented in different transforming viruses; for example, the monkey virus SSV and the PI strain of the feline virus FeSV both carry a *v-onc* derived from *c-sis*. Some viruses carry related *v-onc* genes, such as in the Harvey and Kirsten strains of MuSV, which carry *v-ras* genes derived from two different members of the cellular *c-ras* gene family. In other cases the *v-onc* genes of related viruses represent unrelated cellular progenitors; for example, three different isolates of FeSV may have been derived from the same original (nontransforming) virus, but have transduced the *sis*, *fms*, and *fes* oncogenes. The events involved in formation of a transducing virus can be complex; some viruses include sequences derived from more than one cellular gene (859).

Given the rarity of the transducing event, it is significant that multiple independent isolates occur representing the same *c-onc* gene. For example, several viruses carry *v-myc* genes. They are all derived from a single *c-myc* gene, but the *v-myc* genes differ in their exact ends and in individual point mutations. The identification of such isolates probably means that we have identified most of the genes of the *c-onc* type that can be activated by viral transduction.

Direct evidence that expression of the *v-onc* sequence accomplishes transformation was first obtained with RSV (see *Great Experiments 10.1 Identification of a retroviral transforming gene*). Temperature-sensitive mutations in *v-src* allow the transformed phenotype to be reverted by increase in temperature, and regained by decrease in temperature. This shows clearly that in this case the *v-src* gene is needed both to initiate and maintain the transformed state.

## ONCOGENES AND CANCER

### 6.30.8 Quantitative or qualitative changes can explain oncogenicity

---

#### Key Concepts

- An oncogene usually has qualitatively different (transforming) effects from the proto-oncogene as the result of mutational changes.
- Sometimes the oncogene is transforming because it is expressed at higher levels than the proto-oncogene.

---

Two general types of theory might explain the difference in properties between *v-onc* genes and *c-onc* genes:

- A quantitative model proposes that viral genes are functionally indistinguishable from the cellular genes, but are oncogenic because they are expressed in much greater amounts or in inappropriate cell types, or because their expression cannot be switched off.
- A qualitative model supposes that the *c-onc* genes intrinsically lack oncogenic properties, but may be converted by mutation into oncogenes whose devastating effects reflect the acquisition of new properties (or loss of old properties).

How closely related are *v-onc* genes to the corresponding *c-onc* genes? In some cases, the only changes are a very small number of point mutations. The *mos*, *sis*, and *myc* genes offer examples in which the entire *c-onc* gene has been gained by the virus; in this case, the small number of amino acid substitutions do not seem to affect function of the protein, and in fact are not required for transforming activity. So the *v-onc* product is likely to fulfill the same enzymatic or other functions as the *c-onc* product, but with some change in its regulation; in these cases, overexpression is responsible for oncogenicity. A good example is *c-myc*, where oncogenicity may be caused by overexpression either by a *v-myc* gene carried by a transforming retrovirus or by changes in the cellular genome that cause overexpression of *c-myc* (for review see 338).

Two cases in which point mutations play a critical role in creating an oncogenic protein are presented by *ras* and *src*.

In the case of *ras*, changes in the regulation of Ras activity that activate the protein can be directly attributed to the individual point mutations that have occurred in the *v-onc* gene. Overexpression of *c-ras* may have weak oncogenic effects, but full oncogenicity requires sequence changes in the protein.

In some cases, a *v-onc* gene is truncated by the loss of sequences from the N-terminus or C-terminus (or both) of the *c-onc* gene, probably as a result of the sites involved in the recombination event that generated it. Loss of these regions may

remove some regulatory constraint that normally limits the activity of the *c-onc* product. Such sequence changes are required for oncogenicity of *src*. *v-src* is oncogenic at low levels of protein, but *c-src* is not oncogenic at high protein levels (>10× normal). The viral and cellular *src* genes are coextensive, but *v-src* has replaced the C-terminal 19 amino acids of *c-src* with a different sequence of 12 amino acids. This has an important regulatory consequence, in activating the Src protein constitutively. In cases where *v-onc* genes are truncations of *c-onc* genes, point mutations may also contribute to the oncogenicity of the *v-onc* product. In the case of Src, changes in two tyrosine residues that are targets for phosphorylation have strong effects on oncogenicity (see *Molecular Biology* 6.30.16 *Src is the prototype for the proto-oncogenic cytoplasmic tyrosine kinases*).

The characterization of transforming retroviruses played an important role in the definition of oncogenes. However, most events involved in human cancers do not involve viral intermediates, and other mechanisms are responsible for generating oncogenes. But the concept that oncogenes arise by activation of proto-oncogenes is an important paradigm for animal cancers.

## ONCOGENES AND CANCER

### 6.30.9 Ras oncogenes can be detected in a transfection assay

---

#### Key Concepts

- Transformed cells can be distinguished from normal cells by the formation of foci in a culture dish.
- DNA extracted from tumor cells can transform 3T3 target cells.
- A transforming cellular (*c-onc*) gene often has a homologue (*v-onc*) in a transforming retrovirus.
- The *ras* genes are the most common transforming genes identified by this method.

---

Some oncogenes can be detected by using a direct assay for transformation in which "normal" recipient cells are transfected with DNA obtained from animal tumors (for discussion of the discovery see *Great Experiments 10.3 The discovery of oncogenes in human tumors*). The procedure is illustrated in **Figure 30.15**. The established mouse NIH 3T3 fibroblast line usually is used as recipient. Historically these experiments started by using DNA extracted *en masse*, but now they are usually performed with a purified oncogene. The ability of any individual gene to convert wild-type cells into the transformed state constitutes one form of proof that it is an oncogene. Another assay that can be used is to inject cells into "nude" mice (which lack the ability to reject such transplants immunologically). The ability to form tumors can then be measured directly in the animal.

**Figure 30.15** The transfection assay allows (some) oncogenes to be isolated directly by assaying DNA of tumor cells for the ability to transform normal cells into tumorigenic cells.

When a cell is transformed in a 3T3 culture (or some other "normal" culture), its descendants pile up into a focus. The appearance of foci is used as a measure of the transforming ability of a DNA preparation. Starting with a preparation of DNA isolated from tumor cells, the efficiency of focus formation is low. However, once the transforming gene has been isolated and cloned, greater efficiencies can be obtained. In fact, the transforming "strength" of a gene can be characterized by the efficiency of focus formation by the cloned sequence.

*DNA with transforming activity can be isolated only from tumorigenic cells; it is not present in normal DNA.* The transforming genes isolated by this assay have two revealing properties:

- *They have closely related sequences in the DNA of normal cells.* This argues that transformation was caused by mutation of a normal cellular gene (a proto-oncogene) to generate an oncogene. The change may take the form of a point mutation or more extensive reorganization of DNA around the *c-onc* gene.
- *They may have counterparts in the oncogenes carried by known transforming viruses.* This suggests that the repertoire of proto-oncogenes is limited, and probably the same genes are targets for mutations to generate oncogenes in the cellular genome or to become viral oncogenes.

Oncogenes derived from the *c-ras* family are often detected in the transfection assay. The family consists of several active genes in both man and rat, dispersed in the genome. (There are also some pseudogenes.) The individual genes, *N-ras*, *H-ras*, and *K-ras*, are closely related, and code for protein products ~21 kD and known collectively as p21<sup>ras</sup>.

The *H-ras* and *K-ras* genes have *v-ras* counterparts, carried by the Harvey and Kirsten strains of murine sarcoma virus, respectively (see **Figure 30.14**). Each *v-ras* gene is closely related to the corresponding *c-ras* gene, with only a few individual amino acid substitutions. The Harvey and Kirsten virus strains must have originated in independent recombination events in which a progenitor virus gained the corresponding *c-ras* sequence.

---

**ONCOGENES AND CANCER****6.30.10 Ras proto-oncogenes can be activated by mutation at specific positions**

---

**Key Concepts**

- *v-ras* genes are derived by point mutations of *c-ras* genes.
- The same mutations occur in the *v-ras* genes of transforming viruses and the mutant *c-ras* genes of tumor cells.
- Almost any mutation at either position 12 or 61 converts a *c-ras* proto-oncogene into a transforming variety.
- The effect of the mutations is to increase Ras activity by inhibiting the hydrolysis of bound GTP to GDP.

---

Oncogenic variants of the *c-ras* genes are found in transforming DNA preparations obtained from various primary tumors and tumor cell lines. Each of the *c-ras* proto-oncogenes can give rise to a transforming oncogene by a single base mutation. *The mutations in several independent human tumors cause substitution of a single amino acid, most commonly at position 12 or 61, in one of the Ras proteins.*

Position 12 is one of the residues that is mutated in the *v-H-ras* and *v-K-ras* genes. *So mutations occur at the same positions in v-ras genes in retroviruses and in mutant c-ras genes in multiple rat and human tumors.* This suggests that the normal c-Ras protein can be converted into a tumorigenic form by a mutation in one of a few codons in rat or man (and perhaps any mammal).

The general principle established by this work is that *substitution in the coding sequence can convert a cellular proto-oncogene into an oncogene.* Such an oncogene can be associated with the appearance of a spontaneous tumor in the organism. It may also be carried by a retrovirus, in which case a tumor is induced by viral infection.

The *ras* genes appear to be finely balanced at the edge of oncogenesis. Almost any mutation at either position 12 or 61 can convert a *c-ras* proto-oncogene into an active oncogene:

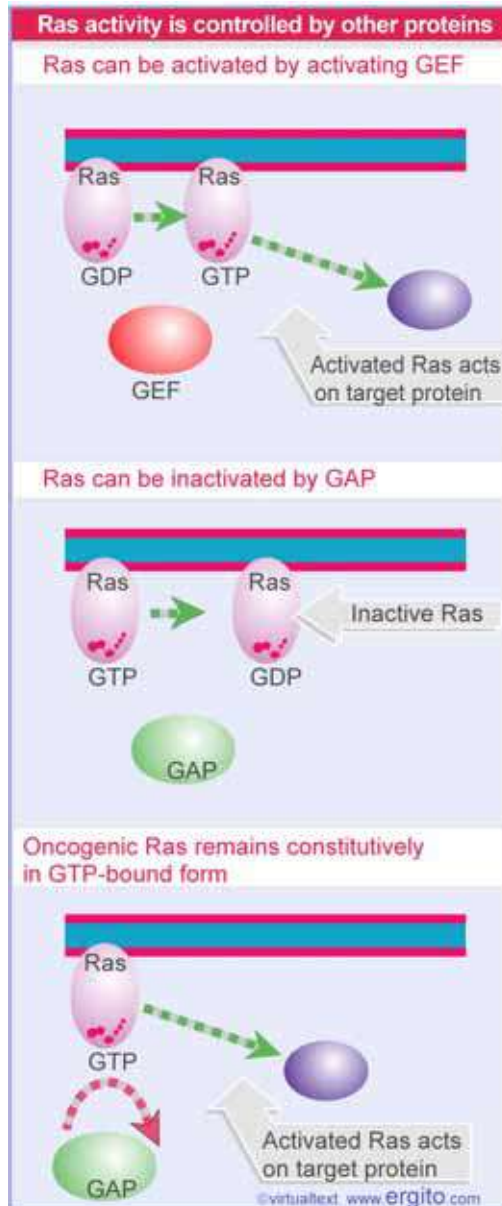

- All three *c-ras* genes have glycine at position 12. If it is replaced *in vitro* by any other of the 19 amino acids except proline, the mutated *c-ras* gene can transform cultured cells. The particular substitution influences the strength of the transforming ability.
- Position 61 is occupied by glutamine in wild-type *c-ras* genes. Its change to another amino acid usually creates a gene with transforming potential. Some substitutions are less effective than others; proline and glutamic acid are the only

substitutions that have no effect.

When the expression of a normal *c-ras* gene is increased, either by placing it under control of a more active promoter or by introducing multiple copies into transfected cells, recipient cells are transformed. Some mutant *c-ras* genes that have changes in the protein sequence also have a mutation in an intron that increases the level of expression (by increasing processing of mRNA ~10×). Also, some tumor lines have amplified *ras* genes. A 20-fold increase in the level of a nontransforming Ras protein is sufficient to allow the transformation of some cells. The effect has not been fully quantitated, but it suggests the general conclusion that oncogenesis depends on over-activity of Ras protein, and is caused either by increasing the amount of protein or (more efficiently) by mutations that increase the activity of the protein (for review see 340).

Transfection by DNA can be used to transform only certain cell types. Limitations of the assay explain why relatively few oncogenes have been detected by transfection. This system has been most effective with *ras* genes, where there is extensive correlation between mutations that activate *c-ras* genes in transfection and the occurrence of tumors.

Ras is a monomeric guanine nucleotide-binding protein that is active when bound to GTP and inactive when bound to GDP. It has an intrinsic GTPase activity. **Figure 30.16** reviews the discussion of *Molecular Biology 6.28.15 The activation of Ras is controlled by GTP* in which we saw that the conversion between the two forms of Ras is catalyzed by other proteins. GAP proteins stimulate the ability of Ras to hydrolyze GTP, thus converting active Ras into inactive Ras. GEF proteins stimulate the replacement of GDP by GTP, thus reactivating the protein.

**Figure 30.16** Pathways that rely on Ras could function by controlling either GEF or GAP. Oncogenic Ras mutants are refractory to control, because Ras remains in the active form.

Constitutive activation of Ras could be caused by mutations that allow the GDP-bound form of Ras to be active or that prevent hydrolysis of GTP. What are the effects of the mutations that create oncogenic *ras* genes? Many mutations that confer transforming activity inhibit the GTPase activity. GAP cannot increase the GTPase activity of Ras proteins that have been activated by oncogenic mutations. In other words, Ras has become refractory to the interaction with GAP that turns off its activity. Inability to hydrolyze GTP causes Ras to remain in a permanently activated form; its continued action upon its target protein is responsible for its oncogenic activity (for review see 353).

This establishes an important principle: *constitutive activation of a cellular protein may be oncogenic*. In the case of Ras, its effects result from activating the ERK MAP kinase pathway and (possibly) other pathways. The level of expression is finely balanced, since overstimulation of Ras by either increase in expression or mutation of the protein has oncogenic consequences (although mutation is required for a full effect).

## ONCOGENES AND CANCER

### 6.30.11 Nondefective retroviruses activate proto-oncogenes

---

#### Key Concepts

- Increased expression of *c-myc* is transforming.
  - *c-myc* can be activated by insertion of a nondefective retrovirus near the gene.
- 

A variety of genomic changes can activate proto-oncogenes, sometimes involving a change in the target gene itself, sometimes activating it without changing the protein product. Insertion, translocation, and amplification can be causative events in tumorigenesis.

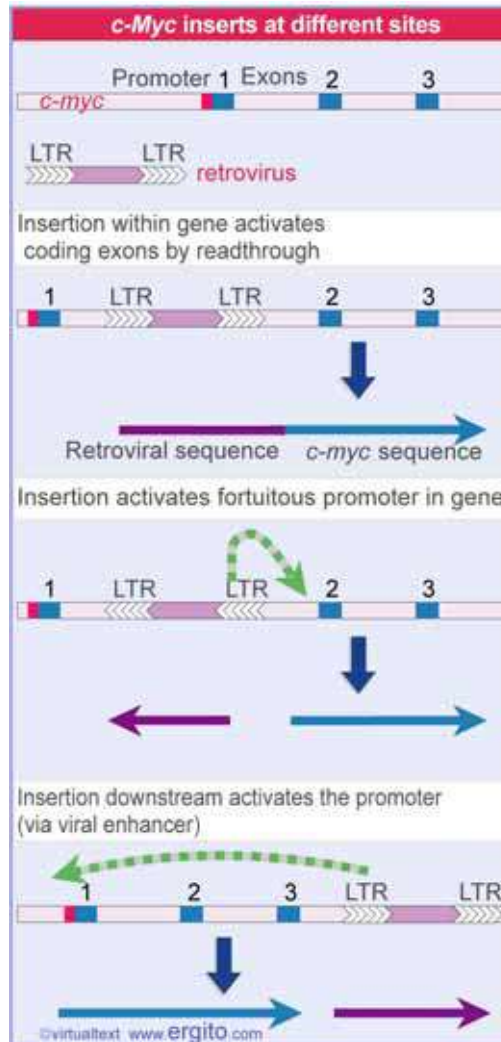

Many tumor cell lines have visible regions of chromosomal amplification, as shown by homogeneously staining regions (see **Figure 18.32**) or double minute chromosomes (see **Figure 18.33**). The amplified region may include an oncogene. Examples of oncogenes that are amplified in various tumors include *c-myc*, *c-abl*, *c-myb*, *c-erbB*, *c-K-ras*, and *Mdm2*.

Established cell lines are prone to amplify genes (along with other karyotypic changes to which they are susceptible). The presence of known oncogenes in the amplified regions, and the consistent amplification of particular oncogenes in many independent tumors of the same type, strengthens the correlation between increased expression and tumor growth.

Some proto-oncogenes are activated by events that change their expression, but which leave their coding sequence unaltered. The best characterized is *c-myc*, whose expression is elevated by several mechanisms. One common mechanism is the insertion of a nondefective retrovirus in the vicinity of the gene.

The ability of a retrovirus to transform without expressing a *v-onc* sequence was first noted during analysis of the bursal lymphomas caused by the transformation of B lymphocytes with avian leukemia virus. Similar events occur in the induction of T-cell lymphomas by murine leukemia virus. In each case, the transforming potential of the retrovirus is due to the ability of its LTR (the long terminal repeat of the integrated form) to cause expression of cellular gene(s).

In many independent tumors, the virus has integrated into the cellular genome within or close to the *c-myc* gene. **Figure 30.17** summarizes the types of insertions. The retrovirus may be inserted at a variety of locations relative to the *c-myc* gene.

**Figure 30.17** Insertions of ALV at the *c-myc* locus occur at various positions, and activate the gene in different ways.

The gene consists of three exons; the first represents a long nontranslated leader, and the second two code for the *c-Myc* protein. The simplest insertions to explain are those that occur within the first intron. The LTR provides a promoter, and transcription reads through the two coding exons. Transcription of *c-myc* under viral control differs from its usual control: the level of expression is increased (because the LTR provides an efficient promoter); expression cannot be switched off in B or T cells in response to the usual differentiation signals; and the transcript lacks its usual nontranslated leader (which may usually limit expression). All of these changes add up to increased constitutive expression.

Activation of *c-myc* in the other two classes of insertions reflects different mechanisms. The retroviral genome may be inserted within or upstream of the first intron, but in reverse orientation, so that its promoter points in the wrong direction. The retroviral genome also may be inserted downstream of the *c-myc* gene. In these cases, the enhancer in the viral LTR may be responsible for activating transcription

of c-Myc, either from its normal promoter or from a fortuitous promoter.

*In all of these cases, the coding sequence of c-myc is unchanged, so oncogenicity is attributed to the loss of normal control and increased expression of the gene.*

Other oncogenes that are activated in tumors by the insertion of a retroviral genome include *c-erbB*, *c-myb*, *c-mos*, *c-H-ras*, and *c-raf*. Up to 10 other cellular genes (not previously identified as oncogenes by their presence in transforming viruses) are implicated as potential oncogenes by this criterion. The best characterized among this latter class are *wnt1* and *int2*. The *wnt1* gene codes for a protein involved in early embryogenesis that is related to the *wingless* gene of *Drosophila*; *int2* codes for an FGF (fibroblast growth factor).

## ONCOGENES AND CANCER

### 6.30.12 Proto-oncogenes can be activated by translocation

---

#### Key Terms

A **reciprocal translocation** exchanges part of one chromosome with part of another chromosome.

#### Key Concepts

- *c-myc* can be activated in lymphocytes by translocations involving the Ig or TCR loci, giving B cell or T cell tumors.

---

Translocation to a new chromosomal location is another of the mechanisms by which oncogenes are activated. A **reciprocal translocation** occurs when an illegitimate recombination occurs between two chromosomes as illustrated in **Figure 30.18**. The involvement of such events in tumorigenesis was discovered via a connection between the loci coding immunoglobulins and the occurrence of certain tumors. Specific chromosomal translocations are often associated with tumors that arise from undifferentiated B lymphocytes. The common feature is that an oncogene on one chromosome is brought by translocation into the proximity of an Ig locus on another chromosome. Similar events occur in T lymphocytes to bring oncogenes into the proximity of a TCR locus (for review see 341).

**Figure 30.18** A chromosomal translocation is a reciprocal event that exchanges parts of two chromosomes. Translocations that activate the human *c-myc* proto-oncogene involve Ig loci in B cells and TCR loci in T cells.

In both man and mouse, the nonimmune partner is often the *c-myc* locus. In man, the translocations in B-cell tumors usually involve chromosome 8, which carries *c-myc*, and chromosome 14, which carries the IgH locus; ~10% involve chromosome 8 and either chromosome 2 (kappa locus) or chromosome 22 (lambda locus). The translocations in T-cell tumors often involve chromosome 8, and either chromosome 14 (which has the TCR  $\alpha$  locus at the other end from the Ig locus) or chromosome 7 (which carries the TCR  $\beta$  locus). Analogous translocations occur in the mouse.

Translocations in B cells fall into two classes, reflecting the two types of recombination that occur in immunoglobulin genes. One type is similar to those involved in the somatic recombination that generates the active genes. These events involve the consensus sequences used for V-D-J recombination. These can occur at all the Ig loci. In the other type, the translocation occurs at a switching site at the IgH locus, presumably reflecting the operation of the system for class switching.

When *c-myc* is translocated to the Ig locus, its level of expression is usually increased. The increase varies considerably among individual tumors, generally being in the range from 2–10 $\times$ . Why does translocation activate the *c-myc* gene? The event has two consequences: *c-myc* is brought into a new region, one in which an Ig or TCR gene was actively expressed; and the structure of the *c-myc* gene may itself be changed (but usually not involving the coding regions). It seems likely that several different mechanisms can activate the *c-myc* gene in its new location (just as

---

retroviral insertions activate *c-myc* in a variety of ways).

The correlation between the tumorigenic phenotype and the activation of *c-myc* by either insertion or translocation suggests that continued high expression of c-Myc protein is oncogenic. Expression of *c-myc* must be switched off to enable immature lymphocytes to differentiate into mature B and T cells; failure to turn off *c-myc* maintains the cells in the undifferentiated (dividing) state.

The oncogenic potential of *c-myc* has been demonstrated directly by the creation of transgenic mice. Mice carrying a *c-myc* gene linked to a B lymphocyte-specific enhancer (the IgH enhancer) develop lymphomas. The tumors represent both immature and mature B lymphocytes, suggesting that overexpression of *c-myc* is tumorigenic throughout the B cell lineage. Transgenic mice carrying a *c-myc* gene under the control of the LTR from a mouse mammary tumor virus, however, develop a variety of cancers, including mammary carcinomas. This suggests that increased or continued expression of *c-myc* transforms the type of cell in which it occurs into a corresponding tumor (for review see 345; 347).

*c-myc* exhibits three means of oncogene activation: retroviral insertion, chromosomal translocation, and gene amplification. The common thread among them is deregulated expression of the oncogene rather than a qualitative change in its coding function, although in at least some cases the transcript has lost the usual (and possibly regulatory) nontranslated leader. *c-myc* provides the paradigm for oncogenes that may be effectively activated by increased (or possibly altered) expression.

Translocations are now known in many types of tumors. Often a specific chromosomal site is commonly involved, creating the supposition that a locus at that site is involved in tumorigenesis. However, every translocation generates reciprocal products; sometimes a known oncogene is activated in one of the products, but in other cases it is not evident which of the reciprocal products has responsibility for oncogenicity. Also, it is not axiomatic that the gene(s) at the breakpoint have responsibility; for example, the translocation could provide an enhancer that activates another gene nearby.

A variety of translocations found in B and T cells have identified new oncogenes. In some cases, the translocation generates a hybrid gene, in which an active transcription unit is broken by the translocation. This has the result that the exons of one gene may be connected to another. In such cases, there are two potential causes of oncogenicity. The proto-oncogene part of the protein may be activated in some way that is independent of the other part, for example, because it is over-expressed under its new management (a situation directly comparable to the example of *c-myc*). Or the other partner in the hybrid gene may have some positive effect that generates a gain-of-function in the part of the protein coded by the proto-oncogene.

---

**ONCOGENES AND CANCER****6.30.13 The Philadelphia translocation generates a new oncogene**

---

**Key Concepts**

- The Philadelphia translocations create new genes with N-terminal sequences from *bcr* and C-terminal sequences from *c-abl*.
  - Both parts of the fusion protein contribute to oncogenicity, which results from activation of the Ras/MAPK pathway.
- 

One of the best characterized cases in which a translocation creates a hybrid oncogene is provided by the *Philadelphia (PH<sup>1</sup>)* chromosome present in patients with chronic myelogenous leukemia (CML). This reciprocal translocation is too small to be visible in the karyotype, but links a 5000 kb region from the end of chromosome 9 carrying *c-abl* to the *bcr* gene of chromosome 22. The *bcr* (*breakpoint cluster region*) was originally named to describe a region of ~5.8 kb within which breakpoints occur on chromosome 22.

The consequences of this translocation are summarized in **Figure 30.19**. The *bcr* region lies within a large (>90 kb) gene, which is now known as the *bcr* gene. The breakpoints in CML usually occur within one of two introns in the middle of the gene. The same gene is also involved in translocations that generate another disease, ALL (acute lymphoblastic leukemia); in this case, the breakpoint in the *bcr* gene occurs in the first intron.

**Figure 30.19** Translocations between chromosome 22 and chromosome 9 generate Philadelphia chromosomes that synthesize *bcr-abl* fusion transcripts that are responsible for two types of leukemia.

The *c-abl* gene is expressed by alternative splicing that uses either of the first two exons. The breakpoints in both CML and ALL occur in the intron that precedes the first common exon. Although the exact breakpoints on both chromosomes 9 and 22 vary in individual cases, the common outcome is the production of a transcript coding for a Bcr-Abl fusion protein, in which N-terminal sequences derived from *bcr* are linked to *c-abl* sequences. In ALL, the fusion protein has ~45 kD of the Bcr protein; in CML the fusion protein has ~70 kD of the Bcr protein.

In each case, the fusion protein contains ~140 kD of the usual ~145 kD *c-Abl* protein, that is, it has lost just a few N-terminal amino acids of the *c-abl* sequence. Changes at the N-terminus are involved in activating the oncogenic activity of *v-abl*, a transforming version of the gene carried in a retrovirus. The *c-abl* gene codes for a tyrosine kinase activity; this activity is essential for transforming potential in oncogenic variants. Deletion (or replacement) of the N-terminal region activates the kinase activity and transforming capacity. So the N-terminus provides a domain that usually regulates kinase activity; its loss may cause inappropriate activation.

Why is the fusion protein oncogenic? The Bcr-Abl protein activates the Ras pathway for transformation. It may have multiple ways of doing so, including activation of the adaptors Grb2 and Shc (see *Molecular Biology 6.28.14 The Ras/MAPK pathway is widely conserved*). Both the Bcr and Abl regions of the joint protein may be important in transforming activity.

---

**ONCOGENES AND CANCER****6.30.14 Oncogenes code for components of signal transduction cascades**

---

**Key Concepts**

- Oncogenes can be derived from any part of a signal transduction cascade, from the initiating growth factor or receptor to the transcription factor that is the ultimate effector.
  - Upstream and downstream components of the Ras pathway are often involved, although not the MAP kinases themselves.
- 

Whether activated by quantitative or qualitative changes, oncogenes may be presumed to influence (directly or indirectly) functions connected with cell growth. Transformed cells lack restrictions imposed on normal cells, such as dependence on serum or inhibition by cell-cell contact. They may acquire new properties, such as the ability to metastasize. Many phenotypic properties are changed when we compare a normal cell with a tumorigenic counterpart, and it is striking indeed that individual genes can be identified that trigger many of the changes associated with this transformation.

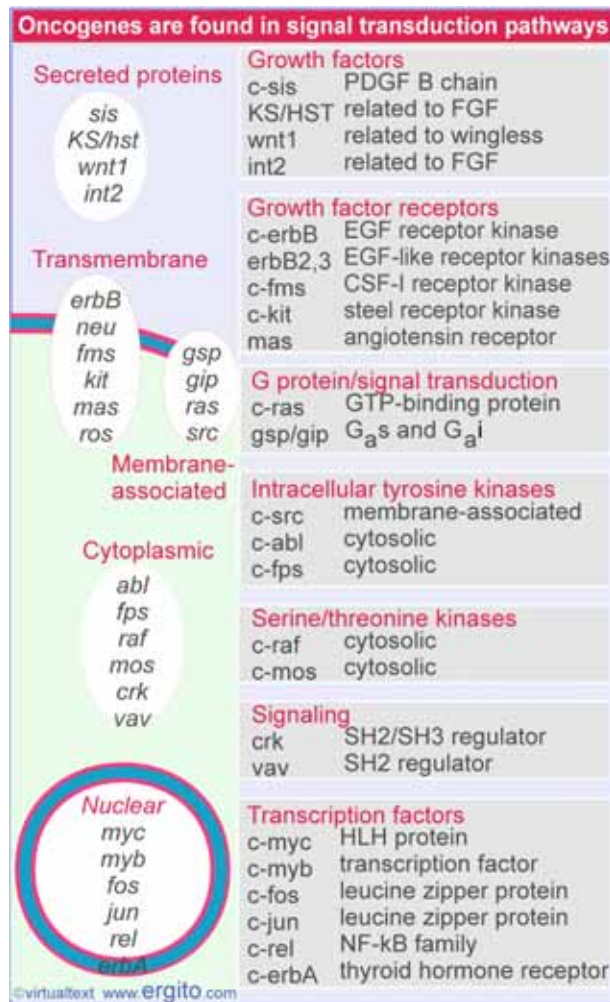

We assume that oncogenes, individually or in concert, set in train a series of phenotypic changes that involve the products of many genes. In this description, we see at once a similarity with genes that regulate developmental pathways: they do not themselves necessarily code for the products that characterize the differentiated cells, but they may direct a cell and its progeny to enter a particular pathway. The same analogy suggests itself for oncogenes and developmental regulators: they provide switches responsible for causing transitions between one discrete phenotypic state and another.

Taking this relationship further, we may ask what activities the products of proto-oncogenes play in the normal cell, and how they are changed in the transformed cell. Could some proto-oncogenes be regulators of normal development whose malfunction results in aberrations of growth that are manifested as tumors? There are some examples of such relationships, but do not yet have any systematic understanding of the connection.

Signal transduction pathways are often involved in oncogenesis. The best characterized example is c-Ras, which plays a central role in transmitting the signal from receptor tyrosine kinases (see *Molecular Biology 6.28.14 The Ras/MAPK pathway is widely conserved*). Oncogenic mutations change the regulation of Ras activity.

Oncoproteins are organized according to their types of functions in **Figure 30.20**. The left part of the figure groups the oncogenes according to the locations of their products. The boxes on the right give details of the corresponding proto-oncogenes. The functions of many oncogenes remain unknown, and further groups will no doubt

be identified:

**Figure 30.20** Oncogenes may code for secreted proteins, transmembrane proteins, cytoplasmic proteins, or nuclear proteins.

- Growth factors are proteins secreted by one cell that act on another. The oncoprotein counterparts can only transform cells bearing the appropriate receptor. (This is called autocrine transformation; for review see 337; 349.)
- The growth factor receptors are transmembrane proteins that are activated by binding an extracellular ligand (usually a polypeptide). Most often the receptor is a protein tyrosine kinase. Oncogenicity may result from constitutive (that is, ligand-independent) activation of the kinase activity (862). Other early stages in signal transduction are identified by Gsp and Gip, which are mutant forms of the  $\alpha$  subunits of the  $G_s$  and  $G_i$  trimeric G proteins.
- An important group of intracellular protein kinases phosphorylate tyrosine residues in target proteins. c-Src, which associates with the cytoskeleton as well as with the membrane, is the prototype of a family of kinases with similar

catalytic activities (including c-Yes, c-Fgr, Lck, c-Fps, Fyn). We understand the effects of oncogenic mutations on the Src kinase activity in some detail, although we have yet to explain why the altered kinase activity is oncogenic. Other protein tyrosine kinases in the intracellular group are cytosolic; c-Abl is found in both cytosol and nucleus (860; 861; for review see 344).

- A group of cytosolic enzymes are protein serine/threonine kinases, that is, they phosphorylate target proteins on serine or threonine. Little is known about the effects of oncogenic mutations beyond the fact they probably increase or constitutively activate the kinase activities. Mos is an example which can activate ERK MAPK.
- Nuclear proteins include transcription factors of several types. The functions of these proto-oncoproteins are rather well described (see *Molecular Biology 5.22 Activating transcription*). Generally we understand what effects the oncogenic mutations have on the factors, but we cannot yet relate these changes to the activation or repression of a set of target genes that defines the oncogenic state (863; 864; 865).

The common feature is that each type of protein is in a position to trigger general changes in cell phenotypes, either by initiating or responding to changes associated with cell growth, or by changing gene expression directly. Before we consider in detail the potential of each group for initiating a series of events that has an oncogenic outcome, we need to consider how many independent pathways are identified by these factors.

Recall the example of the best characterized mitogenic pathway, the MAPK pathway which consists of the following stages:

growth factor

↓

growth factor receptor (tyrosine kinase)

↓

Ras

↓

kinase cascade (serine/threonine kinases)

↓

transcription factor(s)

When a growth factor interacts with its receptor, it activates the tyrosine kinase activity. The signal is passed (via an adaptor) to Ras. At this point, the pathway

switches to a series of serine/threonine kinases. The targets at the end of the pathway may be controlled directly or indirectly by phosphorylation, and include transcription factors, which are in a position to make widespread changes in the pattern of gene expression.

If a pathway functions in a linear manner, in which the signal passes directly from one component to the next, the same results should be achieved by constitutive activation of any component (so that it no longer needs to be activated by a signal from an earlier component).

A signal transduction pathway, of course, is likely to branch at several stages, so that an initial stimulus may trigger a variety of responses. The activation of components that are downstream will therefore activate a smaller number of end-functions than the activation of components at the start of the pathway. But we can analyze any individual part of the pathway by tracing it back to the beginning as though it were strictly linear.

In the example of the Ras pathway, we know that it is activated by many growth factors to generate a mitogenic response. Mutations in the early part of this pathway, including the *ras* and *raf* genes, may be oncogenic. But oncogenic mutations are not usually found in the following components of the cascade, the MEK and MAP kinases. This suggests that there may be a branch in the pathway at the stage of *ras* or *raf*, and that activation of this branch is also necessary for oncogenicity. Ras activates a cytoskeletal GTPase called Rac, which may identify this branch. However, the ERK MAPK pathway terminates in the activation of several "immediate early" genes, including *fos* and *jun*, which themselves have oncogenic counterparts, suggesting that the targets of the MAPK pathway can be sufficient for oncogenicity.

The central role of this pathway is indicated by the number of its components that are coded by proto-oncogenes. One explanation of the discrepancies between the susceptibilities of MAP kinases and other components to oncogenic mutation may be that the *level* or *duration* of expression is important. It could be the case that mutations in MEK or MAP kinases do not activate the enzymes sufficiently to be oncogenic. Alternatively, the oncogenic mutations (which, after all, represent gain-of-function) may cause new targets to be activated in addition to the usual pathway. The general principle is clear: *that aberrant activation of mitogenic pathways can contribute to oncogenicity*, but we cannot yet explain exactly how the activation of these pathways changes the properties of the cell in terms of immortalization or transformation (for review see 348).

## ONCOGENES AND CANCER

### 6.30.15 Growth factor receptor kinases can be mutated to oncogenes

---

#### Key Concepts

- Oncogenes are generated by mutations that constitutively activate growth factor receptor genes.
  - The type of tumor reflects the phenotypes of the cells in which the receptor is expressed.
- 

The protein tyrosine kinases constitute a major class of oncoproteins, and fall into two general groups: transmembrane receptors for growth factors; and cytoplasmic enzymes. We have more understanding about the biological functions of the receptors, because we know the general nature of the signal transduction cascades that they initiate, and we can see how their inappropriate activation may be oncogenic. The normal roles in the cell of the cytoplasmic tyrosine kinases are not so well defined, but in several cases it appears that they provide catalytic functions for receptors that themselves lack kinase activity; that is, the activation of the receptor leads to activation of the cytoplasmic tyrosine kinase. We have a great deal of information about their enzymatic activities and the molecular effects of oncogenic mutations, although it has been more difficult to identify their physiological targets.

Receptors for many growth factors have kinase activity. They tend to be large integral membrane proteins, with domains assembled in modular fashion from a variety of sources. We discussed the general nature of transmembrane receptors and the means by which they are activated to initiate signal transduction cascades in *Molecular Biology 6.28.8 Growth factor receptors are protein kinases*. The EGF receptor is the paradigm for tyrosine kinase receptors. The extracellular N-terminal region binds the ligand that activates the receptor. The intracellular C-terminal region includes a domain that has tyrosine kinase activity. Most of the receptors that are coded by cellular proto-oncogenes have a similar form of organization.

Dimerization of the extracellular domain of a receptor activates the tyrosine kinase activity of the intracellular domain. Various forms of this reaction were summarized previously in **Figure 28.17**. When the cytoplasmic domains of the monomers are brought into contact, they trigger an autophosphorylation reaction, in which each monomer phosphorylates the other (see *Molecular Biology 6.28.9 Receptors are activated by dimerization*).

A (generalized) relationship between a growth factor receptor and an oncogenic variant is illustrated in **Figure 30.21**. The wild-type receptor is regulated by ligand binding. In the absence of ligand, the monomers do not interact. Growth factor binding triggers an interaction, allowing the receptor to form dimers. This in turn activates the receptor, and triggers signal transduction. By contrast, the oncogenic variant spontaneously forms dimers that are constitutively active. Different types of events may be responsible for the constitutive dimerization and activation in different

growth factor receptors (for review see 3648; 3649; 3652).

**Figure 30.21** Activation of a growth factor receptor involves ligand binding, dimerization, and autophosphorylation. A truncated oncogenic receptor that lacks the ligand-binding region is constitutively active because it is not repressed by the N-terminal domain.

The oncogene *v-erb* is a truncated version of *c-erbB*, the gene coding for the EGF receptor. The oncoprotein retains the tyrosine kinase and transmembrane domains, but lacks the N-terminal part of the protein that binds EGF, and does not have the C-terminus. The deletions at both ends may be needed for oncogenicity. The change in the extracellular N-terminal domain allows the protein to dimerize spontaneously; and the C-terminal deletion removes a cytosolic domain that inhibits transforming activity. There is also an activating mutation in the catalytic domain. So the basis for oncogenicity is the combination of mutations that activate the receptor constitutively (3647).

The general principle that constitutive or altered activity may be responsible for oncogenicity applies to the group of growth factor receptors summarized previously in **Figure 30.20**. Another example of an activation event is provided by *erbB2*, which codes for a receptor closely related to the EGF receptor. An oncogenic form has a key mutation in its transmembrane region; this increases the propensity of the receptor monomers to form dimers (3646).

Some proto-oncogenes code for receptors or factors involved in the development of particular cell types. Mutation of such a receptor (or growth factor) may promote unrestricted growth of cells of the appropriate type. The proto-oncogene *c-fms* codes for the CSF-I receptor, which mediates the action of colony stimulating factor I, a macrophage growth factor that stimulates the growth and maturation of myeloid

precursor cells (3651). *c-fms* can be rendered oncogenic by a mutation in the extracellular domain; this increases dimerization and makes the protein constitutively active in the absence of CSF-I. Oncogenicity is enhanced by C-terminal mutations, which could act by inactivating an inhibitory intracellular domain (for review see 3653).

**ONCOGENES AND CANCER****6.30.16 Src is the prototype for the proto-oncogenic cytoplasmic tyrosine kinases**

---

**Key Concepts**

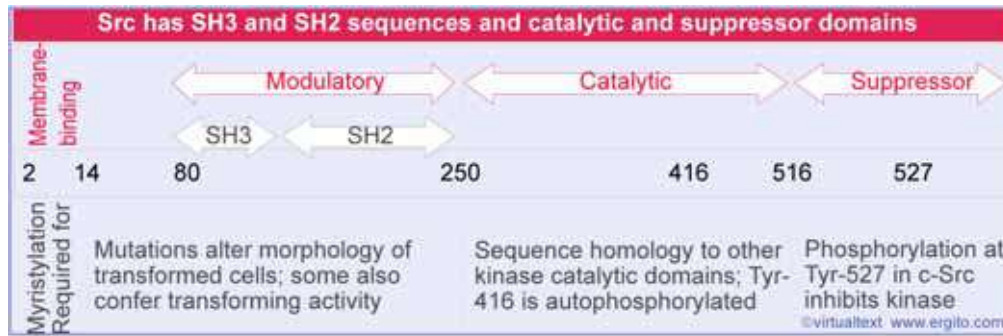

- The cytoplasmic tyrosine kinases phosphorylate tyrosine residues in cytosolic proteins.
  - Myristoylation of the N-terminus enables Src to associate with the plasma membrane.
  - The crucial cellular targets for Src remain unidentified.
- 

The cellular action and basis for oncogenicity of the cytoplasmic group of protein tyrosine kinases is more obscure. The cytoplasmic group is characterized by the viral oncogenes *src*, *yes*, *fgr*, *fps/fes*, *abl*, *ros*. (c-Src is actually associated with membranes.) A major stretch of the sequences of all these genes is related, corresponding to residues 80-516 of *c-src*. This includes the SH2 and SH3 domains and the catalytic domain responsible for kinase activity. Presumably the regions outside this domain control the activities of the individual members of the family. In few cases, however, do we know the cellular function of a *c-onc* member of this group.

The paradigm for a cytoplasmic tyrosine kinase in search of a role is presented by the Src proteins. Since its isolation by Rous in 1911, RSV has been perpetuated under a variety of conditions, and there are now several "strains," carrying variants of *v-src*. The common feature in the sequence of *v-src* is that the C-terminal sequence of *c-src* has been replaced. The various strains contain different point mutations within the *src* sequence (3654; 3655; 3656).

Proteins in the Src family were the first oncoproteins of the kinase type to be characterized. Src was also the first example of a kinase whose target is a tyrosine residue in protein. The level of phosphotyrosine is increased about 10× in cells that have been transformed by RSV. In addition to acting on other proteins, Src is able to phosphorylate itself.

Src proteins have several interesting features. **Figure 30.22** summarizes their activities in terms of protein domains.

**Figure 30.22** A Src protein has an N-terminal domain that associates with the membrane, a modulatory domain that includes SH2 and SH3 motifs, a kinase catalytic domain, and (c-Src only) a suppressor domain.

Both v-Src and c-Src are modified at the N-terminus. The N-terminal amino acid is cleaved, and myristic acid (a rare fatty acid of 14 carbon residues) is covalently added to the N-terminal glycine. Myristoylation enables Src proteins to attach to the cytosolic face of membranes in the cytoplasm. Most of the protein is associated with the cytoplasmic face of the endosomes, and it is enriched in regions where there are cell-to-cell contacts and adhesion plaques.

Myristoylation is essential for oncogenic activity of v-Src, since N-terminal mutants that cannot be myristoylated have reduced tumorigenicity. The simplest explanation for the dependence of transformation on the membrane location of v-Src is that important substrates for Src are located in the membrane.

The biological action of v-Src is qualitatively different from that of c-Src, since increased concentrations of c-Src cannot fully transform cells (3658). The major biochemical difference between v-Src and c-Src lies in their kinase activities. The activity of v-Src is ~20× greater than that of c-Src. The transforming activity of *src* mutants is correlated with the level of kinase activity, and we believe that oncogenicity results from phosphorylation of target protein(s). We do not know whether the increased activity is itself responsible for oncogenicity or whether there is also a change in the specificity with which target proteins are recognized.

Kinase activity plays two roles in Src function (for review see 3657). First, attempts to identify a function for the phosphorylation in cell transformation have concentrated on identifying cellular substrates that may be targets for v-Src (especially those that may not be recognized by c-Src). A variety of substrates has been identified, but none has yet been equated with the cause of transformation. Second, the state of phosphorylation of Src itself controls the transforming activity (see *Molecular Biology 6.30.17 Src activity is controlled by phosphorylation*).

## ONCOGENES AND CANCER

### 6.30.17 Src activity is controlled by phosphorylation

---

#### Key Concepts

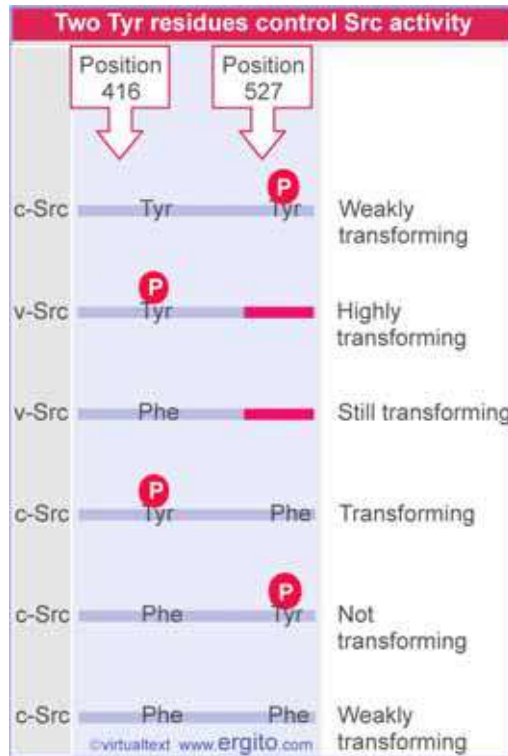

- Src autophosphorylates and its activity is controlled by the state of phosphorylation at two Tyr residues.
- Oncogenic variants are derived from c-Src by mutations that cause decreased phosphorylation at Tyr-527 and increased phosphorylation at Tyr-416.
- v-Src lacks Tyr-527 and is constitutively active.
- Src was the protein in which the SH2 and SH3 motifs were originally identified.

---

Two sites in Src control its kinase activity. It is inactivated by phosphorylation at tyrosine residue 527, which is part of the C-terminal sequence of 19 amino acids that is missing from v-Src. The c-Src protein is phosphorylated *in vivo* at this position by the kinase Csk, which maintains it in an inactive state. Src is activated by phosphorylation at Tyr-416, which is located in the activation loop of the kinase domain.

The importance of these phosphorylations can be tested by mutating the tyrosine residues at 416 and 527 to prevent addition of phosphate groups. The mutations have opposite effects, as summarized in **Figure 30.23**:

**Figure 30.23** Two tyrosine residues are targets for phosphorylation in Src proteins. Phosphorylation at Tyr-527 of c-Src suppresses autophosphorylation at Tyr-416, which is associated with transforming activity. Only Tyr-416 is present in v-Src. Transforming potential of c-Src may be activated by removing Tyr-527 or repressed by removing Tyr-416.

- Mutation of Tyr-527 to the related amino acid phenylalanine activates the transforming potential of c-Src. The protein c-Src<sup>Phe-527</sup> becomes phosphorylated on Tyr-416, has its kinase activity increased ~10×, and it transforms target cells, although not as effectively as v-Src. *Phosphorylation of Tyr-527 therefore represses the oncogenicity of c-Src. Removal of this residue when the C-terminal region was lost in generating v-Src contributes significantly to the oncogenic activity of the transforming protein.*
- Mutation of Tyr-416 in c-Src eliminates its residual ability to transform. This mutation also greatly reduces the activity of the c-Src<sup>Phe-527</sup> mutant. It also reduces the transforming potential of v-Src, but less effectively. *Phosphorylation at Tyr-416 therefore activates the oncogenicity of Src proteins.*

Point mutations at other positions in c-Src support a correlation in which oncogenicity is associated with decreased phosphorylation at Tyr-527 and increased phosphorylation at Tyr-416. The states of these tyrosines may therefore be a general indicator of the oncogenic potential of c-Src. The reduced phosphorylation at Tyr-527 is responsible for the increased phosphorylation at Tyr-416, which is the crucial event. However, v-Src is less dependent on the state of Tyr-416, and mutants at this position retain transforming activity; presumably v-src has accumulated other

mutations that increase transforming potential.

What is the function of c-Src; and how is it related to the oncogenicity of v-Src? The c-Src and v-Src proteins are very similar: they share N-terminal modification, cellular location, and protein tyrosine kinase activity. c-Src is expressed at high levels in several types of terminally differentiated cells, which suggests that it is not involved in regulating cell proliferation. But we have so far been unable to determine the normal function of c-Src. A very large number of proteins have been identified as targets for the Src kinase, most of them identified with signaling pathways, and some with the interactions of the cell with the environment (for review see 3659). c-Src is activated by growth factor receptors, such as the PDGF receptor, suggesting the general view that, like other oncogenes, it is involved in signaling pathways that regulate growth which can be tumorigenic when constitutively activated.

The modulatory region of c-Src contains two motifs that are found in a variety of other cytoplasmic proteins that are involved in signal transduction: these may connect a protein to the components that are upstream and downstream of it in a signaling pathway. The names of these two domains, SH2 and SH3, reflect their original identification as regions of Src homology (see *Molecular Biology 6.28.11 Signaling pathways often involve protein-protein interactions*).

How is c-Src usually activated? Most mutations in the SH2 region reduce transforming activity (suggesting that the SH2 function is required to activate c-Src), and most mutations in SH3 increase transforming activity (suggesting that SH3 has a negative regulatory role). **Figure 30.24** shows a more detailed model for the function of the SH2 domain. The state of phosphorylation at Tyr-527 is critical. In the inactive state, Tyr-527 is phosphorylated, and this enables the C-terminal region of c-Src itself to bind to the N-terminal SH2 domain. When an appropriate receptor tyrosine kinase (such as PDGF receptor) is activated, its autophosphorylation creates an SH2-binding site that displaces Tyr-527. This leads to its dephosphorylation, which triggers a change in conformation allowing Tyr-416 to be phosphorylated.

**Figure 30.24** When a receptor tyrosine kinase is activated, autophosphorylation generates a binding site for the Src SH2 domain, Tyr-527 is released and dephosphorylated, Tyr-416 becomes phosphorylated, and Src kinase is activated. *This is a static version of an interactive figure; see <http://www.ergito.com/main.jsp?bcs=MBIO.6.30.17> to view properly.*

**Figure 30.25** shows a schematic model based on the crystal structure of Src (3660). The SH2 domain binds to a C-terminal projection of the kinase domain that contains Tyr-527. The SH3 domain binds to a short sequence that connects the SH2 and catalytic domains. The SH2 and SH3 domains are at the back of the kinase domain, so these interactions lock the enzyme in an inactive state. The activation loop in the kinase domain is in a state that does not allow Tyr-416 to be phosphorylated. An activator (such as an activated membrane receptor) binds to both the SH2 and SH3 domains. This causes dephosphorylation of Tyr-527, which triggers an unfolding of the activator loop that allows Tyr-416 to be phosphorylated. The oncogenic v-Src protein is constitutively active because it lacks Tyr-527, so the inactive state cannot be formed.

**Figure 30.25** Src is inactive when the SH2 domain binds the Tyr-phosphate at position 527, and the SH3 domain binds the connector between kinase and SH2 domains. These interactions are disrupted when a Src activator binds to the SH2 and SH3 domains. This causes Tyr-527 to be dephosphorylated, and changes the conformation of the activation loop of the kinase domain so that Tyr-416 can be phosphorylated.

Alternative ways for activating c-Src may be involved in some oncogenic reactions. For example, the polyoma middle T antigen activates c-Src by binding to the C-terminal region including Tyr-527 and prevents its phosphorylation. Some mutations in the SH2 domain of c-Src can activate the kinase activity (with oncogenic consequences), presumably because they prevent it from sequestering Tyr-527. Mutations in the SH2 and SH3 domains of c-Src can influence its

specificity with regard to transforming different types of target cells, which suggests that these regions provide the connections to other (cell specific) proteins in the pathway.

**ONCOGENES AND CANCER****6.30.18 Oncoproteins may regulate gene expression**

---

**Key Concepts**

- The *rel* oncogene is a member of the NF  $\kappa$ B family.
  - The *jun* and *fos* oncogenes code for the subunits of the transcription factor AP1.
  - Screening with high density DNA microarrays allows the pattern of gene expression to be compared between tumor cells and normal cells.
- 

It goes almost without saying that it is necessary to make changes in gene expression in order to convert a cell to the transformed phenotype. Many oncogenes act at early stages in pathways that lead ultimately to changes in gene expression. Some act directly at the level of transcription. Retroviral oncogenes include examples derived from the major classes of cellular transcription factors. Several prominent gene families coding for transcription factors are identified by *v-onc* genes: *rel*, *jun*, *fos*, *erbA*, *myc*, and *myb*. In the cases of Rel, Jun, and ErbA proteins, there are differences in transcriptional activity between the c-Onc and v-Onc proteins that may be related to transforming capacity.

The actions of *v-onc* genes may in principle be quantitative or qualitative; and those that affect transcription might either increase or decrease expression of particular genes. By virtue of increased expression or activity they could turn up transcription of genes whose products can be tolerated only in small amounts. Failure to respond to normal regulation of activity by other cellular factors also might lead to increased gene expression. A less likely possibility is the acquisition of specificity for new target promoters. Alternatively, if the oncoproteins are defective in the ability to activate transcription, they might function as dominant negative suppressors of the cellular transcription factors. The first steps towards distinguishing these possibilities lie with determining which functions are altered in v-Onc compared with c-Onc proteins: is DNA-binding altered either quantitatively or qualitatively; is the ability to activate transcription altered? **Figure 30.26** summarizes the properties of some of these oncoproteins.

**Figure 30.26** Oncogenes that code for transcription factors have mutations that inactivate transcription (v-erbA and possibly v-rel) or that activate transcription (v-jun and v-fos).

The oncogene *v-rel* was identified as the transforming function of the avian (turkey) reticuloendotheliosis virus. The retrovirus is highly oncogenic in chickens, where it causes B-cell lymphomas. *v-rel* is a truncated version of *c-rel*, lacking the ~100 C-terminal amino acids, and has a small number of point mutations in the remaining sequence (3661).

The *rel* gene belongs to a family whose best characterized member is the transcription factor NF- $\kappa$ B. This is a dimer of two subunits, p65 and p50, which is held in the cytoplasm by a regulator, I- $\kappa$ B. (Binding of I- $\kappa$ B masks the nuclear localization sequence in NF- $\kappa$ B). When I- $\kappa$ B is phosphorylated, it is degraded and therefore releases NF- $\kappa$ B, which enters the nucleus and activates transcription of target genes whose promoters or enhancers have the  $\kappa$ B motif. This regulatory story is essentially recapitulated in *Drosophila* development, where *dorsal* codes for an NF- $\kappa$ B homologue that is held in the cytoplasm by the *cactus* product, an I  $\kappa$ B homologue (see *Molecular Biology 6.31.11 Dorsal protein forms a gradient of nuclear localization*). The two subunits of NF- $\kappa$ B have related sequences, and *c-rel* has 60% similarity with p50 (3662; 3663; 3664).

NF- $\kappa$ B is one of the most pleiotropic transcription factors; indeed, it has been suggested that it may constitute a general second messenger. Many types of stimulus to the cell result in activation of NF- $\kappa$ B and a broad range of genes is activated via the presence of  $\kappa$ B binding sites. The members of the NF- $\kappa$ B family form various pairwise combinations that regulate transcription. When v-Rel forms dimers with cellular family members, it may influence their activities either negatively or positively, thus changing the pattern of gene expression (for review see 3665). v-Rel is exclusively nuclear, because it has lost the sequences required for export to the cytoplasm.

The transcription factor AP1 is the nuclear factor required to mediate transcription induced by phorbol ester tumor promoters (such as TPA). An AP1 binding site confers TPA-inducibility upon a target gene. The canonical AP1 factor consists of a dimer of two subunits, coded by the genes *c-jun* and *c-fos*, which activates genes whose promoters or enhancers have an AP1 binding site (863; 865; 3666).

Jun and Fos are transcription factors of the leucine zipper class. Each protein is a member of a family, and a series of pairwise interactions between Jun family members and Fos family members may generate a series of transcription factors related to AP1. Mutations of *v-jun* or *v-fos* that abolish the ability to bind DNA or that damage the transactivation function also render the product non-transforming, providing a direct proof that ability to activate transcription is required for transforming activity (3667).

c-Jun is activated by phosphorylation on two serine residues by the action of the kinase JNK, which is activated by the Ras pathway, and this contributes to the transforming action of Ras. The transforming activity of v-Jun has a more complex basis. v-Jun has a deletion of amino acids 34-60 that includes both these sites of phosphorylation, and so is not regulated by the Ras pathway. Other changes in v-Jun make it constitutively active. However, v-Jun can also interfere with the ability of c-Jun to activate some of its target genes. The transforming activity of v-Jun may therefore depend on both quantitative changes (overexpression or under-expression of particular target genes) or qualitative changes (alteration in the pattern of genes that responds to the factor).

The cellular gene *c-erbA* codes for a thyroid hormone receptor, a member of the general class of steroid hormone receptors (see *Molecular Biology 5.22.10 Steroid receptors are activators*). Upon binding its ligand, a typical steroid receptor activates expression of particular target genes by binding to its specific response element in a promoter or enhancer. The mode of action for thyroid hormone is distinct: it is located permanently in the nucleus, and, indeed, may bind its response element whether or not ligand is present. The effect of hormone binding may therefore be to activate transcription by previously bound receptor.

Ability to bind DNA is required for transforming capacity. *v-erbA* is truncated at both ends and has a small number of substitutions relative to *c-erbA*. Hormone binding is altered; the *c-erbA* product binds triiodothyronine ( $T_3$ ) with high affinity, but the *v-erbA* product has little or no affinity for the ligand in mammalian cells. This suggests that loss of the ligand-binding capacity (perhaps together with other changes) may create a protein whose function has become independent of the hormone. The consequence of losing the response to ligand is that the factor can no longer be stimulated to activate transcription.

These results place *v-erbA* as a dominant negative oncogene, one that functions by overcoming the action of its normal cellular counterpart. Its action is to prevent transcription of genes that usually are activated by *c-ErbA* (3668). The implication is that genes activated by *c-ErbA* act to *suppress* transformation. In this particular case, it seems likely that these genes usually promote differentiation; blocking this action allows the cells to proliferate.

*c-jun*, *c-fos*, *c-rel*, and also *c-myc* are "immediate early" genes, members of a class of genes that are rapidly induced when resting cells are treated with mitogens, which suggests that they may be involved in a cascade that initiates cycling. So their targets are likely to be concerned with initiating or promoting growth. We should therefore expect an increase in their activities to be associated with oncogenesis, an expectation that may be fulfilled for *v-fos* and *v-myc*, but does not explain the behavior of *v-rel*.

The adenovirus oncogene E1A provides an example of a protein that regulates gene expression indirectly, that is, without itself binding to DNA. The E1A region is expressed as three transcripts, derived by alternative splicing, as indicated in **Figure 30.27**. The 13S and 12S mRNAs code for closely related proteins and are produced early in infection. They possess the ability to immortalize cells, and can cooperate with other oncoproteins (notably Ras) to transform primary cells (see later). No other viral function is needed for this activity (for review see 343).

**Figure 30.27** The adenovirus E1A region is spliced to form three transcripts that code for overlapping proteins. Domain 1 is present in all proteins, domain 2 in the 289 and 243 residue proteins, and domain 3 is unique to the 289 residue protein. The C-terminal domain of the 55 residue protein is translated in a different reading frame from the common C-terminal domains of the other two proteins.

The E1A proteins exercise a variety of effects on gene expression. They activate the transcription of some genes, but repress others. Mutation of the E1A proteins suggests that transcriptional activation requires only the short region of domain 3, found only in the 289 amino acid protein coded by 13S mRNA. Repression of transcription, induction of DNA synthesis, and morphological transformation all require domains 1 and 2, common to both the 289 and 243 amino acid proteins. This suggests that repression of target genes is required to cause transformation. E1A

proteins act by binding to several cellular proteins that in turn repress or activate transcription of appropriate target genes. Among these targets are the CBP and p300 coactivators, the TBP basal transcription factor, and the cell cycle regulators RB and p27.

A powerful new approach to analyzing the roles of individual genes in cancer has been made possible by the development of techniques to allow simultaneous screening for the expression of many genes. High density DNA microarrays contain probes to the mRNAs of up to 10,000 genes (typically immobilized on a glass slide). The technique is at its most effective for comparing the genes expressed in two related cell types. The technique can be applied to a tumor cell when it is possible to compare it with the original cell type from which it arose, or can be used to compare related tumor cells with different properties. This gives insights into the extent of change in gene expression, and ultimately can be used to identify the particular genes that are involved in stages of cancer development.

Tumor cell lines can be obtained that vary in their ability to metastasize (to spread from the site of origin to colonize new sites in the body). A highly metastatic cell line can be selected from a line that is poorly metastatic without apparently changing the properties of the tumor as such – only the ability to spread appears to be affected. A comparison in two such cases showed that only a small number (<20) genes have a significant change in transcription. This suggests the possibility that metastasis involves relatively minor changes in the pattern of gene expression. Among the affected genes are several whose products act on the actin cytoskeleton, suggesting that changes in cellular motility and/or adhesion to other cells or substratum could be the basis for metastasis (1063).

More widespread changes were detected when benign prostate tumors were compared with metastatic cancers . On average, expression of 55 genes was increased, and expression of 480 genes was decreased (3211). This is interesting in suggesting that cancer progression may have a major contribution from the inhibition of functions that usually suppress cell growth or motility. One of the genes whose expression is increased is *EZH2*, a member of the Polycomb group that forms complex involved in repressing the activity of chromatin (see *Molecular Biology 5.23.16 Polycomb and trithorax are antagonistic repressors and activators*). *EZH2* is responsible for repressing about one third of the genes whose expression is decreased in the metastatic prostate cancer (3212).

**ONCOGENES AND CANCER****6.30.19 RB is a tumor suppressor that controls the cell cycle**

---

**Key Concepts**

- Loss of both alleles of *RB* causes retinoblastomas.
- Nonphosphorylated RB prevents cell proliferation.
- In the normal cell cycle, phosphorylation of RB by cdk-cyclin kinases is necessary to proceed into S phase.
- Certain tumor antigens suppress the inhibitory action by sequestering the nonphosphorylated form of RB.
- Several tumor suppressors act by blocking the cdk-kinase complexes that phosphorylate RB.

---

The common theme in the role of oncogenes in tumorigenesis is that increased or altered activity of the gene product is oncogenic. Whether the oncogene is introduced by a virus or results from a mutation in the genome, it is dominant over its allelic proto-oncogene(s). A mutation that activates a single allele is tumorigenic. Tumorigenesis then results from gain of a function.

Certain tumors are caused by a different mechanism: loss of both alleles at a locus is tumorigenic. Propensity to form such tumors may be inherited through the germline; it also occurs as the result of somatic change in the individual. Such cases identify tumor suppressors: genes whose products are needed for normal cell function, and whose loss of function causes tumors. The two best characterized genes of this class code for the proteins RB and p53.

Retinoblastoma is a human childhood disease, involving a tumor of the retina. It occurs both as a heritable trait and sporadically (by somatic mutation). It is often associated with deletions of band q14 of human chromosome 13. The *RB* gene has been localized to this region by molecular cloning.

**Figure 30.28** summarizes the situation. Retinoblastoma arises when both copies of the *RB* gene are inactivated. In the inherited form of the disease, one parental chromosome carries an alteration in this region. A somatic event in retinal cells that causes loss of the other copy of the *RB* gene causes a tumor. In the sporadic form of the disease, the parental chromosomes are normal, and both *RB* alleles are lost by (individual) somatic events (872).

**Figure 30.28** Retinoblastoma is caused by loss of both copies of the *RB* gene in chromosome band 13q14. In the inherited form, one chromosome has a deletion in this region, and the second copy is lost by somatic mutation in the individual. In the sporadic form, both copies are lost by individual somatic events.

The cause of retinoblastoma is therefore loss of protein function, usually resulting from mutations that prevent gene expression (as opposed to point mutations that affect function of the protein product). Loss of *RB* is involved also in other forms of cancer, including osteosarcomas and small cell lung cancers.

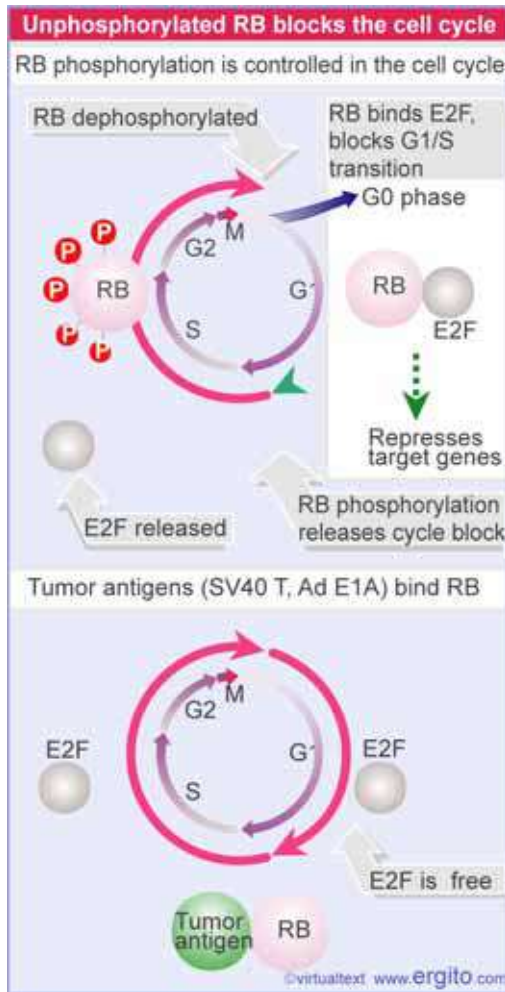

*RB* is a nuclear phosphoprotein that influences the cell cycle (see *Molecular Biology 6.29.17 G0/G1 and G1/S transitions involve cdk inhibitors*). In resting ( $G_0/G_1$ ) cells, *RB* is not phosphorylated. *RB* is phosphorylated during the cell cycle by cyclin/cdk complexes, most particularly at the end of  $G_1$ ; it is dephosphorylated during mitosis. The nonphosphorylated form of *RB* specifically binds several proteins, and these interactions therefore occur only during part of the cell cycle (prior to  $S$  phase). Phosphorylation releases these proteins.

The target proteins include the E2F group of transcription factors, which activate target genes whose products are essential for  $S$  phase. Binding to *RB* inhibits the ability of E2F to activate transcription, which suggests that *RB* blocks the expression of genes dependent on E2F. In this way, *RB* indirectly prevents cells from entering  $S$  phase. Also, the *RB*-E2F complex directly represses some target genes, so its dissociation allows them to be expressed.

Certain viral tumor antigens bind specifically to the nonphosphorylated form of *RB*.

The best characterized are SV40 T antigen and adenovirus E1A. This suggests the model shown in **Figure 30.29**. Nonphosphorylated RB prevents cell proliferation; this activity must be suppressed in order to pass through the cell cycle, which is accomplished by the cyclic phosphorylation. And it may also be suppressed when a tumor antigen sequesters the nonphosphorylated RB. Because the RB-tumor antigen complex does not bind E2F, the E2F is permanently free to allow entry into S phase (and the RB-E2F complex is not available to repress its target genes) (871).

**Figure 30.29** A block to the cell cycle is released when RB is phosphorylated (in the normal cycle) or when it is sequestered by a tumor antigen (in a transformed cell).

Overexpression of RB impedes cell growth. An indication of the importance of RB for cell proliferation is given by the properties of an osteosarcoma cell line that lacks RB; when RB is introduced into this cell line, its growth is impeded. However, the inhibition can be overcome by expression of D cyclins, which form cdk-cyclin combinations that phosphorylate RB. RB is not the only protein of its type: proteins with related sequences, called p107 and p130, have similar properties.

The connection between the cell cycle and tumorigenesis is illustrated in **Figure**

**30.30.** Several regulators are identified as tumor suppressors by the occurrence of inactivating mutations in tumors. As well as occurring in RB itself, mutations are found in the small inhibitory proteins (most notably p16 and possibly p21), and D cyclin(s). Although these proteins (most notably RB) play a role in the cycle of a proliferating cell, the role that is relevant for tumorigenesis is more probably their function in the quiescent (G0) state. In quiescent cells, RB is not phosphorylated, D cyclin levels are low or absent, and p16, p21, and p27 ensure inactivity of cdk-cyclin complexes.

**Figure 30.30** Several components concerned with G0/G1 or G1/S cycle control are found as tumor suppressors.

Cyclin D activity is needed for proliferation. Loss of the circuit that suppresses it (p16 or p21) causes unrestrained growth. The control of cyclin D is particularly important in breast cancer. The cyclin D1 gene is amplified in 20% of human breast cancers, and the protein is overexpressed in >50% of human mammary carcinomas. The role of cyclin D1 has been confirmed in mouse models by showing that increased D1 expression causes increased breast cancer (1922), while the deletion of the cyclin D1 gene prevents certain oncogenes from causing breast cancer (1923). Mammary tumors can be caused in cyclin D1-deficient mice by the oncogenes *myc* or *Wnt-1*, but not by the *ras* or *neu* oncogenes. The *neu* oncogene codes for a growth factor receptor that activates Ras, and the Ras pathway leads to activation of the promoter of the cyclin D1 gene, which explains the result. The *Myc* and *Wnt-1* oncogenes must cause breast cancer by a different pathway.

## ONCOGENES AND CANCER

### 6.30.20 Tumor suppressor p53 suppresses growth or triggers apoptosis

---

#### Key Terms

A **dominant negative** mutation results in a mutant gene product that prevents the function of the wild-type gene product, causing loss or reduction of gene activity in cells containing both the mutant and wild-type alleles. The effect may result from the titration of another factor that interacts with the gene product or by an inhibiting interaction of the mutant subunit on the multimer.

#### Key Concepts

- p53 is a tumor suppressor that is lost or inactivated in >50% of all human cancers.
- Wild-type p53 is activated by damage to DNA.
- The response may be to block cell cycle progression or to cause apoptosis depending on the circumstances.

---

The most important tumor suppressor is p53 (named for its molecular size). More than half of all human cancers either have lost p53 protein or have mutations in the gene, making loss of p53 by far and away the most common alteration in human cancer. Its effects have been demonstrated directly in mice, where loss of p53 alleles causes the occurrence of tumors. **Figure 30.31** shows the survival curves for wild type mice (p53<sup>+/+</sup>), heterozygotes who have lost one allele (p53<sup>+/-</sup>), and homozygotes who have lost both alleles (p53<sup>-/-</sup>). The frequency of tumors is increased from 45% to 80% by loss of the first allele, causing the mice to die sooner; and loss of both alleles shortens the life span dramatically due to the occurrence of tumors in virtually 100% of the mice.

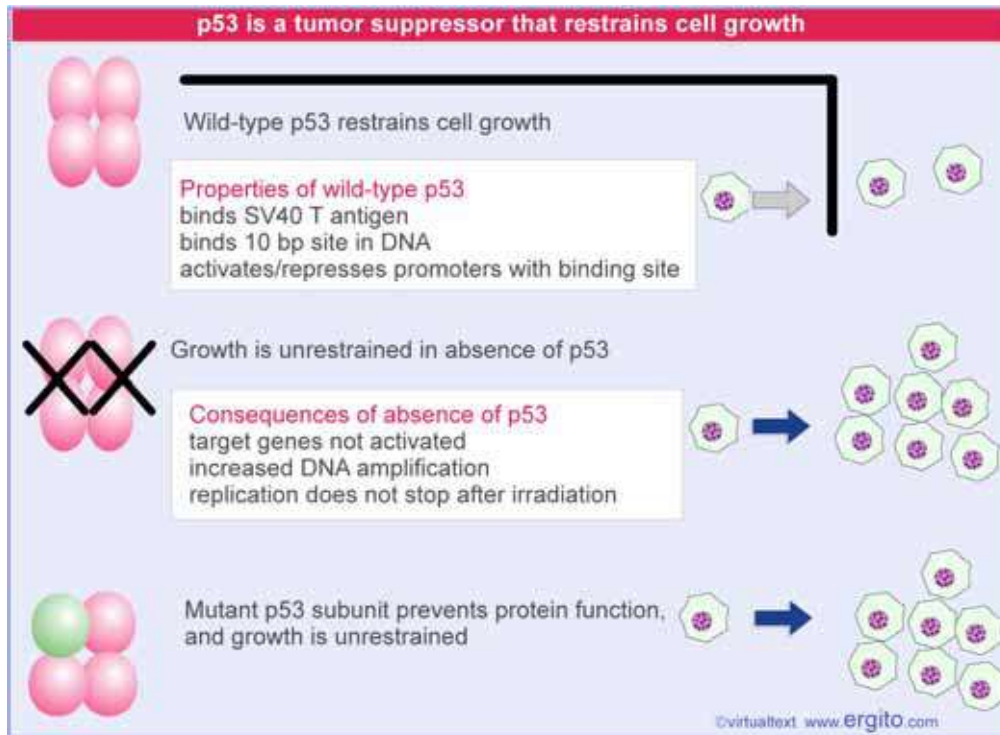

**Figure 30.31** Loss of p53 alleles causes mice to die more rapidly because of the accumulation of tumors.

p53 is a nuclear phosphoprotein. It was originally discovered in SV40-transformed cells, where it is associated with the T antigen coded by the virus (see *Great Experiments 10.4 p53 is a tumor suppressor gene*). T antigen is needed to transform cells, and it was thought it might be acting through its effect on p53. A large increase in the amount of p53 protein is found in many transformed cells or lines derived from tumors. In early experiments, the introduction of cloned p53 was found to immortalize cells. These experiments caused p53 to be classified as an oncogene, with the usual trait of dominant gain-of-function (870; 873).

But all the transforming forms of p53 turned out to be mutant forms of the protein! They fall into the category of **dominant negative** mutants, which function by overwhelming the wild-type protein and preventing it from functioning (see *Molecular Biology Supplement 32.9 Complementation*). The most common form of a dominant negative mutant is one that forms a heteromeric protein containing both mutant and wild-type subunits, in which the wild-type subunits are unable to function. p53 exists as a tetramer. When mutant and wild-type subunits of p53 associate, the tetramer takes up the mutant conformation.

**Figure 30.32** shows that the same phenotype is produced either by the deletion of both alleles or by a missense point mutation in one allele that produces a dominant negative subunit. Both situations are found in human cancers. Mutations in p53 accumulate in many types of human cancer, probably because loss of p53 provides a growth advantage to cells; that is, wild-type p53 restrains growth. The diversity of these cancers suggests that p53 is not involved in a tissue-specific event, but in some general and rather common control of cell proliferation; and the loss of this control may be a secondary event that occurs to assist the growth of many tumors. p53 is defined as a tumor suppressor also by the fact that wild-type p53 can suppress or inhibit the transformation of cells in culture by various oncogenes (for review see 351; 352). Mutant p53 cells also have an increased propensity to amplify DNA, which is likely to reflect p53's role in the characteristic instability of the genome that is found in cancer cells.

**Figure 30.32** Wild-type p53 is required to restrain cell growth. Its activity may be lost by deletion of both wild-type alleles or by a dominant mutation in one allele.

Mutation in p53 is a cause of Li-Fraumeni syndrome, which is a rare form of inherited cancer. Affected individuals display cancers in a variety of tissues. They are heterozygotes that have missense mutations in one allele. These mutations behave as dominant negatives, overwhelming the function of the wild-type allele. This explains the occurrence of the disease as an autosomal dominant (874).

All normal cells have low levels of p53. A paradigm for p53 function is provided by systems in which it becomes activated, the most usual cause being irradiation or other treatments that damage DNA. This results in a large increase in the amount of p53. Two types of event can be triggered by the activation of p53: growth arrest and apoptosis (cell death). The outcome depends in part on which stage of the cell cycle has been reached. **Figure 30.33** shows that in cells early in G<sub>1</sub>, p53 triggers a checkpoint that blocks further progression through the cell cycle. This allows the damaged DNA to be repaired before the cell tries to enter S phase. But if a cell is committed to division, then p53 triggers a program of cell death. The typical results of this apoptosis are the collapse of the cell into a small heteropycnotic mass and the fragmentation of nuclear DNA (see *Molecular Biology 6.29.25 Apoptosis is a property of many or all cells*). The stage of the cell cycle is not the only determinant of the outcome; for example, some cell types are more prone to show an apoptotic response than others.

**Figure 30.33** Damage to DNA activates p53. The outcome depends on the stage of the cell cycle. Early in the cycle, p53 activates a checkpoint that prevents further progress until the damage has been repaired. If it is too late to exercise the checkpoint, p53 triggers apoptosis.

We may rationalize the existence of these two outcomes by supposing that damage to DNA can activate oncogenic pathways, and that the purpose of p53 is to protect the organism against the consequences. If it is possible, a checkpoint is triggered to allow the damage to be repaired, but if this is not possible, the cell is destroyed. We do not know in molecular terms how p53 triggers one pathway or the other, depending on the conditions, but we have an understanding of individual activities of p53 that may be relevant to these pathways (for review see 354).

**ONCOGENES AND CANCER****6.30.21 p53 is a DNA-binding protein**

---

**Key Concepts**

- p53 binds to promoters that contain a 10 bp recognition sequence, and may (usually) activate or (less often) inactive transcription.
  - p53 also binds to single-stranded regions that are generated in damaged DNA, including those at the telomeres.
  - p53 activates the CKI p21, which inhibits the cell cycle in the G1 phase.
  - p53 activates the GADD45 repair protein that responds to radiation damage.
  - The pathway leading to apoptosis has not been identified.
  - p53 is usually present at low levels and has a short half-life.
- 

p53 has a variety of molecular activities. **Figure 30.34** summarizes the responsibilities of individual domains of the protein for these activities:

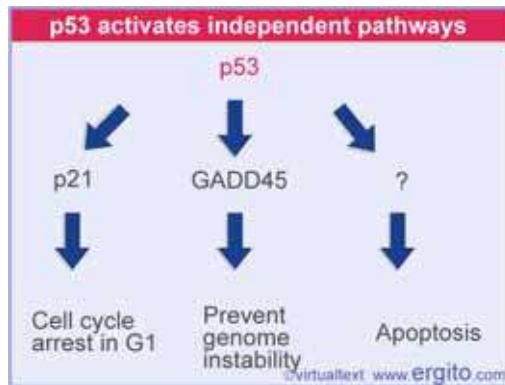

**Figure 30.34** Different domains are responsible for each of the activities of p53.

- p53 is a DNA-binding protein that recognizes an interrupted palindromic 10 bp motif. The ability to bind to its specific target sequences is conferred by the central domain.
- p53 activates transcription at promoters that contain multiple copies of this motif. The immediate N-terminal region provides the transactivator domain. p53 may repress other genes; the mechanism is unknown.
- p53 also has the ability to bind to damaged DNA. The C-terminal domain recognizes single-stranded regions in DNA.
- p53 is a tetramer (oligomerization is a prerequisite for mutants to behave in a dominant negative manner). Oligomerization requires the C-terminal region.
- A (putative) signaling domain contains copies of the sequence PXXP, which forms a binding site for SH3 domains.

Mutations in p53 have various effects on its properties, including increasing its half-life from 20 minutes to several hours, causing a change in conformation that can be detected with an antibody, changing its location from the nucleus to the cytoplasm, preventing binding to SV40 T antigen, and preventing DNA-binding. As shown in **Figure 30.34**, the majority of these mutations map in the central DNA-binding domain, suggesting that this is an important activity.

p53 activates various pathways through its role as a transcription factor. The pathways can be divided into the three groups summarized in **Figure 30.35**. The major pathway leading to inhibition of the cell cycle at G1 is mediated via activation of p21, which is a CKI (cell cycle inhibitor) that is involved with preventing cells from proceeding through G1 (see **Figure 29.30** and **Figure 30.30**). Activation of GADD45 identifies the pathway that is involved with maintaining genome stability. GADD45 is a repair protein that is activated also by other pathways that respond to irradiation damage.

**Figure 30.35** p53 activates several independent pathways. Activation of cell cycle arrest together with inhibition of genome instability is an alternative to apoptosis.

When it functions as a transcription factor, p53 uses the central domain to bind to its target sequence. The N-terminal transactivation domain interacts directly with TBP (the TATA box-binding protein). This region of p53 is also a target for several other proteins. An interaction with E1B 55 kD enables adenovirus to block p53 action, which is an essential part of its transforming capacity. Other regions of p53 can also be targets for inhibition; the SV40 T antigen binds to the specific DNA-binding region, thereby preventing the recognition of target genes (876).

The stability of p53 is an important parameter. It usually has a short half-life. The response to DNA damage stabilizes the protein and activates p53's transactivation activity.

To function as a transcription factor, p53 requires the coactivators p300/CBP (which are also used by many other transcription factors). The coactivator binds to the transactivation (N-terminal) domain of p53. The interaction between p53 and p300 is also necessary in order for p53 to bind the protein Mdm2, which inhibits its activity (see *Molecular Biology 6.30.22 p53 is controlled by other tumor suppressors and oncogenes*).

The C-terminal domain of p53 binds without sequence-specificity to short (<40 base) single-stranded regions of DNA and to mismatches generated by very short (1-3 base) deletions and insertions of bases. Such targets are generated by DNA damage. One important example of a single-stranded region that activates p53 is the overhanging end that is generated at the telomere of a senescent cell (see *Molecular Biology 6.30.25 Immortalization depends on loss of p53*). The consequence of this interaction is to activate the sequence-specific binding activity of the central domain,

so that p53 stimulates transcription of its target genes. The nature of this connection is not clear, but may be a two-stage process. When p53 binds through its C-terminal domain to a damaged site on DNA, a change occurs in its properties; it then dissociates from the damaged site and binds to a target gene, which it activates.

The ability of p53 to trigger apoptosis is less well understood. It probably depends on the transactivation of a different set of target genes from those involved in activating the G1 checkpoint. The two activities can be separated by the response to adenovirus E1B 19 kD protein, which blocks the apoptotic activity of p53, but does not block its activity to activate target genes. The independence of the effects of p53 on growth arrest and apoptosis is emphasized by the fact that the E1B 55 kD protein blocks transactivation capacity but does not interfere with apoptosis.

p53 can activate apoptosis pathways in two ways. One is to cause the production of proteins that act on the mitochondrion to trigger its apoptotic functions (see *Molecular Biology 6.29.28 Apoptosis involves changes at the mitochondrial envelope*). The other is to produce or activate the cell surface receptors that trigger apoptosis (see *Molecular Biology 6.29.26 The Fas receptor is a major trigger for apoptosis*).

The importance of the connection between tumorigenesis and loss of apoptosis is also shown by the properties of the *bcl2* oncogene. *bcl2* was originally identified as a target that is activated by translocations in certain tumors. It turns out to have the property of inhibiting most pathways for apoptosis (see *Molecular Biology 6.29.28 Apoptosis involves changes at the mitochondrial envelope*). This suggests that apoptosis plays an important role in inhibiting tumorigenesis, probably because it eliminates potentially tumorigenic cells. When apoptosis is prevented because *bcl2* is activated, these cells survive instead of dying (868).

Cells with defective p53 function have a variety of phenotypes; this pleiotropy makes it difficult to determine which (if any) of these effects is directly connected to the tumor suppressor function. Most of our knowledge about p53 action comes from situations in which it has been activated. We assume that the pathways it triggers – growth arrest or apoptosis – are connected to its ability to suppress tumors. Certainly it is clear that the failure of p53 to respond to DNA damage is likely to increase susceptibility to mutational changes that are oncogenic. However, we do not know whether this is the sole role played by p53. p53<sup>-</sup> mice develop normally, implying that p53's role is not essential for development.

The general definition of their properties shows that both RB and p53 are tumor suppressors that usually control cell proliferation; their absence removes this control, and contributes to tumor formation.

## ONCOGENES AND CANCER

### 6.30.22 p53 is controlled by other tumor suppressors and oncogenes

#### Key Concepts

- Most human cancer cells either have mutations that inactivate p53 directly or have mutations in other loci that lead to loss of p53.
- p53 is destabilized by Mdm2, which targets it for degradation and also directly inhibits its transactivation activity.
- The INK4a-ARF locus codes for p16<sup>INK4a</sup>, which controls RB, and for p19<sup>ARF</sup>, which controls p53 via inactivating Mdm2.
- Loss of INK4a-ARF is a common cause of human cancer.

p53 does not function correctly in most human tumors, but the cause of the problem lies with the gene itself in only about half of the cases. **Figure 30.36** summarizes the causes of p53 deficiency (for review see 1401):

p53 can be inactivated in several ways		
Target	Inactivation method	Effect on p53
p53	Mutation of DNA-binding domain	cannot bind to DNA and transactivate targets
	Deletion of C-terminal domain	cannot form the active tetrameric form
	Papova virus infection	T antigens inhibit p53 function or trigger degradation
Mdm2	Amplification of Mdm2 gene	Mdm2 stimulates degradation of p53
p19 <sup>ARF</sup>	Deletion of p19 <sup>ARF</sup>	failure to inhibit Mdm2 leads to degradation of p53

**Figure 30.36** p53 is inactivated in human cancers as the result of mutations directly affecting its function or in other genes that affect the level of protein.

- The mutations in p53 itself most often lie in the DNA-binding region, and prevent the protein from binding to promoters to activate the protective response. In some cases, the mutations lie in the C-terminal region that is responsible for forming tetramers, so that active proteins are not produced.
- The major pathway controlling p53 is mediated through the protein Mdm2, which inactivates p53, so the Mdm2 locus behaves as an oncogene. Amplification of the Mdm2 gene causes an increase in expression of the protein,

which reduces p53 function.

- Mdm2 is itself inactivated by the protein p19<sup>ARF</sup>, so deletions of the p19<sup>ARF</sup> gene lead to increase in Mdm2 and thus to decrease in p53.

Because p53 inhibits growth or triggers apoptosis when it is activated, it is obviously crucial for the cell to restrain the activity unless it is needed. The circuitry that controls p53's activity is illustrated in the upper part of **Figure 30.37**. Proteins that activate p53 behave as tumor suppressors; proteins that inactivate p53 behave as oncogenes (875).

**Figure 30.37** p53 activity is antagonized by Mdm2, which is neutralized by p19<sup>ARF</sup>.

A major feature in controlling p53 activity is its interaction with Mdm2 (which was originally identified as the product of an oncogene). Mdm2 inhibits p53 activity in two ways:

- Mdm2 affects p53's stability by acting as an E3 ubiquitin ligase that causes p53 to be targeted by the degradation apparatus.
- Mdm2 also acts directly at the N-terminus to inhibit the transactivation activity

of p53.

In the reverse direction, p53 induces transcription of Mdm2. The consequence of this circuit is that Mdm2 limits p53 activity; and the activation of p53 increases the amount of Mdm2, so the interaction between p53 and Mdm2 forms a negative feedback loop in which the two components limit each other's activities.

INK4A-ARF is an important locus that controls both p53 and RB (for review see 3426). The transcript of the INK4A-ARF gene is alternatively spliced to give two mRNAs that code for proteins with no sequence relationship. p16<sup>INK4a</sup> is upstream of RB. The second protein is called p19<sup>ARF</sup> in mouse and p14<sup>ARF</sup> in man. We will use p19<sup>ARF</sup> to describe it irrespective of source. As we have just seen, p19<sup>ARF</sup> is upstream of p53. Deletions of the locus are common in human cancers (almost as common as mutations in p53), and have a highly significant effect, because they eliminate both p16<sup>INK4a</sup> and p19<sup>ARF</sup> and therefore lead to loss of both the RB and p53 tumor suppressor pathways.

p16<sup>INK4a</sup> inhibits the cdk4/6 kinase (see **Figure 29.30**). So it prevents the kinase from phosphorylating RB. In the absence of this phosphorylation, progress through the cell cycle (and therefore growth) is inhibited. p16<sup>INK4a</sup> is often inhibited by point mutations in human tumors.

p19<sup>ARF</sup> antagonizes Mdm2, as shown in the lower part of **Figure 30.37**. p19<sup>ARF</sup> binds to Mdm2 and directly prevents it from ubiquitinating p53. This stabilizes p53 and allows it to accumulate. In effect, therefore, p19<sup>ARF</sup> functions as a tumor suppressor by inhibiting the inhibitor of the p53 tumor suppressor. Loss of p19<sup>ARF</sup> or loss of p53 have similar effects on cell growth (and tumors usually lose one or the other but not both), suggesting that they function in the same pathway, that is, p19<sup>ARF</sup> in effect functions exclusively through p53. The cellular oncogene c-myc, and the adenoviral oncogene E1, both act via p19<sup>ARF</sup> to activate p53-dependent pathways.

**ONCOGENES AND CANCER****6.30.23 p53 is activated by modifications of amino acids****Key Concepts**

- p53 is modified by (mostly) phosphorylation or by acetylation in response to treatments that damage DNA.
- Different sensor pathways act through kinases that modify different target sites on p53.

p53 responds to environmental signals that affect cell growth, and many of these signals act by causing specific sites on p53 to be modified. The most common form of modification is the phosphorylation of serine, but acetylation of lysine also occurs. Different pathways lead to the modification of different amino acid residues in p53, as summarized in **Figure 30.38**. There is often overlap between the various residues activated by each pathway. Three principal pathways are identified by the agents that act on p53:

**Figure 30.38** Each pathway that activates p53 causes modification of a particular set of residues.

- Ionizing radiation induces DNA breaks that activate the kinase ATM (named for the disease ataxia telangiectasia in which its gene is mutated). ATM phosphorylates S<sup>15</sup>. DNA breaks also activate a DNA-dependent kinase that acts on other sites in the N-terminal region. (Through unknown pathways, ionizing radiation also causes phosphorylation of S<sup>33</sup>, dephosphorylation of S<sup>376</sup>, and acetylation of L<sup>382</sup>.)
- UV radiation and other types of stress activate the kinases ATR (ataxia telangiectasia related) and casein kinase II, which phosphorylate S<sup>15</sup> and S<sup>33</sup>, and also cause phosphorylation of S<sup>392</sup>.

- Some aberrant growth signals, such as those produced by the oncogenes Ras or Myc, may activate p19<sup>ARF</sup>. This inactivates Mdm2 and thus activates p53.

The target sites for these various pathways are located in the terminal regulatory domains of the protein. The modifications may affect stability of the protein, oligomerization, DNA-binding, and binding to other proteins. So p53 acts as a sensor that integrates information from many pathways that affect the cell's ability to divide. *The important point is that each pathway leads to modification of specific residues in p53 that activate its response.*

Phosphorylation can change the properties of a protein by altering the structure in the immediate vicinity, creating or abolishing sites that interact with other proteins. At some of the sites in p53, the phosphorylation has a more widespread effect, and changes the conformation of the polypeptide backbone of the protein. The usual conformation of a protein chain is a series of amino acids arranged in *trans* conformation about the peptide bonds that connect them. This means that the adjacent amino acids lie on opposite sides of the peptide bond. However, as shown in **Figure 30.39**, the ring structure of proline allows a rearrangement in which it lies in *cis* configuration relative to the preceding amino acid. This has a major effect on protein conformation. The reaction is catalyzed by a class of proteins called peptidyl-prolyl-isomerases.

**Figure 30.39** Amino acids usually lie in *trans* on either side of the peptide bond connecting them in a protein chain. The ring structure of proline allows isomerization around the bond connecting it to the preceding amino acid, generating the *cis* configuration in which both amino acids lie on the same side of the peptide bond.

Some of the target sites for phosphorylation in p53 are serine or threonine residues followed by a proline. Phosphorylation changes the energetics to favor the *trans-cis* isomerization. The reaction is assisted by a particular peptidyl-prolyl-isomerase, Pin1, which binds to the dipeptide sequence only when the first amino acid is phosphorylated. The importance of the reaction is demonstrated by the fact that mutations in Pin1 impair the ability of p53 to respond to damage in DNA (3213; 3214). Although Pin1 is essentially part of the mechanism by which p53 is activated, in formal terms it behaves like a tumor suppressor.

There are two aspects to the activation of p53. The amount of p53 protein in the cell is determined principally by its degradation, which is a reflection of the activity of Mdm2. Stabilization of the protein is a prerequisite for the response, but is not sufficient. Conformational changes must be triggered by one or more of the modification events that respond to the various sensor systems.

## ONCOGENES AND CANCER

### 6.30.24 Telomere shortening causes cell senescence

---

#### Key Terms

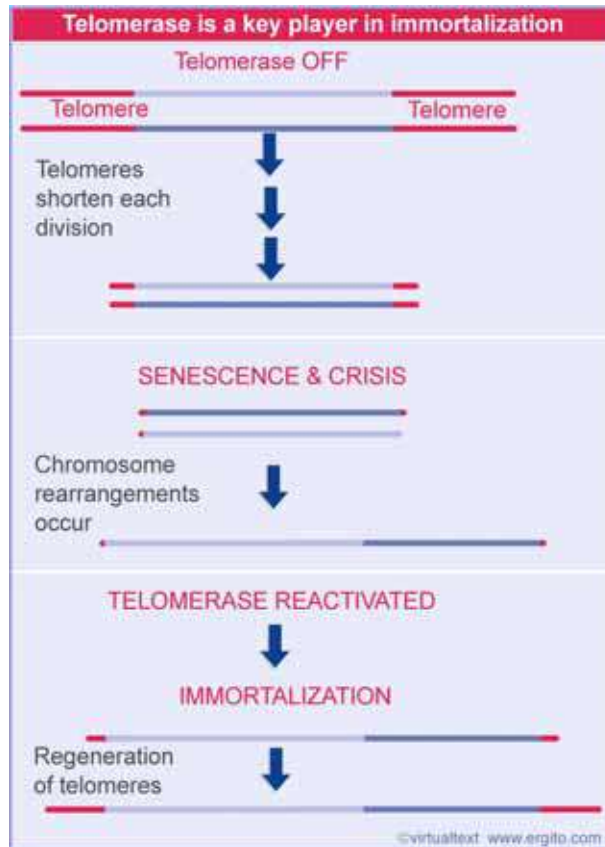

**Senescent** cells show visible changes in the appearance of a culture as the result of limitations posed by telomere shortening on the number of chromosomal replications that can occur.

#### Key Concepts

- Somatic cells usually lack telomerase activity, which means that telomeres shorten with each cell division.
  - Cultured cells may go into crisis as the result of reaching zero telomere length.
  - Reactivation of telomerase enables cells to survive crisis and to become immortal.
- 

A key event in the limited divisions of growth in cell culture is the shortening of telomeres. A special ribonucleoprotein enzyme, called telomerase, is responsible for extending telomeres (see *Molecular Biology 5.19.18 Telomeres are synthesized by a ribonucleoprotein enzyme*). The function of telomerase is to compensate for the shortening of telomeres that occurs at each replication cycle. Telomerase is turned off in many somatic cells, typically when differentiation occurs.

Continued division in cells that lack telomerase activity (for example, when primary cells are placed into culture) will cause the telomeres to shorten in each generation. The cells become unable to propagate properly when the telomeres become too short to ensure stability at the ends of the chromosomes (see *Molecular Biology 5.19.19 Telomeres are essential for survival*). The consequences are visible as changes in the appearance of the culture, and the cells are said to be **senescent**. Crisis occurs when the cells cannot divide any longer, and the culture dies out. **Figure 30.40** summarizes the events involved in approaching crisis and passing through it.

**Figure 30.40** In the absence of telomerase, telomeres shorten each cell generation until crisis occurs. Unstable ends cause chromosome rearrangements in senescent cells. The most common means of immortalization is the reactivation of telomerase.

The rare cells that survive crisis pass through a stage at which the ends of their chromosomes are unstable. These ends interact with one another or with other chromosomal regions, and this is the probable cause of the frequent occurrence of chromosomal abnormalities in cultured cells. The mutations that are caused by these abnormalities can contribute to the tumorigenic state.

To continue to divide after passing through crisis, a cell must regain the capacity to replicate its telomeres. This suggests that a critical parameter for immortalization might be the reactivation of telomerase. Telomerase activity can be restored by transfecting the gene for the catalytic subunit into target cells, and this allows them to be perpetuated in culture without passing through crisis (see *Great Experiments 9.2 Immortalizing human cells with telomerase*; 1380; 1390). We might view the finite replicative capacity of primary human cells, in general, or their inability to continue propagation once telomere lengths have become too short, in particular, as a tumor suppression mechanism that in effect prevents cells from undertaking the indefinite replication that is needed to make a tumor (878).

Immortalization is required for cells to be perpetuated indefinitely in tissue culture, and we have to ask how the relevant events relate to the formation of a tumor *in vivo*. The behavior of telomerase shows a parallel between the immortalization of a cell in

culture and the generation of a tumor *in vivo*. The limiting step in production of telomerase is the transcription of the catalytic subunit, which is repressed in differentiated somatic cells and restored in tumor cells. This resembles the reactivation of telomerase activity in cultured cells that have emerged from crisis.

Can we test the role of telomerase in intact animals? Mice in which the gene coding for the telomerase RNA has been inactivated can survive for >6 generations. Mouse telomeres are exceptionally long, and range from 10-60 kb. In the absence of telomerase, telomeres shorten at 50-100 bp per cell division. There are ~60 divisions in sperm cell production, and ~25 divisions in oocyte production, which fits with the observed rate of shortening of ~4.8 kb per male mouse generation. This gives an expectation that after about 7 generations, a telomerase-negative mouse will have run down its telomeres to around zero length.

By the 6th generation, chromosomal abnormalities become more frequent, and the mice become infertile (due to the inability to produce sperm). The effects of lack of telomerase are first seen in tissues consisting of highly proliferative cells (as might be expected). All of these observations demonstrate the importance of telomerase for continued cell division. However, cells from the telomerase-negative mice can pass through crisis and can be transformed to give tumorigenic cells, so the presence of telomerase is not essential, or at least is not the only means, of supporting an immortal state (although reactivation of telomerase is by far the most common mechanism) (see *Molecular Biology 5.19.19 Telomeres are essential for survival*) (879).

Telomerase-negative mice can develop tumors, but do so at a rate lower than wild-type mice (2852). The effect of telomere loss on formation of a cancer cell is therefore confined to its role in provoking a genetic instability that stimulates tumor initiation. After that, it is in fact inhibitory to cancer formation.

There is a curious inconsistency between the results obtained with cultured cells and the survival of telomerase-negative mice. Crisis of mouse cells occurs typically after 10-20 divisions in culture, but we would not expect the telomeres to have reached a limiting length at this point. Mice of the first telomerase-negative generation have passed a greater number of cell divisions without telomerase, and without suffering any ill effects. Mice of the third telomerase-negative generation are to all intents and purposes normal, although their cells have gone through more divisions than would have triggered crisis in culture.

Lack of telomerase is clearly associated with inability to continue growth, and reactivation of telomerase is one means by which cells can behave as immortal. It is not clear whether telomerase is the only relevant factor in driving cells into crisis and to what extent other mechanisms might be able to compensate for lack of telomerase. We do not know what pathway is responsible for controlling telomerase production *in vivo*, and how it is connected to pathways that control cell growth.

**ONCOGENES AND CANCER****6.30.25 Immortalization depends on loss of p53****Key Concepts**

- Loss of p53 is the crucial step in immortalization.

When cells enter senescence as the result of telomere shortening, p53 is activated, leading to growth arrest or apoptosis. **Figure 30.41** shows that the trigger that activates p53 is the loss of the telomere-binding protein TRF2 from the chromosome ends. In effect, TRF2 protects the end of the DNA, but when it is lost, the free 3' overhanging end activates p53 (1998; 3669).

**Figure 30.41** TRF2 protects telomeres, but when it is lost, the exposed ends can bind and activate p53.

The loss of p53 is the crucial event that allows the cells to survive and divide. A variety of events can be associated with immortalization, but they converge upon causing either the loss or inactivation of p53 protein. Remember that p53 was discovered as the protein of host cells that binds the T antigen (the transforming protein) of polyomaviruses. A major part of the activity of T antigen is its ability to inactivate p53. The T antigens of different viruses work in different ways, but the consequences of the interaction are especially clear in the case of HPV E6 (the equivalent of T antigen), which targets p53 for degradation. In effect, HPV converts a target cell into a p53<sup>-</sup> state.

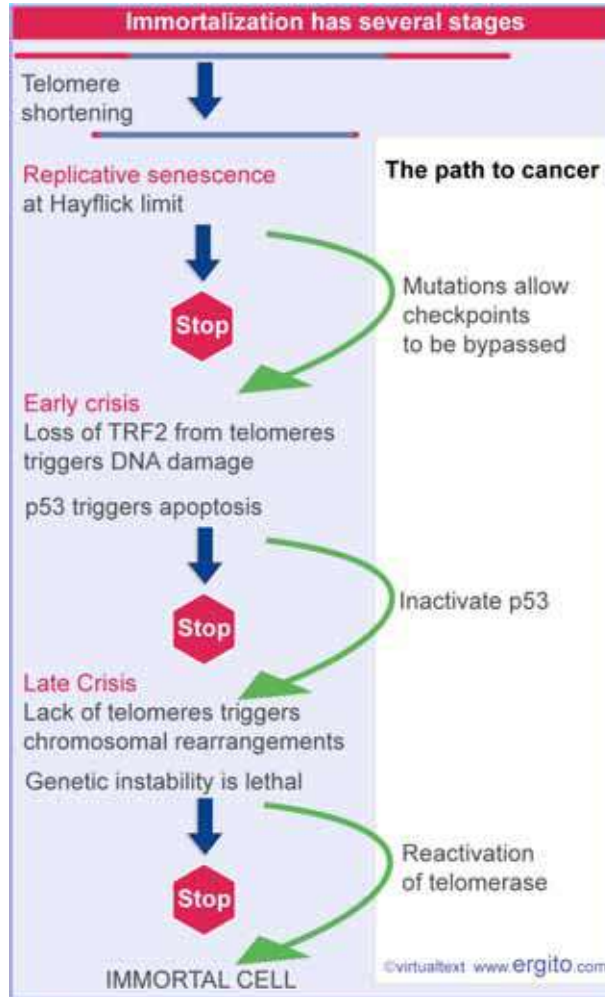

p53 provides an important function in immortalization, but may not be sufficient by itself. Established cell lines have usually lost p53 function, which suggests that the role of p53 is connected with the acquisition of ability to support prolonged growth. However, loss of the known functions of p53 is not enough by itself to explain

immortalization, since, for example, a p53<sup>-</sup> mouse is viable, and therefore is able to undergo the usual pattern of cell cycle arrest and differentiation. Primary cells from a p53<sup>-</sup> mouse can pass into the established state more readily than cells that have p53 function, which suggests that loss of p53 activity facilitates or is required for immortalization (877).

An interesting convergence is seen in the properties of the tumor antigens from different DNA tumor viruses, . The antigens always bind to both the cellular tumor suppressor products RB and p53. The two cellular proteins are recognized independently. Either different T antigens of the virus bind separately to RB and to p53, or different domains of the same antigen do so. So adenovirus E1A binds RB, while E1B binds p53; HPV E7 binds RB, while E6 binds p53. SV40 T antigen can bind both RB and p53. The loss of p53 (and/or RB) is a major step in the transforming action of DNA tumor viruses, and explains some significant part of the action of the T antigens. The critical events are inhibition of p53's ability to activate transcription, and loss of RB's ability to bind substrates such as E2F. Loss of the tumor suppressors (especially p53) is the major route in the immortalization pathway.

Inability to trigger either growth arrest or apoptosis could lead to continued growth. We do not know whether only one or both of these activities are required for immortalization *in vitro*. We know that more than the growth arrest pathway is needed for p53's contribution to tumorigenesis, because a p21<sup>-</sup> mouse shows deficiencies in the G1 checkpoint (as would be expected) but does not develop tumors. The contrast with the increased susceptibility of a p53<sup>-</sup> mouse to tumors shows that other functions of p53 are involved besides its control of p21.

We are now in a position to put together the various events involved in immortalization (for review see 2853). **Figure 30.42** summarizes the order in which they occur. Checkpoints normally stop a cell from dividing when its telomeres become too short. Cells then enter replicative senescence and stop growing. If they manage to bypass the checkpoints to enter early crisis, the loss of TRF2 from the telomeres activates p53, which causes growth arrest and/or apoptosis. In the absence of p53 activity, they pass into late crisis, where the dysfunction of the telomeres causes genetic instability as seen in large scale chromosomal rearrangements. To survive this stage, they must activate telomerase or find an alternative means of maintaining the telomeres. A cell that survives through all of these stages will be immortal, but almost certainly will have an altered genetic constitution.

**Figure 30.42** Several changes are required to allow a cell to pass the replicative limit and to become immortalized, including bypassing the checkpoints that respond to short telomeres, losing or preventing the ability of p53 to trigger apoptosis, and reactivating telomerase or finding other means to stabilize telomeres.

**ONCOGENES AND CANCER****6.30.26 Different oncogenes are associated with immortalization and transformation**

---

**Key Terms**

**Cooperativity** in protein binding describes an effect in which binding of the first protein enhances binding of a second protein (or another copy of the same protein).

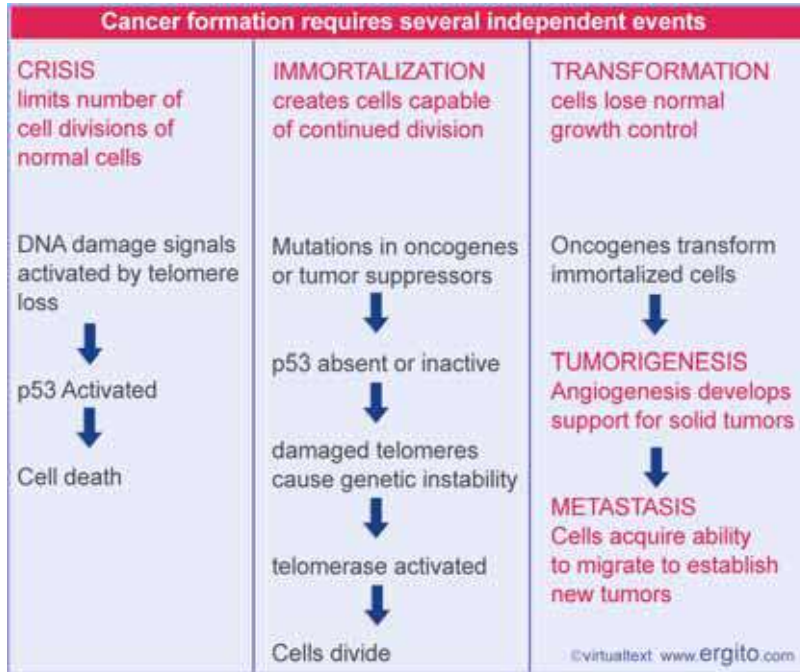

**Key Concepts**

- A tumor cell has independently acquired changes necessary to immortalize it and to transform it.
- Established cell lines grown in culture usually have been immortalized and need to acquire only transforming properties.
- Primary cells require the actions of different oncogenes to be immortalized and to be transformed.

---

Most tumors arise as the result of multiple events. Some of these events involve the activation of oncogenes, while others take the form of inactivation of tumor suppressors. The requirement for multiple events reflects the fact that normal cells have multiple mechanisms to regulate their growth and differentiation, and several separate changes may be required to bypass these controls. Indeed, the existence of single genes in which mutations were tumorigenic would no doubt be deleterious to the organism, and has been selected against. Nonetheless, oncogenes and tumor suppressors define genes in which mutations create a predisposition to tumors, that is, they represent one of the necessary events. It is an open question as to whether the oncogenes and tumor suppressor genes identified in available assays are together sufficient to account entirely for the occurrence of cancers, but it is clear that their properties explain at least many of the relevant events.

**Figure 30.43** gives an overview of the stages of tumor formation. There are two discrete stages, which may loosely be viewed as being concerned with immortalization or with transformation (for review see 346; 350).

**Figure 30.43** Crisis is induced by attempts to divide in the absence of telomerase. Immortalization occurs when p53 activity is lost, as the result of mutation in p53 or in a pathway that acts on it. Transformation requires oncogenes to induce further changes in the growth properties of the cells. For cells that develop solid tumors, angiogenic development is required for provision of nutrients. Metastasis is the result of further changes that allow a cell to migrate to form a colony in a new location.

The immortalization step is to bypass crisis (or its equivalent in the *in vivo* situation). Crisis is provoked when cells continue to divide in the absence of telomerase (see *Molecular Biology 6.30.24 Telomere shortening causes cell senescence*). When the telomeres become too short, damage to DNA is caused by attempts at replication, and this triggers the activation of p53. The role of p53 is to cause cell death. If p53 is absent, a cell may survive, although at the expense of a genetic catastrophe in which telomere malfunction leads to chromosome fusions and other rearrangements.

Immortalized cells can pass through an unlimited number of cell divisions, but they do not have other tumorigenic properties, such as independence of factors required for growth. The second step, transformation, converts immortalized cells into tumorigenic cells. Whether further changes are involved in creating a cancerous state depends on the nature of the tumor cell. A leukemia cell can multiply freely in the blood. However, a cell type that forms a solid tumor needs to develop a blood supply for the tumor (requiring angiogenic development), and may later pass to the stage of metastasis, when cells are detached from the tumor and migrate to form new tumors at other locations.

The minimum requirement to enter the tumorigenic state is therefore the occurrence of successive, independent events that involve different tumor suppressors and/or oncogenes. The need for multiple functions of different types is sometimes described as the requirement for **cooperativity**.

---

The involvement of multiple functions fits with the pattern established by some DNA tumor viruses, in which (at least) two types of functions are needed to transform the usual target cells:

- Adenovirus carries the *E1A* region, which allows primary cells to grow indefinitely in culture, and the *E1B* region, which causes the morphological changes characteristic of the transformed state.
- Polyoma produces three T antigens; large T elicits indefinite growth, middle T is responsible for morphological transformation, and small T is without known function. Large T and middle T together can transform primary cells.
- Consistent with the classification of oncogenic functions, adenovirus E1A together with polyoma middle T can transform primary cells. This suggests that one function of each type is needed.

In the same way, expression of two or more oncogenes in the cellular transfection assay is usually needed to convert a primary cell (one taken directly from the organism) into a tumor cell.

Several cellular oncogenes have been identified by transforming ability in the 3T3 transfection assay; 10-20% of spontaneous human tumors have DNA with detectable transforming activity in this assay. Of course, 3T3 cells have been adapted to indefinite growth in culture over many years, and have passed through some of the changes characteristic of tumor cells (see *Great Experiments 9.1 The story of 3T3 cells: A voyage of discovery without an itinerary*). The exact nature of these changes is not clear, but generally they can be classified as involving functions concerned with immortalization. Oncogenic activity in this assay therefore depends on the ability to induce further changes in an established cell line.

The principal products of 3T3 transfection assays are mutated *c-ras* genes. They do not have the ability to transform primary cells *in vitro*, and this supports the implication that their functions are concerned with the act of transforming cells that have previously been immortalized. *ras* oncogenes clearly provide one major pathway for transforming immortalized cells; we do not know how many other transforming pathways may exist that are independent of *ras*.

Although *ras* oncogenes alone cannot transform primary fibroblasts, dual transfection with *ras* and another oncogene can do so. The ability to transform primary cells in conjunction with *ras* provides a general assay for oncogenes that have an immortalization-like function. This group includes several retroviral oncogenes, *v-myc*, *v-jun*, and *v-fos*. It also includes adenovirus E1A and polyoma large T. Mutant p53 genes have the same effect. In fact, the action of the immortalizing oncogenes is most likely to cause inactivation or loss of p53. However, note that the distinction between immortalizing and transforming proteins is not crystal clear. For example, although E1A is classified as having an immortalizing function, it has (some) of the functions usually attributed to transforming proteins, and loss of p53 confers some properties that are usually considered transforming.

One way to investigate the oncogenic potential of individual oncogenes

independently of the constraints that usually are involved in their expression is to create transgenic animals in which the oncogene is placed under control of a tissue-specific promoter. A general pattern is that increased proliferation often occurs in the tissue in which the oncogene is expressed. Oncogenes whose expression have this effect with a variety of tissues include SV40 T antigen, *v-ras*, and *c-myc* (588).

Increased proliferation (hyperplasia) is often damaging and sometimes fatal to the animal (usually because the proportion of one cell type is increased at the expense of another). However, the expression of a single oncogene does not usually cause malignant transformation (neoplasia), with the production of tumors that kill the animal. Tumors resulting from the introduction of an oncogene (for example, in transgenic mice) are probably due to the occurrence of a second event.

The need for two types of event in malignancy is indicated by the difference between transgenic mice that carry either the *v-ras* or activated *c-myc* oncogene, and mice that carry both oncogenes. Mice carrying either oncogene develop malignancies at rates of 10% for *c-myc* and 40% for *v-ras*; mice carrying both oncogenes develop 100% malignancies over the same period. These results with transgenic mice are even more striking than the comparable results on cooperation between oncogenes in cultured cells (866; 867).

In some systems, immortalization may be connected with an inability of the cells to differentiate. Growth and differentiation are often mutually exclusive, because a cell must stop dividing in order to differentiate. An oncoprotein that blocks differentiation may allow a cell to continue proliferating (in a sense resembling the immortalization of cultured cells); continued proliferation in turn may provide an opportunity for other oncogenic mutations to occur. This may explain the occurrence among the oncoproteins of products that usually regulate differentiation.

A connection between differentiation and tumorigenesis is shown by avian erythroblastosis virus (AEV). The AEV-H strain carries only *v-erbB*, but the AEV-E54 strain carries two oncogenes, *v-erbB* and *v-erbA*. The major transforming activity of AEV is associated with *v-erbB*, a truncated form of the EGF receptor, which is equivalent to the single oncogene carried by other tumor retroviruses: it can transform erythroblasts and fibroblasts. The other gene, *v-erbA*, cannot transform target cells alone, but it increases the transforming efficiency of *v-erbB*. Expression of *v-erbA* itself has two phenotypic effects upon target cells: it prevents the spontaneous differentiation (into erythrocytes) of erythroblasts that have been transformed by *v-erbB*; and it expands the range of conditions under which transformed erythroblasts can propagate. *v-erbA* may therefore contribute to tumorigenicity by a combination of inhibiting differentiation and stimulating proliferation. In fact, *v-erbA* has a similar effect in extending the efficacy of transformation by other oncogenes that induce sarcomas, notably *v-src*, *v-fps*, and *v-ras*.

Correlations between the activation of oncogenes and the successful growth of tumors are strong in some cases, but by and large the nature of the initiating event remains open. It seems clear that oncogene activity assists tumor growth, but activation could occur (and be selected for) after the initiation event and during early growth of the tumor. We hope that the functions of *c-onc* genes will provide insights into the regulation of cell growth in normal as well as aberrant cells, so that it will become possible to define the events needed to initiate and establish tumors.

## ONCOGENES AND CANCER

### 6.30.27 p53 may affect ageing

---

#### Key Concepts

- Shortening of telomeres below a critical length is associated with reduced longevity.
  - Increase of p53 above wild-type levels can decrease tumor formation, but also decreases longevity.
- 

We have very little idea what is responsible for ageing of an animal. The general drift of evolutionary theories of ageing is that natural selection operates only via reproduction, and therefore there is little advantage to the survival of the organism past the stage when it is reproductively active. In other words, there is no selection for longevity beyond the reproductive state. .

We do not know how ageing of the organism relates to changes in individual cells, but one possibility is that ageing results from the accumulation of damage at the cellular level. Within this model, one contribution could be inappropriate expression of genes resulting from failure of regulation.

It is an open question whether aging of the organism is connected with the senescence of individual cells. Cessation of telomerase activity in adult lineages causes telomeres to shorten as cells divide. When telomere lengths reach zero, cells enter the senescent state. Shortened telomeres can reduce lifespan. **Figure 30.44** shows that mice from the fourth or fifth telomerase-negative generations have a slightly reduced lifespan, and mice from the sixth generation have a much reduced lifespan (2248). Whereas normal mice have a 50% survival rate at ~25 months, the figure for the sixth generation mice is ~17 months. Increased cancer incidence accounts for only half of the accelerated deaths. The other mice die from unknown causes (this is typical of ageing), and they prematurely show several of the characteristics of ageing (such as reduced wound healing).

**Figure 30.44** Telomerase-negative mice of the sixth generation (G6) have sharply reduced longevity, and mice of the fourth to fifth generations (G4-5) have slightly reduced longevity.

We know that loss of p53 is one of the mechanisms allowing cultured cells to pass through the crisis provoked by loss of telomeres (see *Molecular Biology 6.30.24 Telomere shortening causes cell senescence*). What role might p53 loss play in telomerase-negative mice? A major role is seen in the pattern of inheritance. An increased proportion of the progeny are p53<sup>-</sup>. This is because loss of p53 reduces the apoptosis (death) of germ line cells that is caused by loss of telomerase (2249).

Direct attempts to see whether p53 might have any effect on ageing have been unsuccessful because p53<sup>-</sup> mice die early as the result of accumulating tumors, and mice that over-express p53 cannot be made, probably because of deleterious effects of excess p53 during embryonic development. However, striking results have been obtained from the serendipitous production of a mouse that has a mutant form of p53 (2250). The mutant gene, called the *m* allele, has lost its first 6 exons, and makes a truncated protein. Heterozygous p53<sup>+/*m*</sup> mice have a reduced frequency of tumor formation. Comparison with wild-type and hemizygous p53 mice shows:

p53 <sup>+/-</sup> (one active allele): >80% tumors  
 p53 <sup>+/+</sup> (two active alleles): > 45% tumors  
 p53 <sup>+/*m*</sup>: 6% tumors.

Mice with two active alleles form tumors at about half the frequency of mice with only one active allele, which corresponds to the relative rate at which one allele is likely to be spontaneously inactivated compared to two alleles (see **Figure 30.31**). The much reduced rate of tumor formation in the p53<sup>+/*m*</sup> mice suggests that the *m* allele has the unexpected effect of increasing p53 activity. This is confirmed by directly measuring some of the known responses to p53 in cells from the p53<sup>+/*m*</sup> mice.

We might expect the reduction in tumor formation in p53<sup>+/*m*</sup> mice to be associated with an increase in longevity, but exactly the reverse is found when they are compared with wild-type mice. Although the p53<sup>+/*m*</sup> mice have only 6% tumors and the wild-type mice develop 45% tumors, half of the p53<sup>+/*m*</sup> mice have died by 22 months, whereas the wild-type mice survive on average to 27 months. (Mice that are p53<sup>+/-</sup> or p53<sup>-/-</sup> die more quickly because of the high accumulation of tumors.) The effect seems to result from the interaction of the *m* mutant protein with the wild-type

protein in the heterozygote, because  $p53^{-/m}$  mice have just as many tumors and die just as quickly as  $p53^{-/-}$  mice. So the *m* allele does not have any protective effect on its own.

The  $p53^{+/m}$  mice show no differences from wild-type mice for the first 12 months, but by 18 months show signs of premature ageing. This suggests that increased activity of p53 has a direct effect in promoting ageing. This raises the possibility that the very same activities of p53 that are needed for protection against cancer also have the effect of causing ageing! This clearly makes the level of p53 activity something that must be very tightly controlled.

## ONCOGENES AND CANCER

### 6.30.28 Genetic instability is a key event in cancer

---

#### Key Terms

**Genetic instability (Genome instability)** refers to a state in which there is large increase ( $\times 100$ -fold) in the frequency of changes in the genome as seen by chromosomal rearrangements or other events that affect the genetic content. This is a key occurrence in the generation of cancer cells.

#### Key Concepts

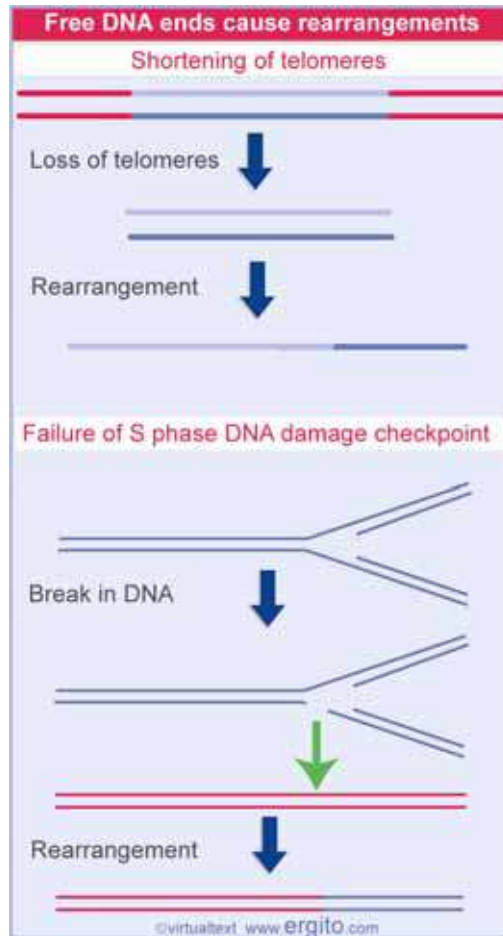

- Tumor cells have rates of genetic change that are increased above the usual rate of somatic mutation.
- Gross chromosomal changes are observed in most types of colorectal cancer.
- Chromosome rearrangements can be generated by mutations of checkpoint pathways and other pathways that act on the genome in a yeast model system.

---

The inactivation of tumor suppressors and the activation of oncogenes are key events in creating a tumor, but several such events (typically 4-10 in the case of human cancers) are required to generate a fully tumorigenic state. This number of events would not be predicted to occur during the life of a cell or organism if the individual changes occurred at the normal rate of spontaneous mutation. Many cancers are associated with **genetic instability** that significantly increases the number of events.

Genetic instability is revealed by increases in the frequency of genomic changes. These range from reorganizations at the level of the chromosome to individual point mutations. We can get a sense of their relative importance from their occurrence in colon cancers, where the genetic changes have been well characterized. The majority of colorectal tumors show high rates of gross alteration in chromosomes, often involving changes in the number of copies of a gene. This is the most common way to generate the basic changes that fuel tumorigenesis. In the minority of cases (~15%), there are no gross changes, but there are many individual mutations, resulting from a highly increased rate of mutation (see *Molecular Biology 6.30.29 Defects in repair systems cause mutations to accumulate in tumors*). Either of these types of change in the cell can propagate a tumor; it is rare for both to occur together.

Gross chromosomal alterations involve deletion, duplication, or translocation. They may result in changes in the number of copies of a gene. **Figure 30.45** illustrates two major causes:

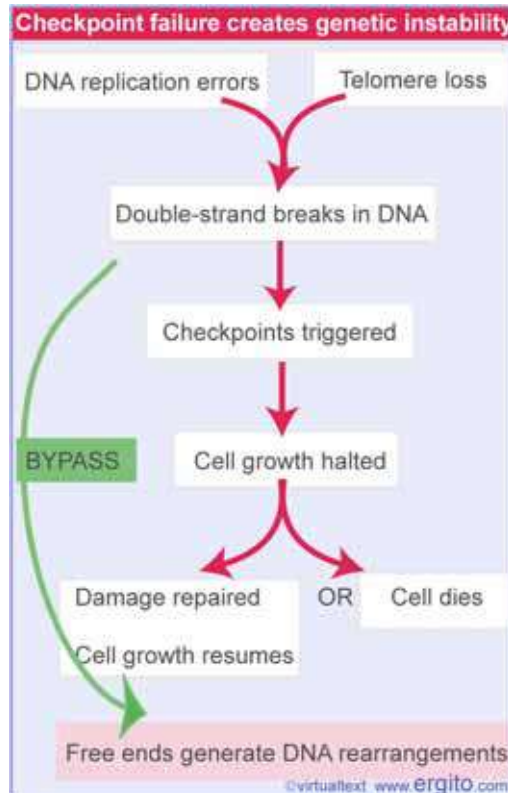

**Figure 30.45** DNA ends induce genome rearrangements. This may happen because of the failure of either telomere maintenance or DNA damage checkpoints.

- loss of telomeres because cells continue to divide in the absence of telomerase;
- creation of free double-strand ends that result from an unrepaired break in DNA.

The events that occur when a cell passes through crisis are a paradigm for the generation of chromosomal alterations (for review see 2853). Loss of telomeres induces DNA rearrangements (see *Molecular Biology 6.30.24 Telomere shortening causes cell senescence*). Failure of the normal protective mechanisms allows the damaged cells to survive.

Gross rearrangements can also be provoked by failure of protective mechanisms during a normal cell cycle (for review see 2854). Checkpoint pathways respond to DNA damage by halting the cell cycle in its current phase (see **Figure 29.21** in *Molecular Biology 6.29.13 DNA damage triggers a checkpoint*). The checkpoint triggers an effector pathway that repairs the damage, after which the cell cycle is allowed to proceed. Mutations in the S phase checkpoint pathway in *S. cerevisiae* result in an increase of more than 100× in the rate of genome rearrangements

(2856; 2857). This happens because the cell cycle is allowed to proceed in spite of the presence of breaks in DNA. **Figure 30.46** shows that similar effects are produced by mutations of some recombination-repair pathways or pathways for telomere maintenance. Analogous events could be involved in creating genetic instabilities that lead to cancer.

**Figure 30.46** DNA replication errors or loss of telomeres may generate double-strand breaks in DNA. Checkpoints detect the breaks and protect the cell from perpetuating errors. If the checkpoints fail, DNA rearrangements occur.

**ONCOGENES AND CANCER****6.30.29 Defects in repair systems cause mutations to accumulate in tumors**

---

**Key Concepts**

- Loss of mismatch-repair systems generates a high mutation rate in HNPCC.
- 

All cells have systems to protect themselves against damage from the environment or errors that may occur during replication (see *Molecular Biology 4.15 Recombination and repair*). The overall mutation rate is the result of the balance between the introduction of mutations and their removal by these systems. One means by which cancer cells increase the rate of mutation is to inactivate some of their repair systems, so that spontaneous mutations accumulate instead of being removed. In effect, a mutation that occurs in a mutator gene causes mutations to accumulate in other genes. (A mutator gene can be any type of gene – such as a DNA polymerase or a repair enzyme – whose function affects the integrity of DNA sequences.)

The MutSL system is a particularly important target. This system is responsible for removing mismatches in newly replicated bacterial DNA. Its homologues perform similar functions in eukaryotic cells. During replication of a microsatellite DNA, DNA polymerase may slip backward by one or more of the short repeating units. The additional unit(s) are extruded as a single-stranded region from the duplex. If not removed, they result in an increase in the length of the microsatellite in the next replication cycle (see **Figure 4.28**). This is averted when homologues of the MutSL system recognize the single-stranded extrusion and replace the newly-synthesized material with a nucleotide sequence that properly matches the template (see **Figure 15.47**).

In the human disease of HNPCC (hereditary nonpolyposis colorectal cancer), new microsatellite sequences are found at a high frequency in tumor cells when their DNA sequences are compared with somatic cells of the same patient (2256; 2257). **Figure 30.47** shows an example. This microsatellite has a repeat sequence of AC (reading just one strand of DNA). The length of the repeat varies from 14–27 copies in the population. Any particular individual shows two repeat lengths, one corresponding to each allele in the diploid cell. In many patients, the repeat length is changed. Most often it is reduced at both alleles, as shown in the example in the figure.

**Figure 30.47** The normal tissue of a patient has two alleles for a microsatellite, each with a different number of repeats of the dinucleotide (AC). In tumor cells, both of these alleles have suffered deletions, one reducing the repeat number from 25 to 23, the other reducing it from 19 to 16. The repeat number of each allele in each situation is in fact probably unique, but some additional bands are generated as an artefact during the amplification procedure used to generate the samples. Data kindly provided by Bert Vogelstein. The bands remaining at the normal position in the tumor samples are due to contamination of the tumor sample with normal tissue. (From 2256).

The idea that this type of change might be the result of loss of the mismatch-repair system was confirmed by showing that *mutS* and *mutL* homologues (*hMSH2*, *hMLH1*) are mutated in the tumors (2258; 2259). As expected, the tumor cells are deficient in mismatch-repair. Change in the microsatellite sequences is of course only one of the types of mutation that result from the loss of the mismatch-repair system (it is especially easy to diagnose).

The case of HNPCC illustrates both the role of multiple mutations in malignancy and the contribution that is made by mutator genes. At least 7 independent genetic events are required to form a fully tumorigenic colorectal cancer. More than 90% of cases have mutations in the mismatch-repair system, and the tumor cells have mutation rates that are elevated by 2-3 orders of magnitude from normal somatic cells (for review see 2253). The high mutation rate is responsible for creating new variants in the tumor that provide the raw material from which cells with more aggressive growth properties will arise.

Several human diseases are caused by mutations in the systems that execute checkpoints, including Ataxia telangiectasia (see *Molecular Biology 6.29.13 DNA damage triggers a checkpoint*), Nijmegen breakage syndrome, and Bloom's syndrome, all of which are characterized by chromosomal rearrangements that are triggered by breaks in DNA.

## ONCOGENES AND CANCER

### 6.30.30 Summary

---

A tumor cell is distinguished from a normal cell by its immortality, morphological transformation, and (sometimes) ability to metastasize. Oncogenes are identified by genetic changes that represent gain-of-functions associated with the acquisition of these properties. An oncogene may be derived from a proto-oncogene by mutations that affect its function or level of expression. Tumor suppressors are identified by loss-of-function mutations that allow increased cell proliferation. The mutations may either eliminate function of the tumor repressor or create a dominant negative version.

DNA tumor viruses carry oncogenes without cellular counterparts. Their oncogenes may work by inhibiting the activities of cellular tumor suppressors. RNA tumor viruses carry *v-onc* genes that are derived from the mRNA transcripts of cellular (*c-onc*) genes. Some *v-onc* oncogenes represent the full length of the *c-onc* proto-oncogene, but others are truncated at one or both ends. Most are expressed as fusion proteins with a retroviral product. Src is an exception in which the retrovirus (RSV) is replication-competent, and the protein is expressed as an independent entity.

Some *v-onc* genes are qualitatively different from their *c-onc* counterparts, since the *v-onc* gene is oncogenic at low levels of protein, while the *c-onc* gene is not active even at high levels. In such cases, proto-oncogenes are activated efficiently only by changes in the protein coding sequence. Other proto-oncogenes can be activated by large (>10×) increases in the level of expression; *c-myc* is an example that can be activated quantitatively by a variety of means, including translocations with the Ig or TCR loci or insertion of retroviruses.

*c-onc* genes may have counterpart *v-onc* genes in retroviruses, but some proto-oncogenes have been identified only by their association with cellular tumors. The transfection assay detects some activated *c-onc* sequences by their ability to transform rodent fibroblasts. *ras* genes are the predominant type identified by this assay. The creation of transgenic mice directly demonstrates the transforming potential of certain oncogenes.

Cellular oncoproteins may be derived from several types of genes. The common feature is that each type of gene product is likely to be involved in pathways that regulate growth, and the oncoprotein has lack of regulation or increased activity.

Growth factor receptors located in the plasma membrane are represented by truncated versions in *v-onc* genes. The protein tyrosine kinase activity of the cellular receptor is activated only when ligand binds, but the oncogenic versions have constitutive activity or altered regulation. In the same way, mutation of genes for polypeptide growth factors gives rise to oncogenes, because a receptor becomes inappropriately activated.

Some oncoproteins are cytoplasmic tyrosine kinases; their targets are largely

unknown. They may be activated in response to the autophosphorylation of tyrosine kinase receptors. The molecular basis for the difference between c-Src and v-Src lies in the phosphorylation states of two tyrosines. Phosphorylation of Tyr-527 in the C-terminal tail of c-Src suppresses phosphorylation of Tyr-416. The phosphorylated Tyr-527 binds to the SH2 domain of Src. However, when the SH2 domain recognizes the phosphopeptide sequence created by autophosphorylation of PDGF receptor; the PDGF receptor displaces the C-terminal region of Src, thus allowing dephosphorylation of Tyr-527, with the consequent phosphorylation of Tyr-416 and activation of the kinase activity. v-Src has lost the repressive C-terminus that includes Tyr-527, and therefore has permanently phosphorylated Tyr-416, and is constitutively active.

Ras proteins can bind GTP and are related to the  $\alpha$  subunits of G proteins involved in signal transduction across the cell membrane. Oncogenic variants have reduced GTPase activity, and therefore are constitutively active. Activation of Ras is an obligatory step in a signal transduction cascade that is initiated by activation of a tyrosine kinase receptor such as the EGF receptor; the cascade passes to the ERK MAP kinase, which is a serine/threonine kinase, and terminates with the nuclear phosphorylation of transcription factors including Fos.

Nuclear oncoproteins may be involved directly in regulating gene expression, and include Jun and Fos, which are part of the AP1 transcription factor. v-ErbA is derived from another transcription factor, the thyroid hormone receptor, and is a dominant negative mutant that prevents the cellular factor from functioning. v-Rel is related to the common factor NF- $\kappa$ B, and influences the set of genes that are activated by transcription factors in this family.

Retinoblastoma (RB) arises when both copies of the *RB* gene are deleted or inactivated. The *RB* product is a nuclear phosphoprotein whose state of phosphorylation controls entry into S phase. Nonphosphorylated RB sequesters the transcription factor E2F. The RB-E2F complex represses certain target genes. E2F is released when RB is phosphorylated by cyclin/cdk complexes; E2F can then activate genes whose products are needed for S phase. Loss of RB prevents repression by RB-E2F, and means that E2F is constitutively available. The cell cannot be restrained from proceeding through the cycle. Adenovirus E1A and papova virus T antigens bind to nonphosphorylated RB, and thus prevent it from binding to E2F.

p53 was originally classified as an oncogene because missense mutations in it are oncogenic. It is now classified as a tumor suppressor because the missense mutants in fact function by inhibiting the activity of wild-type p53. The same phenotype is produced by loss of both wild-type alleles. The level of p53 is usually low, but in response to damage to DNA, p53 activity increases, and triggers either of two pathways, depending upon the stage of the cell cycle and the cell phenotype. Early in the cycle, it provides a checkpoint that prevents further progress; this allows damaged DNA to be repaired before replication. Later in the cycle, it causes apoptosis, so that the cell with damaged DNA dies instead of perpetuating itself. Loss of p53 function is common in established cell lines and may be important in immortalization *in vitro*. Absence of p53 is common in human tumors and may contribute to the progression of a wide variety of tumors, without specificity for cell type.

p53 is activated by binding to damaged DNA, for which it uses a (non

sequence-specific) DNA-binding domain. One important target that activates p53 is the single-stranded overhanging end that is generated at a shortened telomere. When it is activated, p53 uses another DNA-binding domain to recognize a palindromic ~10 bp sequence. Genes whose promoters have this sequence and which are activated by p53 include the cdk inhibitor p21 and the protein GADD45 (which is activated by several pathways for response to DNA damage). Activation of these and other genes (involving a transactivation domain that interacts directly with TBP) is probably the means by which p53 causes cell cycle arrest. p53 has a less well characterized ability to repress some genes. Mutant p53 lacks these activities, and therefore allows the perpetuation of cells with damaged DNA. Loss of p53 may be associated with increased amplification of DNA sequences.

p53 is bound by viral oncogenes such as SV40 T antigen, whose oncogenic properties result, at least in part, from the ability to block p53 function. It is also bound by the cellular proto-oncogene, Mdm2, which inhibits its activity. p53 and Mdm2 are mutual antagonists.

The locus INK4A contains two tumor suppressors that together control both major tumor suppressor pathways. p19<sup>ARF</sup> inhibits Mdm2, so that p19 in effect turns on p53. p16<sup>INK4A</sup> inhibits the cdk4/6 kinase, which phosphorylates RB. Deletion of INK4A therefore blocks both tumor suppressor pathways by leading to activation of Mdm2 (inhibiting p53) and activation of cdk4/6 (inhibiting RB).

Loss of p53 may be necessary for immortalization, because both the G1 checkpoint and the trigger for apoptosis are inactivated. Telomerase is usually turned off in differentiating cells, which provides a mechanism of tumor suppression by preventing indefinite growth. Reactivation of telomerase is usually necessary to allow continued proliferation of tumor cells. The crisis that is encountered by cultured cells results from shortening of telomeres to the point at which genetic instability is created by the chromosome ends. Loss of p53 is important in passing through crisis, because otherwise p53 is activated by the ends generated by telomere loss.

Several independent events are required to convert a normal cell into a cancer cell, typically involving both immortalizing and transforming functions. The required number of events is in the range of 4-10, and would not normally be expected to occur during the life span of a cell. Early events may increase the rate of occurrence of mutational change by damaging the repair or other systems that limit mutational damage. One important target is the MutSL system that is responsible for removing mismatches in replicated DNA.

## GRADIENTS, CASCADES, AND SIGNALING PATHWAYS

### 6.31.1 Introduction

---

#### Key Terms

**Axes** are straight lines passing through an organism, around which the organism is symmetrically arranged.

The **anterior-posterior axis** is the line running from the head to the tail of an animal.

The **dorsal-ventral axis** is the line running from the back to the belly of an animal.

---

Development begins with a single fertilized egg, but gives rise to cells that have different developmental fates. The problem of early development is to understand how this asymmetry is introduced: how does a single initial cell give rise within a few cell divisions to progeny cells that have different properties from one another?

The means by which asymmetry is generated varies with the type of organism. The egg itself may be homogeneous, with the acquisition of asymmetry depending on the process of the initial division cycles, as in the case of mammals. Or the egg may have an initial asymmetry in the distribution of its cytoplasmic components, which in turn gives rise to further differences as development proceeds, as in the case of *Drosophila*.

Early development is defined by the formation of **axes**. By whatever means are used to develop asymmetry, the early embryo develops differences along the **anterior-posterior axis** (head-tail) and along the **dorsal-ventral axis** (top-bottom). At the stage of interpreting the axial information, a relatively restricted set of signaling pathways is employed, and essentially the same pathways are found in flies and mammals.

The paradigm for considering the molecular basis for development is to suppose that each cell type may be characterized by its pattern of gene expression, that is, by the particular gene products that it produces. The principal level for controlling gene expression is at transcription, and components of pathways regulating transcription provide an important class of developmental regulators. We may include a variety of activities within the rubric of transcriptional regulators, which could act to change the structure of a promoter region, to initiate transcription at a promoter, to regulate the activity of an enhancer, or indeed sometimes to repress the action of transcription factors. However, the regulators of transcription most often prove to be DNA-binding proteins that activate transcription at particular promoters or enhancers.

## GRADIENTS, CASCADES, AND SIGNALING PATHWAYS

### 6.31.2 Fly development uses a cascade of transcription factors

---

#### Key Terms

A **maternal gene (maternal effect gene)** (maternal-effect gene) is usually expressed by the mother during oogenesis. Phenotypes resulting from a maternal-effect mutation depend on the genotype of the mother rather than the genotype of the embryo.

**Segmentation genes** are concerned with controlling the number or polarity of body segments in insects.

**Homeotic genes** are defined by mutations that convert one body part into another; for example, an insect leg may replace an antenna.

#### Key Concepts

- The genes that control the early stages of fly development code for transcription factors.
- At each stage, the factors in one area of the egg control the synthesis of further factors that will define smaller areas.
- Maternal genes are expressed during oogenesis and act in the oocyte.
- Three successive groups of segmentation genes are expressed after fertilization to control the number or polarity of segments.
- Homeotic genes control the identity of a segment.

---

The systematic manner in which the regulators are turned on and off to form circuits that determine body parts has been worked out in detail in *D. melanogaster*. The basic principle is that a series of events resulting from the initial asymmetry of the egg is translated into the control of gene expression so that specific regions of the egg acquire different properties. The means by which asymmetry is translated into control of gene expression differ for each of four systems that have been characterized in the insect egg. It may involve localization of factors that control transcription or translation within the egg, or localized control of the activities of such factors. But the end result is the same: spatial and temporal regulation of gene expression.

Early in development, the identities of parts of the embryo are determined: regions are defined whose descendants will form particular body parts. The genes that regulate this process are identified by loci in which mutations cause a body part to be absent, to be duplicated, or to develop as another body part. Such loci are prime candidates for genes whose function is to provide regulatory "switches." Most of these genes code for regulators of transcription. They act upon one another in a hierarchical manner, but they act also upon other genes whose products are actually

responsible for the formation of pattern. The ultimate targets are genes that code for kinases, cytoskeletal elements, secreted proteins, and transmembrane receptors.

The establishment of a specific pattern of transcription in a particular region of the embryo leads to a *cascade* of control, when regulatory events are connected so that a gene turned on (or off) at one stage itself controls expression of other genes at the next stage. Formally, such a cascade resembles those described previously for bacteriophages or for bacterial sporulation (as discussed in *Molecular Biology 3.10 The operon*), although it is more complex in the case of eukaryotic development. The common feature of regulatory proteins is that they are transcription factors that regulate the expression of other transcription factors (as well as other target proteins). As in the case of prokaryotic regulation, the basic relationship between the regulator protein and the target gene is that the regulator recognizes a short sequence in the DNA of the promoter (or an enhancer) of a target gene. All of the targets for a particular regulator are identified by their possession of a copy of the appropriate consensus sequence.

The development of an adult organism from a fertilized egg follows a predetermined pathway, in which specific genes are turned on and off at particular times. From the perspective of mechanism, we have most information about the control of transcription. However, subsequent stages of gene expression are also targets for regulation. And, of course, the cascade of gene regulation is connected to other types of signaling, including cell-cell interactions that define boundaries between groups of cells.

The mechanics of development in terms of cellular events are different in different types of species, but we assume that the principle established with *Drosophila* will hold in all cases: that a regulatory cascade determines the appropriate pattern of gene expression in cells of the embryo and ultimately of the adult. Indeed, homologous genes in distantly related organisms play related roles in development. The same pathways are found in (for example) flies and mammals, although the consequences of their employment are rather different in terms of the structures that develop.

Genes involved in regulating development are identified by mutations that are lethal early in development or that cause the development of abnormal structures. A mutation that affects the development of a particular body part attracts our attention because a single body part is a complex structure, requiring expression of a particular set of many genes. Single mutations that influence the structure of the entire body part therefore identify potential regulator genes that switch or select between developmental pathways.

In *Drosophila*, the body part that is analyzed is the segment, the basic unit that can be seen looking at the adult fly. Mutations fall into (at least) three groups, defined by their effect on the segmental structure:

- **Maternal genes** are expressed during oogenesis by the mother. They may act upon or within the maturing oocyte.
- **Segmentation genes** are expressed after fertilization. Mutations in these genes alter the number or polarity of segments. Three groups of segmentation genes act sequentially to define increasingly smaller regions of the embryo.

- **Homeotic genes** control the identity of a segment, but do not affect the number, polarity, or size of segments. Mutations in these genes cause one body part to develop the phenotype of another part.

The genes in each group act successively to define the properties of increasingly more restricted parts of the embryo. The maternal genes define broad regions in the egg; differences in the distribution of maternal gene products control the expression of segmentation genes; and the homeotic genes determine the identities of individual segments (for review see 355; 362).

## GRADIENTS, CASCADES, AND SIGNALING PATHWAYS

### 6.31.3 A gradient must be converted into discrete compartments

---

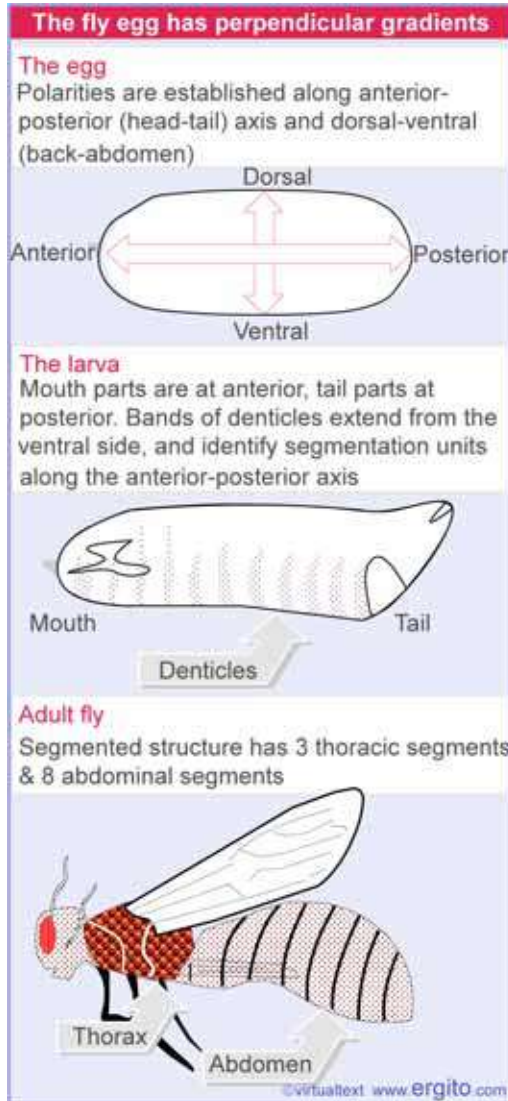

#### Key Terms

A **denticle** is a pigmented, hardened spike of cuticle protruding from the ventral epidermis of a *Drosophila* embryo.

#### Key Concepts

- During the first 13 division cycles, nuclei divide in a common cytoplasm; cells form only at blastoderm.
  - Gradients define the polarity of the egg along both the anterior-posterior and dorsal-ventral axes.
  - The gradients consist of RNAs or proteins that are differentially distributed in the common cytoplasm.
  - The location of a nucleus in the cytoplasm with regard to the two axes determines the fate of the cells that descend from it.
- 

The basic question of *Drosophila* development is illustrated in **Figure 31.1** in terms of three stages of development: the egg; the larva; and the adult fly.

**Figure 31.1** Gradients in the egg are translated into segments on the anterior-posterior axis and into specialized structures on the dorsal-ventral axis of the larva, and then into the segmented structure of the adult fly.

At the start of development, gradients are established in the egg along the anterior-posterior and dorsal-ventral axes. The anterior end of the egg becomes the head of the adult; the posterior end becomes the tail. The dorsal side is on top (looking down on a larva); the ventral side is underneath. The gradients consist of molecules (proteins or RNAs) that are differentially distributed in the cytoplasm. The gradient responsible for anterior-posterior development is established soon after fertilization; the dorsal-ventral gradient is established a little later. It is only a modest oversimplification to say that the anterior-posterior systems control positional information along the larva, while the dorsal-ventral system regulates tissue differentiation (that is, the specification of distinct embryonic tissues, including mesoderm, neuroectoderm, and dorsal ectoderm).

Insect development involves two quite different types of structures. The first part of development is concerned with elaborating the larva; then the larva metamorphoses into the fly. This means that the structure of the embryo (the larva) is distinct from the structure of the adult (the fly), in contrast with development of (for example) mammals, where the embryo develops the same body parts that are found in the adult. As the larva develops, it forms some body parts that are exclusively larval (they will not give rise to adult tissues; often they are polyploid), while other body parts are the progenitors that will metamorphose into adult structures (usually they are diploid). In spite of the differences between insect development and vertebrate development, the same general principles appear to govern both processes, and we discover relationships between *Drosophila* regulators and mammalian regulators.

Discrete regions in the embryo correspond to parts of the adult body. They are shown in terms of the superficial organization of the larva in the middle panel of **Figure 31.1**. Bands of **denticles** (small hairs) are found in a particular pattern on the surface (cuticle) of the larva. The cuticular pattern has features determined by both the anterior-posterior axis and the dorsal-ventral axis:

- Along the anterior-posterior axis, the denticles form discrete bands. Each band corresponds to a segment of the adult fly: in fact, the 11 bands of denticles correspond on a 1:1 basis with the 11 segments of the adult.
- Along the dorsal-ventral axis, the denticles that extend from the ventral surface are coarse; those that extend from the dorsal surface are much finer.

Although the cuticle represents only the surface body layer, its structure is diagnostic of the overall organization of the embryo in both axes. Much of the analysis of phenotypes of mutants in *Drosophila* development has therefore been performed in terms of the distortion of the denticle patterns along one axis or the other.

The difference in form between the gradients of the egg and the segments of the adult poses some prime questions. How are gradients established in the egg? And how is a continuous gradient converted into discrete differences that define individual cell types? How can a large number of separate compartments develop from a single gradient?

The nature of the gradients, and their ability to affect the development of a variety of cell types located throughout the embryo, depend upon some idiosyncratic features of *Drosophila* development. The early stages are summarized in **Figure 31.2**.

**Figure 31.2** The early development of the *Drosophila* egg occurs in a common cytoplasm until the stage of cellular blastoderm.

At fertilization the egg possesses the two parental nuclei and is distinguished at the posterior end by the presence of a region called polar plasm. For the first 9 divisions, the nuclei divide in the common cytoplasm. Material can diffuse in this cytoplasm (although there are probably constraints imposed by cytoskeletal organization). At division 7, some nuclei migrate into the polar plasm, where they become precursors to germ cells. After division 9, nuclei migrate and divide to form a layer at the surface of the egg. Then they divide 4 times, after which membranes surround them to form somatic cells.

Up to the point of cellularization, the nuclei effectively reside in a common cytoplasm. At the stage of the cellular blastoderm, the first discrete compartments become evident, and at this time particular regions of the egg are *determined* to

become particular types of adult structures. (Determination is progressive and gradual; over the next few cell divisions, the fates of individual regions of the egg become increasingly restricted.) At the start of this process, nuclei migrate to the surface to form the monolayer of the blastoderm, but they do not do so in any predefined manner. It is therefore the location in which the nuclei find themselves at this stage that determines what types of cells their descendants will become. *A nucleus determines its position in the embryo by reference to the anterior-posterior and dorsal-ventral gradients, and behaves accordingly.*

---

## GRADIENTS, CASCADES, AND SIGNALING PATHWAYS

### 6.31.4 Maternal gene products establish gradients in early embryogenesis

---

#### Key Terms

In *Drosophila*, a **female sterile** mutation is one in that causes sterility in the female, often because of abnormalities in oogenesis.

A **morphogen** is a factor that induces development of particular cell types in a manner that depends on its concentration.

In *Drosophila*, the **anterior system** is one of the maternal systems that establishes the polarity of the oocyte. The set of genes in the anterior system play a role in the proper formation of the head and the thorax.

In *Drosophila*, the **posterior system** is one of the maternal systems that establishes the polarity of the oocyte. The set of genes in the posterior system play a role in the proper formation of the pole plasm and the abdomen.

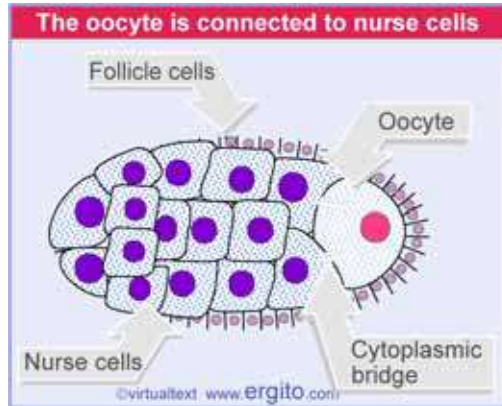

In *Drosophila*, the **terminal system** is one of the maternal systems that establishes the polarity of the oocyte. The set of genes in the terminal system play a role in the proper formation of the terminal structures at both ends of the fly.

#### Key Concepts

- Four signaling pathways are initiated outside the egg and each leads to production of a morphogen in the egg.
- The anterior system is responsible for development of head and thorax.
- The posterior system is responsible for the segments of the abdomen.
- The terminal system is responsible for producing the acron (in the head) and the telson (at the tail).
- The dorsal-ventral system determines development of tissue types (mesoderm, neuroectoderm, ectoderm).

---

An initial asymmetry is imposed on the *Drosophila* oocyte during oogenesis. **Figure 31.3** illustrates the structure of a follicle in the *Drosophila* ovary. A single progenitor undergoes four successive mitoses to generate 16 interconnected cells. The connections are known as "cytoplasmic bridges" or "ring canals." Individual cells have 2, 3, or 4 such connections. One of the two cells that has 4 connections undergoes meiosis to become the oocyte; the other 15 cells become "nurse cells." Cytoplasmic material, including protein and RNA, passes from the nurse cells to the oocyte; the accumulation of such material accounts for a considerable part of the volume of the egg. The cytoplasmic connections are made at one end of the oocyte, and this end becomes the anterior end of the egg.

**Figure 31.3** A *Drosophila* follicle contains an outer surface of follicle cells that surround nurse cells that are in close contact with the oocyte. Nurse cells are connected by cytoplasmic bridges to each other and to the anterior end of the oocyte. Follicle cells are somatic; nurse cells and the oocyte are germline in origin.

Genes that are expressed within the mother fly are important for early development. These maternal genes are identified by **female sterile** mutations. They do not affect the mother itself, but are required in order to have progeny. Females with such mutations lay eggs that fail to develop into adults; the embryos can be recognized by defects in the cuticular pattern, and they die during development.

The common feature in all maternal genes is that they are expressed prior to fertilization (although their products may act either at the time of expression or be stored for later use). The maternal genes are divided into two classes, depending on their site of expression. Genes that are expressed in somatic cells of the mother that affect egg development are called *maternal somatic genes*. For example, they may act in the follicle cells. Genes that are expressed within the germline are called *maternal germline genes*. These genes may act either in the nurse cell or the oocyte. Some genes act at both stages.

Four groups of genes concerned with the development of particular regions of the embryo can be identified by mutations in maternal genes. The genes in each group can be organized into a pathway that reflects their order of action, by conventional genetic tests (such as comparing the properties of double mutants with the individual mutants) or by biochemical assays (showing which mutants contain components that can bypass the stages that are blocked in other mutants; for review see 355; 362).

The components of these pathways are summarized in **Figure 31.4**, which shows that there is a common principle to their operation. *Each pathway is initiated by localized events outside the egg; this results in the localization of a signal within the egg.* This signal takes the form of a protein with an asymmetric distribution; this is called a **morphogen**. Formally, we may define a morphogen as a protein whose local concentration (or activity) causes the surrounding region to take up a particular structure or fate. In each of these systems, the morphogen either is a transcriptional regulator or leads to the activation of a transcription factor in the localized region. Three systems are concerned with the anterior-posterior axis, and one with the dorsal-ventral axis:

Maternal systems are initiated outside the egg				
	Anterior	Posterior	Terminal	Dorsoventral
Maternal somatic			<i>torsolike</i>	<i>pipe</i> <i>nudel</i> <i>windbeutel</i>
Maternal germline	<i>exuperantia</i> <i>swallow</i> <i>staufen</i>	<i>capuccino</i> <i>spire</i> <i>staufen</i> <i>oskar</i> <i>vasa</i> <i>valois</i> <i>tudor</i> <i>mago nashi</i>	<i>trunk</i> <i>Nasrat</i> <i>polehole</i>	Gastrulation- defective <i>snake</i> <i>easter</i>  <i>spatzle</i>
Transmembrane receptors			<i>torso</i>	<i>Toll</i>
Morphogen		<i>nanos</i> <i>pumilio</i>	<i>polehole</i>	<i>tube</i> <i>pelle</i> <i>cactus</i>
Transcription regulators	<i>bicoid</i>	<i>hunchback</i>	?	<i>dorsal</i>
Zygotic targets	<i>hunchback</i> <i>buttonhead</i> <i>orthodenticle</i> <i>empty spiracles</i>	<i>knirps</i> <i>giant</i>	<i>tailless</i> <i>huckebein</i>	<i>zerknüllt (zen)</i> <i>decapentaplegic</i> <i>twist</i> <i>snail</i>

**Figure 31.4** Each of the four maternal systems that functions in the egg is initiated outside the egg. The pathway is carried into the egg, where each pathway has a localized product that is the morphogen. This may be a receptor or a regulator of gene expression. The final component is a transcription factor, which acts on zygotic targets that are responsible for the next stage of development.

- The **anterior system** is responsible for development of the head and thorax. The maternal germline products are required to localize the *bicoid* product at the anterior end of the egg. In fact, *bicoid* mRNA is transcribed in nurse cells and transported into the oocyte. Bicoid protein is the morphogen: it functions as a transcriptional regulator, and controls expression of the gene *hunchback* (and probably also other segmentation and homeotic genes).
- The **posterior system** is responsible for the segments of the abdomen. The nature of the initial asymmetric event is not clear. A large number of products act to cause the localization of the product of *nanos*, which is the morphogen. This leads to localized repression of expression of *hunchback* (via control of translation of the mRNA).
- The **terminal system** is responsible for development of the specialized structures at the unsegmented ends of the egg (the acron at the head, and the telson at the tail). As indicated by the dependence on maternal somatic genes, the initial events that create asymmetry occur in the follicle cells. They lead to localized activation of the transmembrane receptor coded by *torso*; the end product of the pathway has yet to be identified.
- The fourth system is responsible for dorsal-ventral development. The pathway is initiated by a signal from a follicle cell on the ventral side of the egg. It is transmitted through the transmembrane receptor coded by *Toll*. This leads to a gradient of activation of the transcription factor produced by *dorsal* (by

controlling its localization within the cell).

About 30 maternal genes involved in pattern formation have been identified. All of the components of the four pathways are maternal, so we see that the systems for establishing the initial pattern formation all depend on events that occur prior to fertilization. The two body axes are established independently. Mutations that affect polarity cause posterior regions to develop as anterior structures, or ventral regions to develop in dorsal form. On the anterior-posterior axis, the anterior and posterior systems provide opposing gradients, with sources at the anterior and posterior ends of the embryo, respectively, that control development of the segments of the body. Defects in either system affect the body segments. The terminal and dorsal-ventral systems operate independently of the other systems (for review see 359).

## GRADIENTS, CASCADES, AND SIGNALING PATHWAYS

### 6.31.5 Anterior development uses localized gene regulators

---

#### Key Terms

**Ectopic** refers to something being out of place.

A gene or protein that plays an **instructive** role in development is one that gives a signal telling the cell what to do.

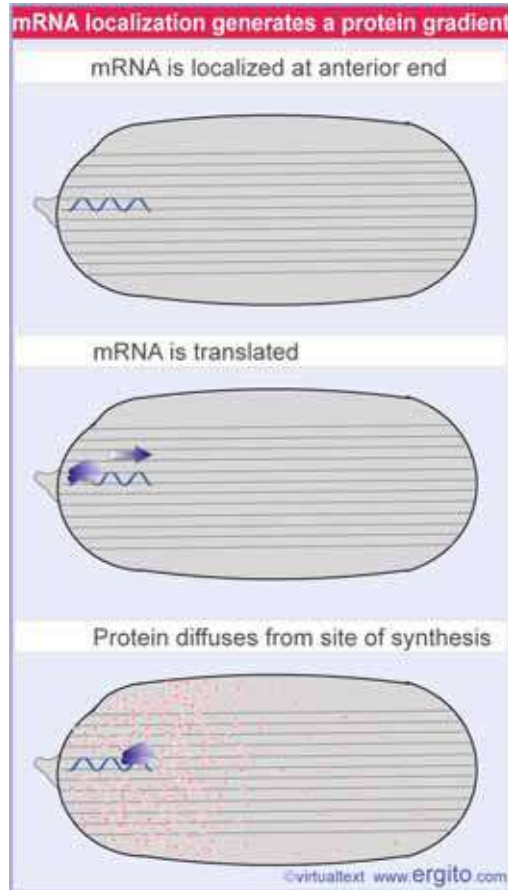

#### Key Concepts

- The anterior system localizes bicoid mRNA at the anterior end of the egg, generating a gradient of protein that extends along the anterior 40% of the egg.
- The concentration of bicoid protein determines the types of anterior (head) structures that are produced in each region.
- This system is instructive because it is required for development of the head structures.

---

Establishing asymmetry in an egg requires that some components – either RNAs or proteins – are *localized* instead of being diffused evenly through the cytosol. In anterior-posterior development in *Drosophila*, certain mRNAs are localized at the anterior or posterior end. **Figure 31.5** shows that when they are translated, their protein products diffuse away from the ends of the egg, generating a gradient along the anterior-posterior axis.

**Figure 31.5** Translation of a localized mRNA generates a gradient of protein as the products diffuse away from the site of synthesis.

The existence of localized concentrations of materials needed for development can be tested by the rescue protocol summarized in **Figure 31.6**. Material is removed from a wild-type embryo and injected into the embryo of a mutant that is defective in early development. If the mutant embryo develops normally, we may conclude that the mutation causes a deficiency of material that is present in the wild-type embryo. This allows us to distinguish components that are necessary for morphogenesis, or that are upstream in the pathway, from the morphogen itself – only the morphogen has the property of localized rescue.

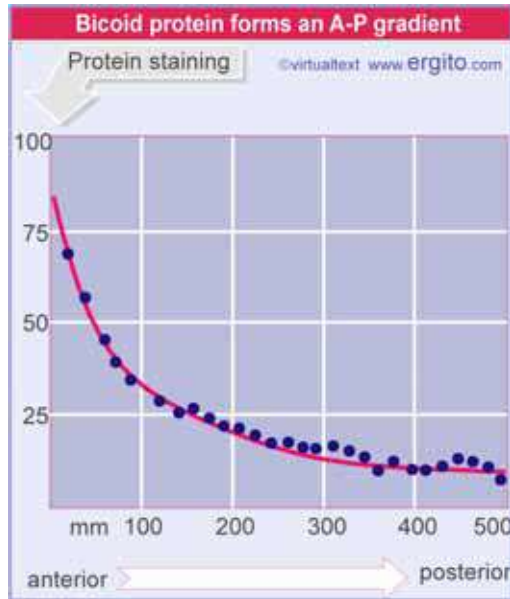

**Figure 31.6** Mutant embryos that cannot develop can be rescued by injecting cytoplasm taken from a wild-type embryo. The donor can be tested for time of appearance and location of the rescuing activity; the recipient can be tested for time at which it is susceptible to rescue and the effects of injecting material at different locations.

The rescue technique identifies *bicoid* as the morphogen required for anterior development. *bicoid* mutants do not develop heads; but the defect can be remedied by injecting mutant eggs with cytoplasm taken from the anterior tip of a wild-type embryo. Indeed, anterior structures develop elsewhere in the mutant embryo if wild-type anterior cytoplasm is injected! (This is called **ectopic** expression.) The extent of the rescue depends on the amount of wild-type cytoplasm injected. And the efficacy of the donor cytoplasm depends on the number of wild-type *bicoid* genes carried by the donor.

These results suggest that the anterior region of a wild-type embryo contains a concentration of some product that depends on the *bicoid* gene dosage. By purifying the active component in the preparation, it is possible to show that purified *bicoid* mRNA can substitute for the anterior cytoplasm. *This implies that the components on which bicoid acts are ubiquitous, and all that is required to trigger formation of anterior structures is an appropriate concentration of bicoid product.*

The product of *bicoid* establishes a gradient with its source (and therefore the highest concentration) at the anterior end of the embryo. The RNA is localized at the anterior tip of the embryo, but it is not translated during oogenesis. Translation begins soon after fertilization. The protein then establishes a gradient along the embryo, as indicated in **Figure 31.7** (888). The gradient could be produced by diffusion of the

protein product from the localized source at the anterior tip. The gradient is established by division 7, and remains stable until after the blastoderm stage.

**Figure 31.7** Bicoid protein forms a gradient during *D. melanogaster* development that extends for ~200 mm along the egg of 500 mm.

What is the consequence of establishing the bicoid gradient? The gradient can be increased or decreased by changing the number of functional gene copies in the mother. The concentration of bicoid protein is correlated with the development of anterior structures. Weakening the gradient causes anterior segments to develop more posterior-like characteristics; strengthening the gradient causes anterior-like structures to extend farther along the embryo. So the bicoid protein behaves as a morphogen that determines anterior-posterior position in the embryo in a concentration-dependent manner.

The fate of cells in the anterior part of the embryo is determined by the concentration of bicoid protein. The *bicoid* product is a sequence-specific DNA-binding protein that regulates transcription by binding to the promoters of its target genes. The immediate effect of *bicoid* is exercised on other genes that in turn regulate the development of yet further genes. A major target for *bicoid* is the gene *hunchback*. Transcription of *hunchback* is turned on by *bicoid* in a dose-dependent manner, that is, *hunchback* is activated above a certain threshold of bicoid protein. The effect of bicoid on *hunchback* is to produce a band of expression that occupies the anterior part of the embryo (see **Figure 31.21**; for review see 365).

The relationship between *bicoid* and *hunchback* establishes the principle that a gradient can provide a spatial on-off switch that affects gene expression. In this way, quantitative differences in the amount of the morphogen (bicoid protein) are transformed into qualitatively different states (cell structures) during embryonic development. *bicoid* plays an **instructive** role in anterior development, since it is a positive regulator that is *needed for expression* of genes that in turn determine the synthesis of anterior structures (for review see 3699).

## GRADIENTS, CASCADES, AND SIGNALING PATHWAYS

### 6.31.6 Posterior development uses another localized regulator

---

#### Key Terms

A protein that plays a **permissive** role in development is one that sets up a situation where a certain activity can occur, but does not cause the occurrence itself.

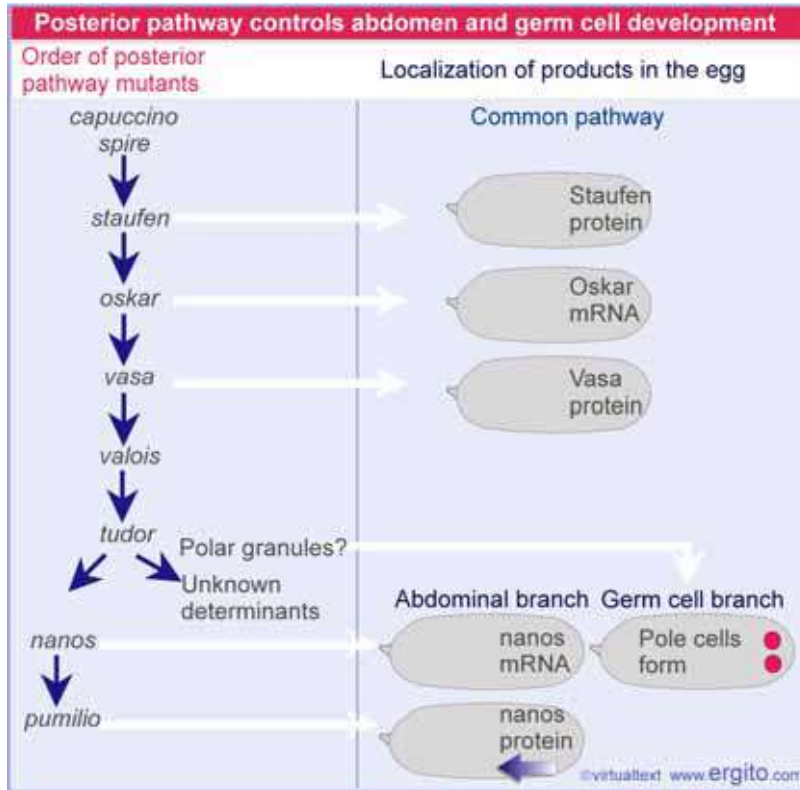

#### Key Concepts

- The posterior system localizes nanos mRNA at the posterior end of the egg, generating a gradient of nanos protein that extends along the abdominal region.
- This system is permissive because its function is to repress genes whose products would interfere with posterior development.

---

Posterior development depends on the expression of a large group of genes. Embryos produced by females who are mutant for any one of these genes develop normal head and thoracic segments, but lack the entire abdomen. Some of these genes are concerned with exporting material from the nurse cells to the egg; others are required to transport or to localize the material within the egg.

The posterior pathway functions by a series of events in which one product is responsible for localizing the next. **Figure 31.8** correlates the order of genes in the genetic pathway with the activities of their products in the embryo. The functions *spir* and *capu* are needed for Staufen protein to be localized at the pole. Staufen protein in turn localizes *oskar* RNA; possibly a complex of Staufen protein and *oskar* RNA is assembled. These functions are needed to localize Vasa, which is an RNA-binding protein. Its specificity and targets are not known.

**Figure 31.8** The posterior pathway has two branches, responsible for abdominal development and germ cell formation.

If *oskar* is over-expressed or mislocalized in the embryo, it induces germ cell formation at ectopic sites. It requires only the products of *vasa* and *tudor*. This implies that all of the activities that precede *oskar* in the pathway are needed only to localize *oskar* RNA. The ability both to form pole cells and to induce abdominal structures is possessed by *oskar*, in conjunction with *vasa* and *tudor* (and of course any components that are ubiquitously expressed in the egg). One effect of *oskar* function is to localize Vasa protein at the posterior end. The functions of *valois* and *tudor* are not known, but it is possible that *valois* is off the main pathway.

Two types of pattern-determining event occur at the posterior pole, and the pathway branches at *tudor*. The polar plasm contains two morphogens: the posterior determinant (*nanos*) controls abdominal development; and another signal controls formation of the pole cells, which will give rise to the germline (see **Figure 31.2**). All of the posterior genes except *nanos* and *pumilio* are required for both processes, that is, they are defective in both abdominal development and pole cell formation. *nanos* and *pumilio* identify the abdominal branch. We do not know whether there are additional functions representing a separate branch for germ cell formation, or whether the pathway up to *tudor* is by itself sufficient (901).

The posterior system resembles the anterior system in the basic nature of the morphogenetic event: a maternal mRNA is localized at the posterior pole. This is the product of *nanos*, and provides the morphogen. There are two important differences between the systems. Localization is more complex than in the case of the anterior system, because posterior determinants that originate in the nurse cells must be

transported the full length of the oocyte to the far pole. And *nanos* protein acts to *prevent* translation of a transcription factor (*hunchback*). Its role is said to be **permissive**, since it functions to repress genes whose products would interfere with posterior development.

How do we know that *nanos* is the morphogen at the end of the pathway? Rescue experiments (along the lines shown previously in **Figure 31.6**) with the mutants in the posterior group showed that in all but one case the cytoplasm of the nurse cell contained the posterior determinant (although it was absent from the posterior end of the oocyte itself). This indicates that these mutants all act in some subsidiary role, most probably concerned with transporting or localizing the morphogen in the egg. The exception was *nanos*, whose mutants did not contain any posterior-rescuing activity. Purified *nanos* RNA can rescue mutants in any of the other posterior genes, indicating that it is the last, or most downstream, component in the pathway. Indeed, injection of *nanos* RNA into ectopic locations in embryos can induce the formation of abdominal structures, showing that it provides the morphogen.

The upper part of **Figure 31.9** shows the localization of *nanos* mRNA at the posterior end of an early embryo. But the localization poses a dilemma: *nanos* activity is required for development of abdominal segments, that is, for structures occupying approximately the posterior half of the embryo. How does *nanos* RNA at the pole control abdominal development? The lower part of **Figure 31.9** shows that *nanos* protein diffuses from the site of translation to form a gradient that extends along the abdominal region.

**Figure 31.9** nanos products are localized at the posterior end of a *Drosophila* embryo. The upper photograph shows the tightly localized RNA in the very early embryo (at the time of the 3rd nuclear division). The lower photograph shows the spreading of nanos protein at the 8th nuclear division. Photographs kindly provided by Ruth Lehmann.

Both *bicoid* and *nanos* act on the expression of the *hunchback* gene. *hunchback* codes for a repressor of transcription: its presence is needed for formation of anterior structures (in the region of the thorax), and its absence is required for development of posterior structures. It has a complex pattern of expression. It is transcribed during oogenesis to give an mRNA that is uniformly distributed in the egg. After fertilization, the *hunchback* pattern is changed in two ways. The *bicoid* gradient activates synthesis of *hunchback* RNA in the anterior region. And *nanos* prevents translation of *hunchback* mRNA in the posterior region; a result of this inhibition is that the mRNA is degraded.

The anterior and posterior systems together therefore enhance *hunchback* levels in the anterior half of the egg, and remove it from the posterior half. The significance of this distribution lies with the genes that *hunchback* regulates. It represses the genes *knirps* and (probably) *giant*, which are needed to form abdominal structures. So the basic role of *hunchback* is to repress formation of abdominal structures by preventing the expression of *knirps* and *giant* in more anterior regions (894).

---

**GRADIENTS, CASCADES, AND SIGNALING PATHWAYS****6.31.7 How are mRNAs and proteins transported and localized?**

---

**Key Concepts**

- The mRNAs that establish the anterior and posterior systems are transcribed in nurse cells and transported through cytoplasmic bridges into oocytes.
  - *bicoid* mRNA is localized close to the point of entry, but *oskar* and *nanos* mRNAs are transported the length of the oocyte to the posterior end.
  - Movement is accomplished by a motor attached to microtubules.
- 

Anterior and posterior development both depend on the localization of an mRNA at one end of the egg. How does the mRNA reach the appropriate location and what is responsible for maintaining it there? Similar processes are involved for the anterior-posterior axis and for the dorsal-ventral axis. On the antero-posterior axis, *bicoid* and *oskar* mRNAs are localized at opposite ends of the egg. On the dorsal-ventral axis, *gurken* mRNA is initially localized at the posterior end and then becomes localized on the dorsal side of the anterior end. The principle is that the sites of transcription are distinct from the sites where the mRNAs are localized and translated, and an active transport process is required to localize the mRNAs.

*bicoid*, *oskar*, and *nanos* all are transcribed in nurse cells. **Figure 31.10** shows that mRNA is transported through the cytoplasmic bridges into the oocyte. Within the oocyte, *bicoid* mRNA then remains at the anterior end, but *oskar* mRNA is transported the length of the oocyte to the posterior end. The typical means by which an mRNA is transported to a specific location in a cell involves movement along "tracks", which in principle can be either actin filaments or microtubules. This basically means that the mRNA is attached to the tracks by a motor protein that uses hydrolysis of ATP to drive movement (see **Figure 31.10**). In the example of the *Drosophila* egg, microtubules are the tracks used to transport these and other mRNAs (960). In fact, the microtubules form a continuous network that connects the oocyte to the nurse cells through the ring canals (2233).

**Figure 31.10** Some mRNAs are transported into the *Drosophila* egg as ribonucleoprotein particles. They move to their final sites of localization by association with microtubule.

Genes whose products are needed to transport these mRNAs are identified by mutants in which the mRNAs are not properly localized. The most typical disruption of the pattern is for the mRNAs simply to be distributed throughout the egg. The best characterized of these transport genes are *exuperantia* (*exu*) and *swallow* (*swa*). Exu protein is part of a large ribonucleoprotein complex (961). This complex assembles in the nurse cell, where it uses microtubule tracks to move to the cytoplasmic bridge (962). Then it passes across the bridge into the oocyte in a way that is independent of microtubules. In the oocyte, it attaches to microtubules to move to its location.

The properties of *exu* and *swa* mutants show that there are common components for the transport and localization of different mRNAs. We do not yet know what differences exist between the complexes involved in transporting different mRNAs. However, we assume that there must be a component of each complex that is responsible for targeting it to the right location. By following different mRNAs, it seems that in each case the complex is transported to the anterior end of the oocyte, where it aggregates. Then a decision is made on further localization, and the complex is transported to the appropriate site (for review see 2295; 2304).

Similar events occur at a later stage of development, in the syncytial blastoderm, when some mRNAs become localized on the apical side of the embryo. The same

apparatus seems to be involved as in development of the oocyte. Usually it is responsible for apical localization of the products of several pair rule and segmentation genes. However, if the maternal transcripts of *gurken*, *bicoid*, or *nanos* are injected into the syncytial blastoderm, the apparatus localizes them on the apical side of the embryo (2235). This suggests that the RNAs that are localized at early and at later times have the same set of signals to identify themselves as substrates to the localization apparatus.

mRNAs that are localized in the syncytial blastoderm are found in particles that are connected to microtubules by the motor dynein (2234). The parallels between the transport systems of the oocyte and the blastoderm suggest that dynein also connects the maternal mRNAs to the microtubules. The proteins Egl (egalitarian) and BicD (Bicaudal-D) associate with localizing transcripts and bind to dynein (2235). In their absence, maternal transcripts do not localize properly in the oocyte. This suggests that an Egl/BicD complex may be the means of connecting the mRNA to the motor.

We know that the localization of the *bicoid* RNA to the anterior end of the oocyte depends upon sequences in the 3' untranslated region (887; 888). This is a common theme, and localization of *oskar* and *nanos* mRNAs is controlled in the same way (963). We assume that the 3' sequences provide binding sites for specific protein(s) that are involved in localization. Corresponding sequences in each mRNA will provide binding sites for the proteins that target the RNA to the appropriate sites in the oocyte. However, we are still missing the identification of the crucial protein that binds to the localizing sequence in the mRNA.

Localization of RNAs is not sufficient to ensure the pattern of expression. Translation is also controlled. The production of *oskar* and *nanos* proteins is controlled by repression of the mRNAs outside of the posterior region. In each case, translation is repressed by a protein that binds to the 3' region (964). In the case of *nanos*, there is overlap between the elements required for localization and repression (965; 966; 1434). The consequence of this overlap is to make localization and repression mutually exclusive, so that when a *nanos* mRNA is localized to the posterior end, it cannot be repressed (1433).

## GRADIENTS, CASCADES, AND SIGNALING PATHWAYS

### 6.31.8 How are gradients propagated?

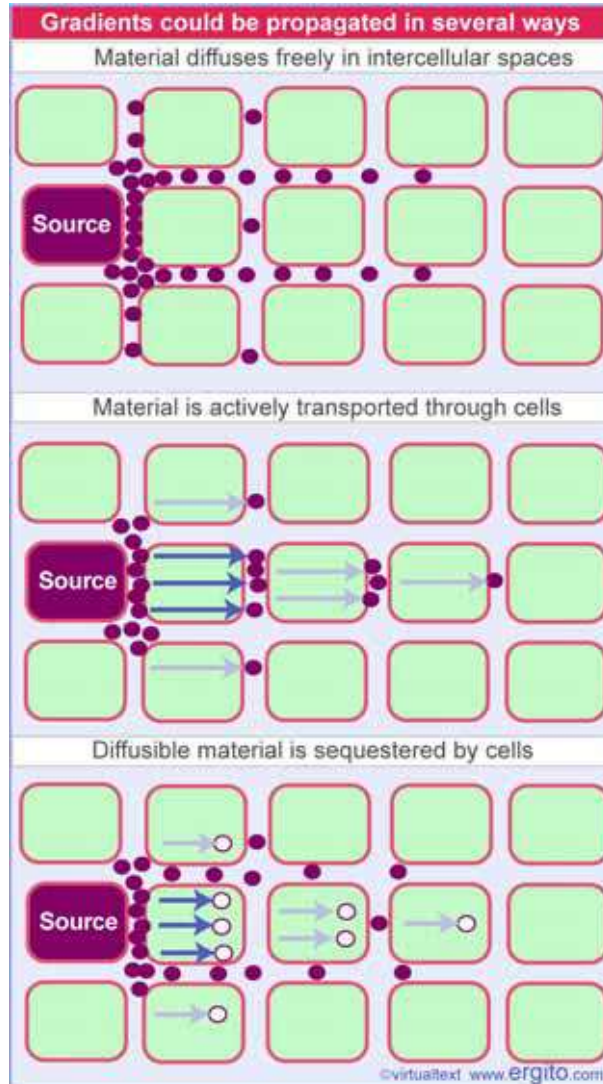

---

#### Key Concepts

- Many morphogens form gradients that control differential expression of genes.
  - A gradient in an egg or in the early *Drosophila* embryo is propagated by passive diffusion from a localized source.
  - A gradient in a cellular tissue may be propagated by passive diffusion in the intercellular spaces or by an active process in which cells transmit the morphogen to other cells.
  - A gradient may also be influenced by degradation of morphogen within cells.
- 

The cytosol of an egg forms a single compartment, as indeed does the syncytium of the early *Drosophila* embryo. A protein may form a gradient simply by diffusing away from a localized source (see **Figure 31.5**). In the case of *Drosophila*, such sources are provided by localized mRNAs at either the anterior end (**Figure 31.7**) or posterior end (**Figure 31.9**).

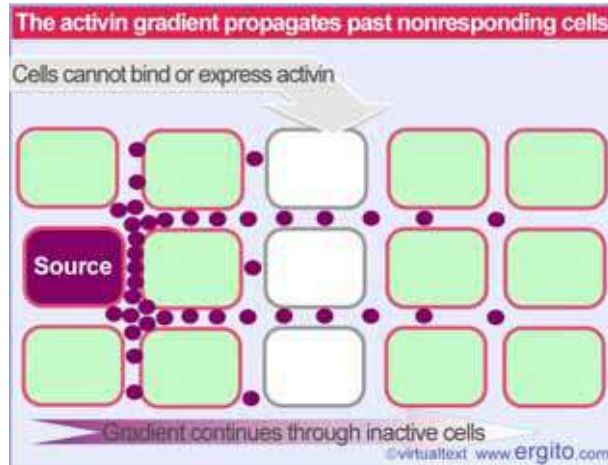

Gradients are also important in development of tissues consisting of cells. We know several cases in which a morphogen forms a gradient, and the cells in that gradient respond differently depending upon the local concentration of the morphogen. The differential response of cells can be seen by placing them in tissue culture on a medium that contains a gradient of morphogen. In the tissue, however, there may be more constraints upon the movement of morphogen. For a gradient to form, material must move in intercellular spaces between the cells or must be transported through the cells. **Figure 31.11** distinguishes some possible models.

**Figure 31.11** A gradient can form by passive diffusion or by active transport or may be affected by removing the diffusing material.

The simplest situation is for passive diffusion. This appears to be responsible for the gradient of activin (a TGF  $\beta$  homologue) that is secreted by cells in the amphibian embryo and induces formation of the mesoderm tissue layer (see *Molecular Biology 6.31.13 TGF  $\beta$ /BMPs are diffusible morphogens*). **Figure 31.12** shows that the critical experiment is to create a tissue (*in vitro*) whose continuity is interrupted by a layer of cells that can neither respond to activin nor synthesize it. If the gradient is not stopped by these cells, the activin must be able either to pass freely through them or (more likely) diffuse past them. This turns out to be the case (2169).

**Figure 31.12** Insertion of a layer of cells that cannot interact with activin does not prevent propagation of the gradient.

Formation of the anterior-posterior axis of the *Drosophila* wing is determined by a gradient of the TGF  $\beta$  homologue, Dpp (2172). Gradient formation may involve both of the mechanisms shown in **Figure 31.11** for controlling distribution. The gradient cannot be propagated unless the cells in the issue have an active receptor for TGF  $\beta$  and also the protein dynamin, which is involved in endocytosis (internalization) of Dpp (2171). The basic means of propagating the gradient appears to be transcytosis, in which Dpp is taken up at one face of the cell, transported across the cell, and secreted through the membrane at the other side. Some of the Dpp may be degraded instead of being passed on to the next cell. **Figure 31.13** implies that the shape of the gradient may be influenced by the balance between these two processes.

**Figure 31.13** A gradient can be propagated by transcytosis, when a morphogen is endocytosed (internalized) at one face of a cell and secreted at the other face. The gradient will be sharpened if some of the morphogen is degraded within the cell.

**GRADIENTS, CASCADES, AND SIGNALING PATHWAYS****6.31.9 Dorsal-ventral development uses localized receptor-ligand interactions**

---

**Key Concepts**

- Gurken mRNA is localized on the dorsal side of the oocyte.
  - It is translated into a TGF  $\alpha$ -like growth factor that interacts with the Torpedo receptor on the adjoining follicle cell.
  - The Torpedo receptor triggers a Ras/MAPK pathway that prevents the follicle cell from acquiring a ventral fate.
- 

Dorsal-ventral development displays a complex interplay between the oocyte and follicle cells, involving separate pathways that are required to develop ventral and dorsal structures. The formation of ventral pattern starts with the expression of genes in the oocyte that are needed for proper development of the follicle cells. And then expression of genes in the follicle cells transmits a signal to the oocyte that results in development of ventral structures. Another pathway is responsible for development of dorsal structures in the developing egg. Each of these systems functions by activating a localized ligand-receptor interaction that triggers a signal transduction pathway (886).

The localization of *gurken* mRNA initiates dorsal development, but also plays a role earlier in anterior-posterior patterning. These are key events that define the spatial asymmetry of the egg chamber. (The requirement of *gurken* for both pathways is the only feature that breaches their independence.)

First *gurken* mRNA is localized on the posterior side of the oocyte. This results in a signal that causes adjacent follicle cells to become posterior. The follicle cells signal back to the oocyte in a process that results in the establishment of a polarized network of microtubules. This is necessary for the localization of the maternal transcripts of *bicoid* and *oskar* to opposite poles (see *Molecular Biology 6.31.5 Anterior development uses localized gene regulators*).

Dorsal-ventral polarity is established later when *gurken* mRNA becomes localized on the dorsal side of the oocyte. **Figure 31.14** illustrates the pathway and its consequences. The products of *cornichon* and *brainiac* are needed for proper localization of the *gurken* mRNA or for activation of the protein. Of the group of loci that act earlier, the products of *K10* and *squid* are needed to localize the RNA; and *cappuccino* and *spire* mutants have an array of defects that suggest their products have a general role in organizing the cytoskeleton of the oocyte. Accordingly, *cappuccino* and *spire* are required also for the earlier localization of *gurken* mRNA involved in anterior-posterior patterning.

**Figure 31.14** Dorsal and ventral identities are first distinguished when *grk* mRNA is localized on the dorsal side of the oocyte. Synthesis of Grk activates the receptor coded by *torpedo*, which triggers a MAPK pathway in the follicle cells.

*gurken* codes for a protein that resembles the growth factor TGF  $\alpha$  (2885; 2886). The next locus in the pathway is *torpedo*, which codes for the *Drosophila* EGF receptor. It is expressed in the follicle cells. So the pathway moves from oocyte to follicle cells when the ligand (Gurken), possibly in a transmembrane form that exposes the extracellular domain on the oocyte, interacts with the receptor (Torpedo) on the plasma membrane of a follicle cell (for review see 2887).

An interesting and general principle emerges from the activation of Torpedo, which is a typical receptor tyrosine kinase. Activation of Torpedo leads to the activation of a Ras signaling pathway, which proceeds through Raf and D-mek (the equivalent of MAPKK), to activate a classic MAP kinase pathway. The ultimate readout of this pathway is not known, but its effect is to prevent activation on the dorsal side of the embryo of the ventral-determining pathway (see *Molecular Biology 6.31.10 Ventral development proceeds through Toll*).

The utilization of this pathway shows that similar pathways may be employed in

different circumstances to produce highly specific effects. The trigger to activate the pathway in the oocyte-follicle cell interaction is the specific localization of Gurken. The consequence is a change in the properties of follicle cells that prevents them from acquiring ventral fates. The basic components of the pathway, however, are the same as those employed in signal transduction of proliferation signals in vertebrate systems. The same pathway is employed again in the specific development of retinal cells in *Drosophila* itself, where another receptor-counter receptor interaction activates the Ras pathway, with specific, but very different effects on cell differentiation. So essentially the same pathway can be employed to interpret an initial signal and produce a response that is predetermined by the cell phenotype.

---

**GRADIENTS, CASCADES, AND SIGNALING PATHWAYS****6.31.10 Ventral development proceeds through Toll**

---

**Key Concepts**

- The follicle cell on the ventral side produces an enzyme that modifies a proteoglycan.
- The proteoglycan triggers a series of proteolytic cleavages in the perivitelline space of the oocyte that activate the spätzle ligand.
- spätzle activates the receptor Toll, which is related to IL1 receptor, and triggers a pathway leading to activation of dorsal, which is related to the vertebrate transcription factor NF- $\kappa$ B.

---

Development of ventral structures requires a group of 11 maternal genes whose products establish the dorsal-ventral axis between the time of fertilization and cellular blastoderm (see **Figure 31.4**). **Figure 31.15** shows that the dorsal-ventral pattern can be viewed from the side by the phenotype of the cuticle, and can be seen in cross-section to represent the formation of different types of tissues. The *dorsal* system is necessary for the development of ventral structures including the mesoderm and neurogenic ectoderm. (The system was named for the effects of mutations [to dorsalize], rather than for the role of the gene products [to ventralize].) Mutants in any genes of the *dorsal* group lack ventral structures, and have dorsal structures on the ventral side, as indicated in the figure. But injecting wild-type cytoplasm into mutant embryos rescues the defect and allows ventral structures to develop (for review see 367).

**Figure 31.15** Wild-type *Drosophila* embryos have distinct dorsal and ventral structures. Mutations in genes of the *dorsal* group prevent the appearance of ventral structures, and the ventral side of the embryo is dorsalized. Ventral structures can be restored by injecting cytoplasm containing the Toll gene product.

The ventral-determining pathway also begins in the follicle cell and ends in the oocyte. The pathway is summarized in **Figure 31.16**. The initial steps are not well defined, and require the expression of three loci in the follicle cells on the ventral side (2888). These loci function before fertilization, but the egg does not receive the signal until after fertilization.

**Figure 31.16** The dorso-ventral pathway is summarized on the right and shown in detail on the left. It involves interactions between follicle cells and the oocyte. The pathway moves into the oocyte when spatzle binds to Toll and activates the morphogen. The pathway is completed by transporting the transcription factor dorsal into the nucleus.

The three loci that act in the follicle cells are *nudel* (*ndl*), *windbeutel* (*wind*), and *pipe*. The roles of *ndl* and *wind* are not known, but *pipe* plays an interesting and novel role. *pipe* codes for an enzyme whose sequence suggests that it is similar to the enzyme heparan sulfate 2-O-sulfotransferase (HSST) that is involved in the synthesis of a class of proteins called proteoglycans. They are components of the extracellular

matrix. These proteins have covalently attached carbohydrate side-chains called glycosaminoglycans that have a characteristic pattern of attached monosaccharides. HSST is an enzyme that adds sulfate to the 2-O position of certain sugar residues in the monosaccharide.

The *pipe* gene is expressed in follicle cells on the ventral side of the embryo (2883). We assume that, like HSST, it functions within the Golgi apparatus of the follicle cell. Its substrate is not known, but **Figure 31.17** shows that it is probably secreted from the follicle cell into the perivitelline space (the outermost layer of the oocyte). Because the proteoglycan is synthesized on the ventral side, this creates an asymmetry at the surface of the egg.

**Figure 31.17** Pipe modifies a proteoglycan within the follicle cells. The modified protein is exported to the perivitelline space

The presence of the proteoglycan in some unknown way triggers a series of proteolytic cleavages that occur in the perivitelline space. Several proteases act in succession, ending with the cleavage of the *spatzle* product (2884). *spatzle* provides a ligand for a receptor coded by the *Toll* gene. *Toll* is the first component of the pathway that functions in the oocyte.

Rescue experiments identify *Toll* as the crucial gene that conveys the signal into the oocyte. *Toll*<sup>-</sup> mutants lack any dorsal-ventral gradient, and injection of *Toll* induces

the formation of dorsal-ventral structures. The other genes of the dorsal group code for products that either regulate or are required for the action of *Toll*, but they do not establish the primary polarity (896).

There is a paradox in the distribution of Toll protein. *Toll* gene product activity is found in all parts of a donor embryo when cytoplasm is extracted and tested by injection. Yet it induces ventral structures only in the appropriate location in normal development. An initial general distribution of *Toll* gene product must therefore in some way be converted into a concentration of active product by local events.

Toll is a transmembrane protein homologous to the vertebrate interleukin-1 (IL1) receptor. It is located in the plasma membrane of the egg cell, with its ligand-binding domain extending into the perivitelline space (2889). Binding of ligand is sufficient to activate the ventral-determining pathway. The reaction occurs on the ventral side of the perivitelline space. The spatzle ligand either cannot diffuse far from the site where it is generated, or perhaps it binds to Toll very rapidly, with the result that Toll is activated only on the ventral side of the embryo. Loss-of-function mutations in Toll are dorsalized, because the receptor cannot be activated. There are also dominant (*Toll<sup>D</sup>*) mutations, which confer ventral properties on dorsal regions; these are gain-of-function mutations, which are ventralized because the receptor is constitutively active. Genetic analysis shows that *toll* acts via *tube* and *pelle*. Tube is probably an adaptor protein that recruits the kinase *pelle* to the activated receptor. The target for the *pelle* kinase is not proven, but its activation leads to phosphorylation of the product of *cactus*, which is the final regulator of the transcription factor coded by *dorsal*.

**GRADIENTS, CASCADES, AND SIGNALING PATHWAYS****6.31.11 Dorsal protein forms a gradient of nuclear localization**

---

**Key Concepts**

- The activation of dorsal is achieved by releasing it in the cytoplasm so that it can enter the nucleus.
  - A gradient of dorsal with regard to nuclear localization is established along the ventral to dorsal axis.
- 

**Figure 31.18** shows the parallels between the *toll* signaling pathway in flies and the IL1 vertebrate pathway (where the biochemistry is well characterized). Activation of the receptor causes a complex to assemble that includes adaptor proteins (several in vertebrates), which bind a kinase. Activation of the vertebrate kinase (IRAK) in turn activates the kinase NIK, which phosphorylates I- $\kappa$ B. It is not clear whether the fly kinase (*pelle*) acts directly on cactus (the equivalent of I- $\kappa$ B) or through an intermediate.

**Figure 31.18** Activation of IL1 receptor triggers formation of a complex containing adaptor(s) and a kinase. The IRAK kinase activates NIK, which phosphorylates I- $\kappa$ B. This triggers degradation of I- $\kappa$ B, releasing NF- $\kappa$ B, which translocates to the nucleus to activate transcription.

At all events, dorsal and cactus form an interacting pair of proteins that are related to the transcription factor NF- $\kappa$ B and its regulator I- $\kappa$ B (3662; 3663; 3692). NF- $\kappa$ B consists of two subunits (related in sequence) which are bound by I- $\kappa$ B in the cytoplasm. When I- $\kappa$ B is phosphorylated, it releases NF- $\kappa$ B, which then moves into the nucleus, where it functions as a transcription factor of genes whose promoters have the  $\kappa$ B sequence motif. (An example of the pathway is illustrated in **Figure 22.12**.) Cactus regulates dorsal in the same way that I- $\kappa$ B regulates NF- $\kappa$ B (3693). A cactus-dorsal complex is inert in the cytoplasm, but when cactus is phosphorylated, it releases dorsal protein, which enters the nucleus. The pathway is therefore conserved from receptor to effector, since activation of interleukin-1 receptor has as a principal effect the activation of NF- $\kappa$ B, and activation of Toll leads to activation of dorsal. A related pathway, triggered by a Toll-like receptor (TLR), is found in the system of innate immunity that is conserved from flies to mammals (see *Molecular Biology 5.25.21 Innate immunity utilizes conserved signaling pathways*).

As a result of the activation of Toll, a gradient of dorsal protein in the nucleus is established, from ventral to dorsal side of the embryo. On the ventral side, dorsal protein is released to the nucleus, but on the dorsal side of the embryo it remains in the cytoplasm. A steep gradient is established at the stage of syncytial blastoderm, and becomes sharper during the transition to cellular blastoderm. The proportion of dorsal protein that is in the nucleus correlates with the ventral phenotype that will be displayed by this region. An example of a gradient visualized by staining with antibody against dorsal protein is shown in **Figure 31.19**. The total amount of dorsal protein in the embryo does not change: the gradient is established solely by a redistribution of the protein between nucleus and cytoplasm (899; 3694; for review see 368).

**Figure 31.19** Dorsal protein forms a gradient of nuclear localization from ventral to dorsal side of the embryo. On the ventral side (lower) the protein identifies bright nuclei; on the dorsal side (upper) the nuclei lack protein and show as dark holes in the bright cytoplasm. Photograph kindly provided by Michael Levine.

Dorsal both activates and represses gene expression. It activates the genes *twist* and *snail*, which are required for the development of ventral structures. And it represses the genes *dpp* and *zen*, which are required for the development of dorsal structures; as a result, these genes are expressed only in the 40% most dorsal of the embryo (see *Molecular Biology 6.31.13 TGF  $\beta$ /BMPs are diffusible morphogens*).

One of the crucial aspects of dorsal-ventral development is the relationship between the different pathways. This is summarized in **Figure 31.20**. The ability of one system to repress the next is responsible for restricting the localized activities to the appropriate part of the embryo. The initial interaction between *gurken* and *torpedo* leads to the repression of *spatzle* activity on the dorsal side of the embryo. This restricts the activation of dorsal protein to the ventral side of the embryo. Nuclear localization of dorsal protein in turn represses the expression of *dpp*, so that it forms a gradient diffusing from the dorsal side. In this way, ventral structures are formed in the nuclear gradient of dorsal protein, and dorsal structures are formed in the gradient of *dpp* protein.

**Figure 31.20** Dorsal-ventral patterning requires the successive actions of three localized systems.

The terminal system is initiated in a way that is similar to the dorsal-ventral system. A transmembrane receptor, coded by the *torso* gene, is produced by translation of a maternal RNA after fertilization. The receptor is localized throughout the embryo. It is activated at the poles by local production of an extracellular ligand. Torso protein has a kinase activity, which initiates a cascade that leads to local expression of the *tailless* and *huckebein* RNAs, which code for factors that regulate transcription.

## GRADIENTS, CASCADES, AND SIGNALING PATHWAYS

### 6.31.12 Patterning systems have common features

The pattern of regulators at each stage of development for each of the systems is summarized in **Figure 31.21**. Two types of mechanism are used to create the initial asymmetry. For the anterior-posterior axis, an RNA is localized at one end of the egg (*bicoid* for the anterior system, *nanos* for the posterior system); localization depends upon the interaction of sequences in the 3' end of the RNA with maternal proteins. In the case of the dorsal-ventral and terminal systems, a receptor protein is specifically activated in a localized manner, as the result of the limited availability of its ligand. All of these interactions depend on RNAs and/or proteins expressed from maternal genes.

**Figure 31.21** In each axis-determining system, localized products in the egg cause other maternal RNAs or proteins to be broadly localized at syncytial blastoderm, and zygotic RNAs are transcribed in bands at cellular blastoderm.

The local event leads to the production of a morphogen, which forms a gradient, either quantitatively (*bicoid*) or by nucleocytoplasmic distribution (dorsal), or is localized in a broad restricted region (*nanos*). The extent of the region in which the morphogen is active is ~50% across the egg for each of these systems. The morphogens are translated from maternal RNAs, and development is therefore still dependent on maternal genes up to this stage.

Establishing anterior-posterior and dorsal-ventral gradients is the first step in determining orientation and spatial organization of the embryo. Under the direction of maternal genes, gradients form across the common cytoplasm and influence the

behavior of the nuclei located in it. The next step is the development of discrete regions that will give rise to different body parts. This requires the expression of the zygotic genome, and the loci that now become active are called *zygotic genes*. Genes involved at this stage are identified by segmentation mutants.

The products of the segmentation genes form bands that distinguish individual regions on the anterior-posterior axis. When we consider the results of the anterior and posterior systems together, we see that there are several broad regions (the two regions generated by the anterior system are adjacent to the two regions defined by the posterior system; see **Figure 31.27**). On the dorsal-ventral axis, there are three rather broad bands that define the regions in which the mesoderm, neuroectoderm, and dorsal ectoderm form (proceeding from the ventral to the dorsal side).

**GRADIENTS, CASCADES, AND SIGNALING PATHWAYS****6.31.13 TGF  $\beta$ /BMPs are diffusible morphogens**

---

**Key Concepts**

- The TGF  $\beta$ /BMP family provides ligands for receptors that activate Smads transcription factors.
  - Synthesis of the Dpp member of this family is repressed on the ventral side of the fly embryo.
  - It diffuses from a source on the ventral side and induces neural tissues.
  - A similar pathway functions in vertebrates but is inverted with regard to the dorsal-ventral axis.
- 

The principle of dorsal-ventral development in flies, amphibians, and mammals is the same. On one side of the animal, neural structures (including the CNS) develop. This is the ventral side in flies, and the dorsal side in vertebrates. On the other side, mesenchymal structures develop. This is the dorsal side in flies, and the ventral side in vertebrates. The important point here is that the same relative development is seen from one side of the animal to the other, but its absolute direction is reversed between flies and vertebrates. This must mean that the dorsal-ventral axis was inverted at some point during evolution, causing the CNS to be displaced from the ventral side to the dorsal side. This idea is supported by the fact that the same signaling pathway is initiated on the dorsal side of flies and on the ventral side of vertebrate embryos (for review see 369).

Mesenchymal (non-neural) structures are determined by diffusible factors in the TGF  $\beta$ /BMP family. These factors are small polypeptide ligands for receptors that activate the Smads transcription factors (see **Figure 28.46**). Formation of neural structures requires counteracting activities that also diffuse from a center; they prevent the TGF  $\beta$ /BMP ligands from activating the target receptors. (The names reflect the histories of their discoveries as transforming growth factor  $\beta$  and bone morphogenetic proteins; but in fact the most important role of these polypeptides is as morphogens in development.)

The involvement of this pathway in development was first described in *Drosophila*, where the product of *dpp* is a member of the TGF  $\beta$  growth factor family. The receptors typically are heterodimers that form transmembrane proteins with serine/threonine kinase activity. The heterodimer consists of a type I component and a type II component. In the *dpp* pathway, there are two type I members (coded by *thick veins* and *saxophone*) and a single type II member (coded by *punt*). Mutations in *tkv* and *punt* have the same phenotype as mutations in *dpp*, suggesting that the *tkv/punt* heterodimer is the principal receptor (3695; 3696).

The activated receptor phosphorylates the product *mad*. This is the founding member of the Smad family. The typical pattern of activation in mammalian cells is for the

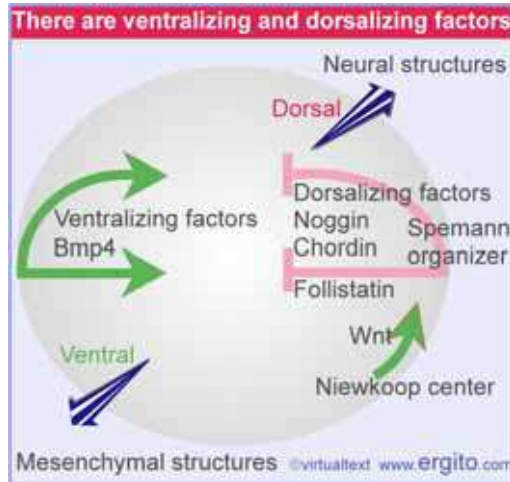

regulated Smad to associate with a general partner to form a heterodimer that is imported into the nucleus, where it activates transcription (see *Molecular Biology 6.28.21 TGF  $\beta$  signals through Smads*).

Because the gene is repressed on the ventral side, Dpp protein is secreted from cells only across the dorsal side of the embryo, as depicted in **Figure 31.22**. So Dpp is in effect the morphogen that induces synthesis of dorsal structures (902). Several loci influence the production of Dpp, largely by post-translational mechanisms. The net result is to increase Dpp activity on the dorsal side, and to repress it on the ventral side, of the embryo. The concentration of Dpp directly affects the cell phenotype, the most dorsal phenotypes requiring the greatest concentration (2172).

**Figure 31.22** The morphogen Dpp forms a gradient originating on the dorsal side of the fly embryo. This prevents the formation of neural structures and induces mesenchymal structures.

The same pathway is involved in inducing the analogous structures in frog or mouse, but it is inverted with regard to the Dorsal-ventral axis. **Figure 31.23** shows that Bmp4 is secreted from one side of the egg. It is antagonized by a variety of factors. Neural tissues develop in the (dorsal) regions which Bmp4 is prevented from reaching.

**Figure 31.23** Two common pathways are used in early development of *Xenopus*. The Nieuwkoop center uses the Wnt pathway to induce the Spemann organizer. The organizer diffuses dorsalizing factors that counteract the effects of the ventralizing BMPs.

The crucial unifying feature is that neural tissues are induced when the activity of Dpp/Bmp4 is antagonized. Typically the Dpp/Bmp diffuses from a source, and different phenotypes may be produced by different concentrations of the morphogen. It is controversial whether the morphogen diffuses extracellularly or whether there may be a relay system that propagates it from cell to cell. Analogous pathways, triggered by different Bmps, are involved in the development of many organs.

**Figure 31.24** compares the pathways in fly and frog. The basic principle is to control the availability of Dpp/Bmp. An antagonist binds to Dpp/Bmp and prevents it from binding to its receptor. The antagonists are large extracellular proteins. The antagonist is destroyed by a protease, releasing Dpp/Bmp. Neural tissue is formed in regions where Dpp/Bmp actions is prevented, whereas ectodermal tissue is formed in regions where Dpp/Bmp is activated.

**Figure 31.24** The TGF  $\beta$ /Bmp signaling pathway is conserved in evolution. The ligand may be sequestered by an antagonist, which is cleaved by a protease. Ligand binds to a dimeric receptor, causing the phosphorylation of a specific Smad, which together with a Co-Smad translocates to the nucleus to activate gene expression.

The fly pathway is well characterized for dorsal-ventral development. There are two types of mutants. Mutations in *sog* and *tsg* identify genes whose products antagonize Dpp, whereas mutations in *tolloid* suggest that it activates Dpp. Sog fulfills the role of antagonist illustrated in **Figure 31.24**, and is destroyed by the protease tolloid. Tsg is a sort of co-antagonist, which enhances the effect of Sog (1637; 1638; 1669).

The biochemical reactions actually have been better characterized for the corresponding frog proteins (Chordin is related to Sog). Frogs may have several such pathways, with a variety of Bmp ligands that interact in an overlapping manner with a family of receptors. The frog pathway shown in **Figure 31.24** is for the ventralizing effects of Bmp4, but the others are similar, although their specific effects on morphogenetic determination are of course different. There can be variation in specificity at each stage of the pathway. The antagonists, ligands, and receptors may be expressed in different places and times, providing specificity with regard to local concentrations of the morphogen, but there may also be partial redundancy. The genes for two proteins (Noggin and Chordin) both must be knocked out in mouse to produce a phenotype. Each receptor has specificity for certain Smads, so that

different target genes can be activated in different tissues.

## GRADIENTS, CASCADES, AND SIGNALING PATHWAYS

### 6.31.14 Cell fate is determined by compartments that form by the blastoderm stage

---

#### Key Terms

Many organisms have a **segmented** body plan that divides the body into a number of repeating units, called segments, along the anterior-posterior axis.

In *Drosophila*, a **parasegment** is a unit composed of the rear of one segment and the front of the adjacent segment.

In *Drosophila* the **gap genes** are a set of genes that help set up the segmentation of the embryo. Gap genes encode transcription factors that are expressed in broad regions of the embryo. Gap genes activate transcription of the pair-rule genes.

In *Drosophila* the **pair-rule** genes are a set of genes that help set up the segmentation of the embryo. They are expressed in a striped pattern with one stripe in every other future segment.

In *Drosophila*, **segment polarity** genes are a set of genes that help set up the segmentation of the embryo. They are expressed in a striped pattern with one stripe in every future segment. Each stripe indicates the posterior margin of a segment.

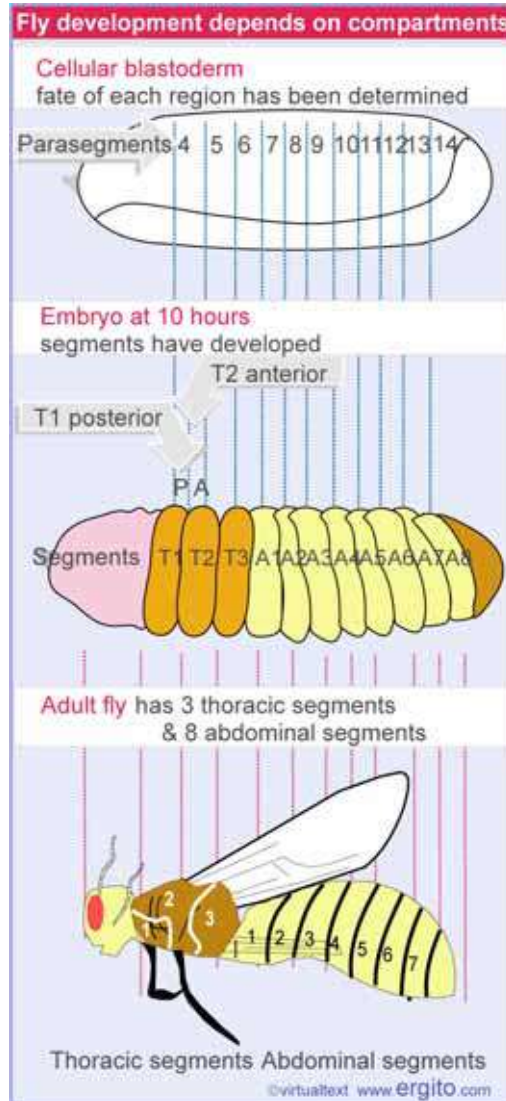

#### Key Concepts

- A compartment of cells is defined at blastoderm and will give rise to a specific set of adult structures.
- Each segment consists of an anterior compartment and posterior compartment.
- Segmentation loci are divided into three groups of genes.

---

By the blastoderm stage, cells have begun to acquire information about the pathways they will follow and the structures they will therefore form. This information derives initially from the maternal regulators, and then it is further refined by the actions of zygotic genes. This makes it possible to draw a "fate map" of the blastoderm embryo to identify each region in terms of the adult segments that will develop from the descendants of the embryonic cells. The concept that is intrinsic in the fate map is that a region identified at blastoderm consists of a "compartment" of cells that will give rise specifically to a particular adult structure.

We can consider the development of *D. melanogaster* in terms of the two types of unit depicted in **Figure 31.25**: the segment and parasegment.

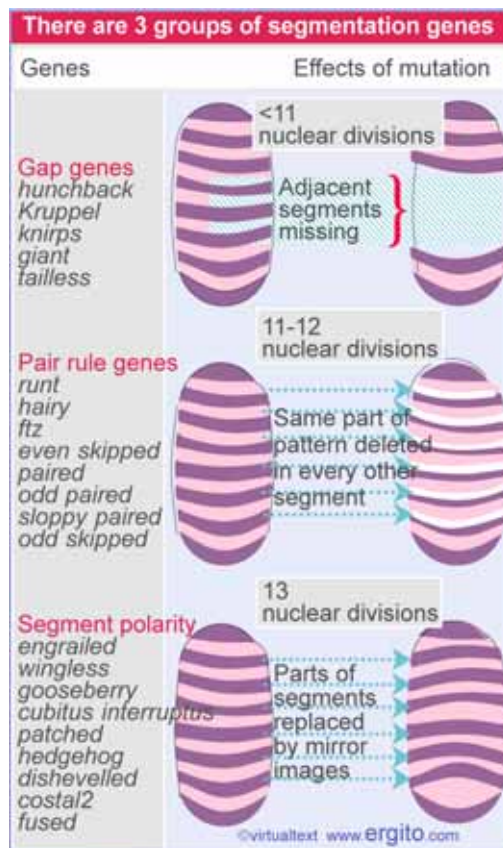

**Figure 31.25** *Drosophila* development proceeds through formation of compartments that define parasegments and segments.

- The **segment** is a visible morphological structure. The adult fly consists of a series of clearly demarcated segments, and the larva has a series of corresponding segments separated by grooves. We are concerned primarily with the three thoracic (T) and eight abdominal (A) segments, about whose development most is known. The pattern of segmental units is determined by blastoderm, when the main mass of the embryo is divided into a series of alternating anterior (A) and posterior (P) compartments. So a segment consists of an A compartment succeeded by a P compartment; segment A3, for example, consists of compartments A3A and A3P.
- Another type of classification originates earlier, when divisions can first be seen at gastrulation. The embryo can be divided into **parasegments**, each consisting of a P compartment succeeded by an A compartment. Parasegment 8, for

example, consists of compartments A2P and A3A. In the 5-6 hour embryo, shallow grooves on the surface separate the adjacent parasegments. When segments form at around 9 hours, the grooves deepen and move, so that each segmental boundary represents the center of a parasegment. So the anterior part of the segment is derived from one parasegment, and the posterior part of the segment is derived from the next parasegment. In effect, the segmental units are initially evident as P-A pairs in parasegments, and then are recognized as A-P pairs in segments.

How are these compartments defined during embryogenesis? The general nature of segmentation mutants suggests that the functions of segmentation genes are to establish "rules" by which segments form; *a mutation changes a rule in such a way as to cause many or all segments to form improperly*. The drastic consequences of segment malformation make these mutants embryonic lethals – they die at various stages before metamorphosis into adults (880).

Probably ~30 loci are involved in segment formation. **Figure 31.26** shows that they can be classified according to the size of the unit that they affect:

**Figure 31.26** Segmentation genes affect the number of segments and fall into three groups.

- **Gap gene** mutants have a group of several adjacent segments deleted from the

final pattern. Four gap genes are involved in formation of the major body segments, and others are concerned with the head and tail structures.

- **Pair-rule** mutants have corresponding parts of the pattern deleted in every other segment. The afflicted segments may be even-numbered or odd-numbered. There are 8 pair-rule genes.
- **Segment polarity** mutants most often lose part of the P compartment of each segment, and it is replaced by a mirror image duplication of the A compartment. Some mutants cause loss of A compartments or middle segments. There are ~16 segment polarity genes.

These groups of genes are expressed at successive periods during development; and they define increasingly restricted regions of the egg, as can be seen from **Figure 31.27**. The maternal genes establish gradients from the anterior and posterior ends. The maternal gradients either activate or repress the gap genes, which are amongst the earliest to be transcribed following fertilization (following the 11th nuclear division); they divide the embryo into 4 broad regions. The gap genes regulate the pair-rule genes, which are transcribed slightly later; their target regions are restricted to *pairs* of segments. The pair-rule genes in turn regulate the segment polarity genes, which are expressed during the 13th nuclear division, and by now the target size is the *individual* segment.

**Figure 31.27** Maternal and segmentation genes act progressively on smaller regions of the embryo.

Many of the maternal genes, the gap genes, and the pair-rule genes are regulators of transcription. Their effects may be either to activate or to repress transcription; in some cases, a given protein may activate some target genes and repress other target genes, depending on its level or the context. The genes in any one class regulate one another as well as regulating the genes of the next class. When we reach the level of segment polarity genes, the nature of the regulatory event changes, and many of the gene products act on communication between cells to maintain borders between compartments, for example, to control the secretion of a protein from one cell to influence its neighbor (for review see 363; 358).

The principle that emerges from this analysis is that at each stage *a small number of maternal, gap, and pair-rule regulator proteins is used in combinatorial associations to specify the pattern of gene expression in a particular region of the embryo* (for review see 3705).

---

**GRADIENTS, CASCADES, AND SIGNALING PATHWAYS****6.31.15 Gap genes are controlled by bicoid and by one another**

---

**Key Concepts**

- Gap genes affect a group of segments, and are controlled by bicoid and by interactions among themselves.
  - Pair-rule genes are expressed in either even- or odd-numbered segments, and are controlled by the gap genes.
  - Segment polarity mutants are controlled by the pair-rule genes, and are expressed in segments where they affect anterior or posterior identification of the compartments.
- 

The gap genes are controlled in two ways: they may respond directly to the bicoid morphogen; and they regulate one another. The four bands shown in **Figure 31.27** are created by the levels of the two proteins bicoid and hunchback (3704). The synthesis of hunchback mRNA is activated by bicoid (3702). Hunchback protein forms a gradient in the egg that in turn controls the expression of other genes.

The most anterior band in **Figure 31.27** consists of hunchback protein. The next band consists of Kruppel protein; transcription of the *Kruppel* gene is activated by hunchback protein. The next two bands consist of knirps and giant proteins. Transcription of these genes is repressed by hunchback. They are expressed in the posterior part of the embryo because nanos has prevented the expression of hunchback there.

**Figure 31.28** examines the transition from the 4 band to the 7 striped stage in more detail. The detailed interactions among the gap proteins are determined by examining the pattern of the distribution of other gap proteins in a mutant lacking one particular gap protein. Hunchback plays an especially important role. It is expressed in a broad anterior region, with a gradient of decline in the middle of the embryo. High levels of hunchback repress *Kruppel*; this determines the anterior boundary of Kruppel expression, which rises just as hunchback falls off, in parasegment 3. But some level of hunchback is needed for *Kruppel* expression, so when the level of hunchback decreases further, *Kruppel* is turned off, around parasegment 5. In the same way, expression of *giant* responds to successive changes in the level of hunchback; and *knirps* expression requires the absence of hunchback.

**Figure 31.28** Expression of the gap genes defines adjacent regions of the embryo. The gap genes control the pair-rule genes, each of which is expressed in 7 stripes.

The control is refined further by interactions among the proteins. *The general principle is that one interaction may be required to express a protein in a particular region, and other interactions may be required to repress its expression at the boundaries.* The effects are worked out by examining pairwise interactions. For example, overexpression of *giant* causes the Kruppel band to become much narrower, suggesting that *giant* contributes to repressing the boundaries of Kruppel. The posterior margins of *knirps* and *giant* are determined by the operation of the terminal system. Altogether, these interactions mean that, as we proceed along the egg from anterior to posterior, any particular position can be defined by the levels of the various gap proteins.

## GRADIENTS, CASCADES, AND SIGNALING PATHWAYS

## 6.31.16 Pair-rule genes are regulated by gap genes

## Key Concepts

- Pair-rule genes are expressed in either even- or odd-numbered segments, and are controlled by the gap genes.

All the gap proteins are regulators of transcription, and in addition to regulating one another, they regulate the expression of the pair-rule genes that function at the next stage. Each pair-rule protein is found in a pattern of 7 "stripes" along the embryo, and **Figure 31.28** shows the approximate positions that these stripes will take as the result of expression of the gap genes (3707). (Of course, the parasegments have not developed yet, and are shown just to relate their positions to the protein distribution.) The 7 stripes of a pair-rule gene identify either all the odd-numbered parasegments (like *eve*) or all the even-numbered parasegments (like *ftz*). Two of the pair-rule genes, *hairy* and *eve*, are called primary pair-rule genes, because they are expressed first, and their pattern of expression influences the expression of the other pair-rule genes.

Recall that mutations in pair-rule genes delete half the segments. **Figure 31.29** compares the segmentation patterns of wild-type and *fushi tarazu* (*ftz*) larvae. The mutant has only half the number of segments, because every other segment is missing.

**Figure 31.29** *ftz* mutants have half the number of segments present in wild-type. Photographs kindly provided by Walter Gehring.

The *ftz* mRNA is present from early blastoderm to gastrula stages of development.

**Figure 31.30** shows the locations of the transcripts, visualized *in situ* at blastoderm in wild type. The gene is expressed in 7 stripes, each 3-4 cells wide, running across the embryo. As shown previously in **Figure 31.28**, the stripes correspond to even-numbered parasegments (4 = T1P/T2A, 6= T3P/A1A, 8 = A2P/A3A, etc.).

**Figure 31.30** Transcripts of the *ftz* gene are localized in stripes corresponding to even numbered parasegments. The expressed regions correspond to the regions that are missing in the *ftz* mutant of the previous figure. Photograph kindly provided by Walter Gehring.

This pattern suggests a function for the *ftz* gene: *it must be expressed at blastoderm for the structures that will be descended from the even-numbered parasegments to develop*. Mutants in which *ftz* is defective lack these parasegments because the gene product is absent during the period when they must be formed. In other words, expression of *ftz* is required for survival of the cells in the regions in which it is expressed.

The expression of *ftz* is an example of the general rule that the stripes in which a pair-rule gene is expressed correspond to the regions that are missing from the embryo when the gene is mutated. *Compartments are therefore determined by the pattern of expression of segmentation genes*. The width of the stripe in which a gene is expressed corresponds to the size of the segmental unit that it affects. Different mechanisms are used to specify the expression patterns of different pair-rule genes; we have the most information about *ftz* and *eve*.

In the early embryo, *ftz* is uniformly expressed. If protein synthesis is blocked before the stripes develop, the embryo retains the initial pattern. So the development of stripes depends on the specific degradation of *ftz* RNA in the regions between the bands and at the anterior and posterior ends of the embryo. Once the stripes have developed, transcription of *ftz* ceases in the interbands and at the ends of the embryo. The specificity of transcription depends on regions upstream of the *ftz* promoter, and also on the function of several other segmentation genes. The transcription of *ftz* responds to other pair-rule genes (and perhaps gap genes) through elements that act on all stripes.

The expression pattern of *eve* is complementary to *ftz*, but has a different basis: it is controlled separately in each stripe. A detailed reconstruction using subregions of the *eve* promoter shows that the information for localization in each stripe is coded in a separate part of the promoter; the promoter can be divided into regions that respond to the local levels of gap gene products in particular parasegments. For example, the promoter region that is responsible for *eve* expression in parasegment 3 has binding

sites for the gap proteins bicoid, hunchback, giant, and Kruppel. **Figure 31.31** shows that this part of the promoter extends for 480 bp. It works in the following way. *eve* transcription is activated by hunchback and bicoid. The two boundaries are determined because the promoter is repressed by giant on the anterior side and by Kruppel on the posterior side (see also **Figure 31.28**). Other parts of the promoter respond to the protein levels in other parts of the embryo. So the different stripes of the primary pair-rule gene products are regulated by separate pathways, each of which is susceptible to activation by a particular combination of gap gene products and other regulators.

**Figure 31.31** The *eve* stripe in parasegment 3 is activated by hunchback and bicoid. Repression by giant sets the anterior boundary; repression by Kruppel sets the posterior boundary. Multiple binding sites for these proteins in a 480 bp region of the promoter control expression of the gene.

This illustrates in miniature the principle that combinations of proteins control gene expression in local areas. The general principle is that generally distributed proteins (such as bicoid or hunchback) are needed for activation, whereas the borders are formed by selective repression (by giant and Kruppel in this particular example). We should emphasize that the hierarchy of gene control is not exclusively restricted to interactions between successive stages of control (maternal gap pair-rule). For

example, the involvement of bicoid protein in regulating *eve* transcription in parasegment 3 shows that a maternal gene may have a direct effect on a pair-rule gene.

The stripes of *eve* and *ftz* are fuzzy to begin with, and become sharper as development proceeds, corresponding to more finely defined units. **Figure 31.32** shows an example of an embryo simultaneously stained for expression of *ftz* and *eve*. Initially there is a series of alternating fuzzy stripes, but the stripes narrow from the posterior margin and sharpen on the anterior side as they intensify during development. This may depend on an autoregulatory loop, in which the expression of the gene is regulated by its own product.

**Figure 31.32** Simultaneous staining for *ftz* (brown) and *eve* (grey) shows that they are first expressed as broad alternating stripes at the time of blastoderm (upper), but narrow during the next 1 hour of development (lower). Photographs kindly provided by Peter Lawrence.

**GRADIENTS, CASCADES, AND SIGNALING PATHWAYS****6.31.17 Segment polarity genes are controlled by pair-rule genes**

---

**Key Concepts**

- Segment polarity genes are expressed in segments where they affect anterior or posterior identification of the compartments.
- 

The pair-rule genes control the expression of the segment polarity genes, which are expressed in 14 stripes. Each stripe identifies a segment. The compartmental pattern in which segment polarity genes are expressed is exceedingly precise. Perhaps the ultimate demonstration of precision is provided by the pattern gene *engrailed*. The function coded by *engrailed* is needed in all segments and is concerned with the distinction between the A and P compartments. *engrailed* is expressed in every P compartment, but not in A compartments (3701; 3700; 3702). Mutants in this gene do not distinguish between anterior and posterior compartments of the segments.

Antibodies against the protein coded by *engrailed* react against the nucleus of cells expressing it. The regions in which *engrailed* is expressed form a pattern of stripes. When the stripes of engrailed protein first become apparent, *they are only one cell wide*. **Figure 31.33** shows the pattern at a stage when each segment has a stripe just 1 cell in width, with the stripe beginning to widen into several cells.

**Figure 31.33** Engrailed protein is localized in nuclei and forms stripes as precisely delineated as 1 cell in width. Photograph kindly provided by Patrick O#Farrell.

Actually, the pattern of stripes becomes established over a 30 minute period, moving along the embryo from anterior to posterior. Initially one stripe is apparent; then every other segment has a stripe; and finally the complete pattern has a stripe 3-4 cells wide corresponding to the P compartment of every segment.

The expression of *engrailed* is of particular importance, because it defines the boundaries of the actual compartments from which adult structures will be derived.

The initial 1-cell-wide stripes of engrailed protein form at the anterior boundaries of both the *ftz* and *eve* stripes, and delineate what will become the anterior boundary of every P compartment. Why is *engrailed* initially transcribed exclusively in this anterior edge, within the broader stripes of *ftz* and *eve* expression? This question is a specific example of a more general question: how can a broad stripe be subdivided into more restricted, narrower stripes? We can consider two general types of model:

- A combinatorial model supposes that different genes are expressed in overlapping patterns of stripes. A pattern of stripes develops for each of the pair-rule genes. The different pair-rule gene stripes overlap, because they are out of phase with one another. As a result of these patterns, different cells in the cellular blastoderm express different combinations of pair-rule genes. Each compartment is defined by the particular combination of the genes that are expressed, and these combinations determine the responses of the cells at next stage of development. In other words, the segmentation genes are controlled by the pair-rule genes in the same general manner that the pair-rule genes are controlled by the gap genes.
- A boundary model supposes that a compartment is defined by the striped pattern of expression, but that interactions involving cell-cell communication at the boundaries cause subdivisions to arise within the compartment. In the case of *engrailed*, we would suppose that some unique event is triggered by the juxtaposition of cells possessing *ftz* (or *eve*) with cells that do not, and this is necessary to trigger *engrailed* expression.

Each of the 14 segments is subdivided further into anterior and posterior compartments by the activities of the segment polarity genes. The actions of the segment polarity genes are the same in every segment. For example, *engrailed* distinguishes the A and P compartments.

*engrailed* is a transcription factor, but other segment polarity genes have different types of functions. The products of the segment polarity genes include secreted proteins, transmembrane proteins, kinases, cytoskeletal proteins, as well as transcription factors. Cell-cell interactions become important at this stage for defining and maintaining the nature of the compartments (see *Molecular Biology* 6.31.18 *Wingless and engrailed expression alternate in adjacent cells*).

**GRADIENTS, CASCADES, AND SIGNALING PATHWAYS****6.31.18 Wingless and engrailed expression alternate in adjacent cells**

---

**Key Concepts**

- Wingless and engrailed have a mutually reinforcing interaction between neighboring cells.
- Wingless is secreted at the posterior boundary of a cell.
- It activates the Fz (or dFz2) receptor in the adjacent cell, which triggers the translocation of Armadillo to the nucleus.
- Armadillo causes engrailed to be expressed, and engrailed causes secretion of hedgehog at the anterior boundary, where it acts on the neighboring cell to maintain Wingless expression.

---

The circuit that defines the boundaries between anterior and posterior compartments is based on mutual interactions between segment polarity genes. *wingless* codes for a protein that is secreted and taken up by the adjacent row of cells. It is initially expressed in a row of cells immediately adjacent to the anterior side of the cells expressing *engrailed*; so *wingless* comes to identify the posterior boundary of the preceding parasegment. The initial expression of *engrailed* in response to *ftz* and *eve* is shortly replaced by an autoregulatory loop in which secretion of wingless protein from the adjacent cells is needed for expression of *engrailed*; and expression of *engrailed* is needed for expression of *wingless*. This keeps the boundary sharp.

The wingless signaling pathway is one of the most interesting, and has close parallels in all animal development. Like other signaling pathways utilized in development, it is initiated by an extracellular ligand, and results in the expression of a transcription factor, although the interactions between components of the pathway are somewhat unusual.

In fly embryonic development at the stage of segmental definition, the cells that define the boundaries of the A and P compartments express wingless (Wg) and engrailed (En) in a reciprocal relationship. **Figure 31.34** shows that wingless protein is secreted from a cell at a boundary, and acts upon the cell on its posterior side. The *wingless* signaling pathway causes the *engrailed* gene to be expressed. Engrailed causes the production of hedgehog (Hh) protein, which in turn is secreted. Hedgehog acts on the cell on its anterior side to maintain *wingless* expression. Wg is also required for patterning of adult eyes, legs, and wings (hence its name) (898).

**Figure 31.34** Reciprocal interactions maintain Wg and Hh signaling between adjacent cells. Wg activates a receptor, which activates a pathway leading to translocation of Arm to the nucleus. This activates engrailed, which leads to expression of Hedgehog protein, which is secreted to act on the neighboring cell, where it maintains Wg expression.

The identification of the receptor for Wg on the posterior cell has actually been very difficult. Wg interacts with frizzled *in vitro*, but mutational analysis suggests that the related protein, DFz2 (*Drosophila frizzled-2*) is the receptor. It is possible that these may play redundant roles. Another protein that is required for reception/signaling is the product of *arrow*, which is a single-pass membrane protein and is classified as a coreceptor (2894). The frizzled family members are 7-membrane pass proteins, with the appearance of classical receptors (although the major pathway does not appear to involve G proteins) (903; 2896).

**GRADIENTS, CASCADES, AND SIGNALING PATHWAYS****6.31.19 The wingless/wnt pathway signals to the nucleus**

---

**Key Concepts**

- Wingless (in *Drosophila*) and Wnt (in vertebrates) activate a receptor that blocks the action of a cytosolic Ser/Thr kinase.
- The kinase phosphorylates Armadillo/  $\beta$ -catenin that is localized in cytosolic complexes.
- In the absence of phosphorylation, Armadillo/  $\beta$ -catenin is stabilized, and translocates to the nucleus where it activates transcription.
- A separate pool of Armadillo/  $\beta$ -catenin is present in complexes at the cell surface, but is not a target for the pathway.
- The function of the cancer-causing gene APC is to destabilize  $\beta$ -catenin, and colon cancers caused by mutation in APC have elevated levels of  $\beta$ -catenin.

---

The interaction between Wingless and its receptor activates a signaling pathway. The effector of the pathway is a protein called Arm (Armadillo) in *Drosophila* and  $\beta$ -catenin in vertebrate cells. A cytoplasmic pool of the effector protein is constitutively degraded, and the role of the signaling pathway is to block the degradation. When this happens, Arm/  $\beta$ -catenin is transported to the nucleus, where it activates transcription of a set of target genes.

Mutants in other genes that have segment polarity defects similar to *wg* mutants identify the other components of the pathway. They signal positively to execute the pathway. Mutations that have the opposite phenotype, and that block the pathway, identify proteins that are required to degrade Arm/  $\beta$ -catenin. **Figure 31.35** shows the results of ordering the genes genetically, and defining the biochemical interactions between their products.

**Figure 31.35** Wg secretion is assisted by porc. Wg activates the Dfz2 receptor, which inhibits Zw3 kinase. Active Zw3 causes turnover of Arm. Inhibition of Zw3 stabilizes Arm, allowing it to translocate to the nucleus. In the nucleus, Arm partners Pan, and activates target genes (including engrailed). A similar pathway is found in vertebrate cells (components named in blue).

The fly and vertebrate transduction pathways have homologous components. The components in the order of their function in the pathway are:

- Dsh (coded by *Dishevelled*) is a phosphoprotein that responds to the interaction of wingless/Wnt with the frizzled receptor.
- Dsh signals to a Ser/Thr kinase, called Zw3 in *Drosophila*, but called GSK3 in vertebrates (named for its historical identification as glycogen synthase kinase, but in fact a homologue of Zw3). Zw3/GSK3 is constitutively active, unless and until it is inactivated by Dsh.

Zw3/GSK phosphorylates a serine in the N-terminus of Arm/  $\beta$ -catenin. This creates a binding site for the small polypeptide ubiquitin, which causes the protein to be degraded by the proteasome (see *Molecular Biology 2.8.31 Ubiquitination targets proteins for degradation*).

Zw3/GSK is the catalytic component of a protein aggregate called *the  $\beta$ -catenin destruction complex*. A scaffolding protein called Axin enables Zw3/GSK to bind to the Arm/  $\beta$ -catenin target. Another component, called APC, dissociates the phosphorylated Arm/  $\beta$ -catenin from Zw3/GSK after the reaction is complete 4518.

This signaling pathway is also implicated in colon cancer. Mutations in *APC* (adenomatous polyposis coli) are common in colon cancer. As a component of the  $\beta$ -catenin destruction complex, APC is required for destabilizing Arm/  $\beta$ -catenin. The mutant proteins found in colon cancer allow levels of  $\beta$ -catenin to increase. Mutations in  $\beta$ -catenin that increase its stability have the same effect. Inappropriate activation of the Wnt signaling pathway therefore contributes to colon cancer.

When its degradation is inhibited and Arm/  $\beta$ -catenin accumulates, it translocates to the nucleus. There it binds to a partner (called Pan in *Drosophila*, and called Tcf/LEF1 in vertebrates, depending on the system). The complex activates transcription at promoters that are bound by the Pan/Tcf subunit. When Tcf1 binds to DNA,  $\beta$ -catenin can activate transcription at the target promoters (904; 905).

So wingless/Wnt signaling controls the availability of Arm/  $\beta$ -catenin by causing its degradation to be inhibited. The most surprising feature of this pathway is the nature of the Arm/  $\beta$ -catenin protein. It has two unconnected activities.

- It is a component of a complex that links the cytoskeleton at adhesion complexes.  $\beta$ -catenin binds to cadherin. Mutations of *armadillo* that disrupt the cadherin-binding site show a defect in cell adhesion.
- A separate domain of Arm/  $\beta$ -catenin has a transactivation function when the protein translocates to the nucleus (2167).

How does Arm/  $\beta$ -catenin participate in two so very different activities? It is in fact bound by a large number of potential partners. Most of them recognize a series of repeats in the central sequence of the protein, with the result that most of these complexes are mutually exclusive. The various complexes are localized in different places in the cell. When Arm/  $\beta$ -catenin binds to cadherins or certain other proteins of the plasma membrane, it forms a complex that participates in cell-cell adhesion. This complex is not a target for the wingless/Wnt pathway, which acts on Arm/  $\beta$ -catenin that is free in the cytosol (for review see 2897).

**GRADIENTS, CASCADES, AND SIGNALING PATHWAYS****6.31.20 Complex loci are extremely large and involved in regulation**

---

**Key Terms**

**Homeotic genes** are defined by mutations that convert one body part into another; for example, an insect leg may replace an antenna.

A **complex locus** (of *D. melanogaster*) has genetic properties inconsistent with the function of a gene representing a single protein. Complex loci are usually very large (>100 kb) at the molecular level.

**Key Concepts**

- Complex loci were identified by interallelic interactions that did not fit the usual complementation behavior.
- They are extremely large and may include multiple protein-coding units as well as *cis*-acting regulatory sites.
- The order of mutations from upstream to downstream corresponds to the order of the body parts that are affected from anterior to posterior.
- *ANT-C* includes several genes that affect head segments, whereas *BX-C* has only three genes and many regulatory sites.
- A segment is distinguished from the preceding (anterior-side) segment by expression of an additional protein-coding unit.
- Loss of a protein-coding unit causes a homeotic transformation in which a segment has the identity of the segment on its anterior-side.

---

Segment polarity genes control the anterior-posterior pattern within each segment. **Homeotic genes** impose the program that determines the unique differentiation of each segment. Most homeotic genes are expressed in a spatially restricted manner that corresponds to parasegments.

Homeotic genes interact in complicated interlocking patterns. Many homeotic genes code for transcription factors that act upon other homeotic genes as well as upon other target loci. As a result, a mutation in one homeotic gene influences the expression of other homeotic genes. The consequence is that *the final appearance of a mutant depends not only on the loss of one homeotic gene function, but also on how other homeotic genes change their spatial patterns in response to the loss.*

Homeotic genes act during embryogenesis. Their expression depends on the prior expression of the segmentation genes; we might regard the homeotic genes as integrating the pattern of signals established by the segmentation genes. Homeotic mutants "transform" part of a segment or an entire segment into another type of segment; they may cause one segment of the abdomen to develop as another, legs to

develop in place of antennae, or wings to develop in place of eyes. Note that homeotic genes do not *create* patterns *de novo*; they modify cell fates that are determined by genes such as the segment polarity genes, by switching the set of genes that functions in a particular place. Indeed, the segment polarity genes are active at about the same time as the peak of expression of the homeotic genes.

The genetic properties of some homeotic mutations are unusual and led to the identification of complex loci (for review see 357; 2881; 2882). A conventional gene – even an interrupted one – is identified at the level of the genetic map by a cluster of noncomplementing mutations. In the case of a large gene, the mutations might map into individual clusters corresponding to the exons. A hallmark of a **complex locus** is that, in addition to rather well-spaced groups of mutations, extending over a relatively large map distance, there are complex patterns of complementation, in which some pairwise combinations complement but others do not. The individual mutations may have different and complex morphological effects on the phenotype. These relationships are caused by the existence of an array of regulatory elements. Many of the bizarre results that are obtained in complementation assays turn out to result from mutations in promoters or enhancers that affect expression in one cell type but not another. We now recognize that complex loci do not have any novel features of genetic organization, apart from the fact that they have many regulatory elements that control expression in different parts of the embryo.

Two of the complex loci are involved in regulating development of the adult insect body. The *ANT-C* and *BX-C* complex loci together provide a continuum of functions that specify the identities of all of the segmented units of the fly. Each of these complexes contains several homeotic genes. The two separate complexes may have evolved from a split in a single ancestral complex, as suggested by the evolution of the corresponding genes in other species. In the beetle *Tribolium*, the *ANT-C* and *BX-C* complexes are found together at a single chromosomal location. The individual genes may have been derived from duplications and mutations of an original ancestral gene. And in mammals, there are arrays of related genes whose individual members are related sequentially to the genes of the *ANT-C* and *BX-C* complexes (see *Molecular Biology 6.31.22 The homeobox is a common coding motif in homeotic genes*).

The homeotic genes clustered at the *ANT-C* and *BX-C* complexes show a relationship between genetic order and the position in which they are expressed in the body of the fly. *Proceeding from left to right, each homeotic gene in the complex acts upon a more posterior region of the fly. The basic principle is that formation of a compartment requires the gene product(s) expressed in the previous compartment, plus a new function coded by the next gene along the cluster.* So loss-of-function mutations usually cause one compartment to have the phenotype of the corresponding compartment on its anterior side. The individual genes code for a set of transcription factors that have related DNA-binding domains (see next section).

The identities of the most anterior parts of the fly (parasegments 1-4) are specified by *ANT-C*, which contains several homeotic genes, including *labial (lab)*, *proboscipedia (pb)*, *Deformed (Dfd)*, *Sex combs reduced (Scr)*, and *Antennapedia (Antp)*. The homeotic genes lie in a cluster over a region of ~350 kb, but several other genes are interspersed; most of these genes are regulators that function at different stages of development (356).

**Figure 31.36** correlates the organization of *ANT-C* with its effects upon body parts. Adjacent genes are expressed in successively more posterior parts of the embryo, ranging from the leftmost gene *labial* (the most anterior acting, which affects the head) to the rightmost gene *Antp* (the most posterior acting, which affects segments T2–T3).

**Figure 31.36** The homeotic genes of the *ANT-C* complex confer identity on the most anterior segments of the fly. The genes vary in size, and are interspersed with other genes. The *antp* gene is very large and has alternative forms of expression.

The *Antp* gene gave its name to the complex, and among the mutations in it are alleles that change antennae into second legs, or second and third legs into first legs. *Antp* usually functions in the thorax; it is needed both to promote formation of segments T2-T3 and to suppress formation of head structures. Loss of function therefore causes T2-T3 to resemble the more anterior structure of T1; gain of function, for example, by overexpression in the head, causes the anterior region to develop structures of the thorax. (The molecular action of *Antp* is to prevent the action of genes *hth* and *exd* that promote formation of antennal structures. *Hth* causes *exd* to be imported into the nucleus, where it switches on the genes that make the antenna.)

**Figure 31.36** summarizes the organization of the gene. It has 8 exons, separated by very large introns, and altogether spanning ~103 kb. The single open reading frame begins only in exon 5, and apparently gives rise to a protein of 43 kD. The discrepancy between the length of the locus and the size of the protein means that only 1% of its DNA codes for protein (882).

Transcription starts at either of two promoters, located ~70 kb apart! One promoter is located upstream of exon 1, the other upstream of exon 3. Use of the first promoter is associated with omission of exon 3. The transcripts generated from either promoter end either within or after exon 8. All the transcripts appear to code for the same protein. Each promoter has its own tissue-specific expression pattern (3708). We do not know if there is any significance to the difference in the structure of the two types of transcript.

The other genes of the *ANT-C* complex are expressed in the head and first thoracic segment. In the most anterior compartments, *lab*, *pb*, *Dfd*, have unique patterns of expression, so that deletions of segmental regions can result from loss-of-function mutations. An exception to the left-right/anterior-posterior order of action is that loss of *Scr* allows the overlapping *Antp* to function, that is, the direction of transformation is opposite from usual.

---

**GRADIENTS, CASCADES, AND SIGNALING PATHWAYS****6.31.21 The *bithorax* complex has *trans*-acting genes and *cis*-acting regulators**

---

**Key Terms**

The **bithorax complex** is a group of homeotic genes which are responsible for the diversification of the different segments of the fly.

**Key Concepts**

- *bithorax* controls body structures from T2 to A8.
- The ultrabithorax domain has the *Ubx* transcription unit.
- The infraabdominal domain has the *AbdA* and *AbdB* transcription units.
- The order of units on the genetic map coincides with the order of body parts.
- Expression of additional units specifies more posterior body parts.

---

The classic complex homeotic locus is *BX-C*, the **bithorax complex**, characterized by several groups of homeotic mutations that affect development of the thorax, causing major morphological changes in the abdomen. When the whole complex is deleted, the insect dies late in embryonic development. Within the complex, however, are mutations that are viable, but which change the phenotype of certain segments. An extreme case of homeotic transformation is shown in **Figure 31.37**, in which a triple mutation converts T3A (which carries the halteres [truncated wings]) into the tissue type of the T2 (which carries the wings). This creates a fly with four wings instead of the usual two (881).

**Figure 31.37** A four-winged fly is produced by a triple mutation in *abx*, *bx*, and *pbx* at the *BX-C* complex. Photograph kindly provided by Ed Lewis.

The genetic map of *BX-C* is correlated with the body structures that it controls in the fly in **Figure 31.38**. The body structures extend from T2 to A8. The *BX-C* complex is therefore concerned with the development of the major part of the body of the fly.

Like *ANT-C*, a crucial feature of this complex is also that mutations affecting particular segments lie in the same order on the genetic map as the corresponding segments in the body of the fly. Proceeding from left to right along the genetic map, mutations affect segments in the fly that become successively more posterior (895; for review see 3709).

**Figure 31.38** The bithorax (*BX-C*) locus has 3 coding units. A series of regulatory mutations affects successive segments of the fly. The sites of the regulatory mutations show the regions within which deletions, insertions, and translocations confer a given phenotype.

A difference between *ANT-C* and *BX-C* is that *ANT-C* functions largely or exclusively via its protein-coding loci, but *BX-C* displays a complex pattern of *cis*-acting interactions in addition to the effects of mutations in protein-coding

regions. The *BX-C* occupies 315 kb, of which only 1.4% codes for protein. The individual mutations fall into two classes:

- Three transcription units (*Ubx*, *abdA*, *AbdB*) produce mRNAs that code for proteins. The transcription units are large (>75 kb for *Ubx*, and >20 kb each for *abdA* and *AbdB*). Each contains several large introns. (The *bxl* and *iab4* regions produce RNAs that do not code for proteins; again, the transcription units are large, and the RNA products are spliced. Their functions are unknown.)
- There are *cis*-acting mutations at intervals throughout the entire cluster. They control expression of the transcription units. *Cis*-acting mutations of any particular type may occur in a large region. The locations shown on the map are only approximate, and the boundaries within which mutations of each type may occur are not well defined.

As a historical note, the complex was originally defined in terms of two "domains." Mutations in the *Ultrabithorax* domain were characterized first; they have the thoracic segments T2P-T3P and the abdominal compartment A1A as their targets (this corresponds to parasegments 5-6). These mutations lie either in the *Ubx* transcription unit or in the *cis*-acting sites that control it. The mutations within the ultrabithorax domain are named for their phenotypes. The *bx* and *bxl* types are identified by a series of mutations, in each case dispersed over ~10 kb. The *abx* and *pbx* mutations are caused by deletions, which vary from 1-10 kb.

Mutations in the *Infraabdominal* domain were found later; they have the abdominal segments A1P-A8P (parasegments 7-14) as targets. These mutations lie either in the *AbdA,B* transcription units, or in the *cis*-acting sites that control them. Within the infraabdominal domain, *cis*-acting mutations are named systematically as *iab2-9*. These mutations affect individual compartments, or sometimes adjacent sets of compartments, as shown at the top of the figure (885).

Proceeding from left to right along the cluster, transcripts are found in increasingly posterior parts of the embryo, as shown at the bottom of the figure. The patterns overlap. *Ubx* has an anterior boundary of expression in compartment T2P (parasegment 5), *abdA* is expressed from compartment A1P (parasegment 7), and *AbdB* is expressed in compartments posterior to compartment A4P (parasegment 10).

Transcription of *Ubx* has been studied in the most detail. The *Ubx* transcription unit is ~75 kb, and has alternative splicing patterns that give rise to several short RNAs. A transient 4.7 kb RNA appears first, and then is replaced by RNAs of 3.2 and 4.3 kb. A feature common to both the latter two RNAs is their inclusion of sequences from both ends of the primary transcript. Of course, there may be other RNAs that have not yet been identified.

We do not yet have a good idea of whether there are significant differences in the coding functions of these RNAs. The first and last exons are quite lengthy, but the interior exons are rather small. Small exons from within the long transcription unit may enter mRNA products by means of alternative splicing patterns. So far, however, we do not know of any functional differences in the *Ubx* proteins produced by the various modes of expression.

Ubx proteins are found in the compartments that correspond to the sites of transcription, that is in T2P-A1 and at lower levels in A2-A8. So the Ubx unit codes for a set of related proteins that are concentrated in the compartments affected by mutations in the *Ultrabithorax* domain. Ubx proteins are located in the nucleus, and they fall into the general type of transcriptional regulators whose DNA-binding region consists of a homeodomain.

We can understand the general function of the *BX-C* complex by considering the effects of loss-of-function mutations. If the entire complex is deleted, the larva cannot develop the individual types of segments. In terms of parasegments (which are probably the affected units), all the parasegments differentiate in the same way as parasegment 4; the embryo has 10 repetitions of the repeating structure T1P/T2A all along its length, in place of the usual compartments between parasegments 5 and 14. In effect, the absence of *BX-C* functions allows *Antp* to be expressed throughout the abdomen, so that all the segments take on the characteristic of a segment determined by *Antp*; *BX-C* functions are needed to add more posterior-type information.

Each of the transcription units affects successive segments, according to its pattern of expression. So if *Ubx* alone is present, the larva has parasegment 4 (T1P/T2A), parasegment 5 (T2P/T3A), and then 8 copies of parasegment 6 (T3P/A1A). This suggests that the expression of *Ubx* is needed for the compartments anterior to A1A. *Ubx* is also expressed in the more posterior segments, but in the wild type, *abdA* and *AbdB* are also present. If they are removed, the expression of *Ubx* alone in all the posterior segments has the same effect that it usually has in parasegment 6 (T3P/A1A).

The addition of *abdA* to *Ubx* adds the wild-type pattern to parasegments 7, 8, and 9. In other words, *Ubx* plus *abdA* can specify up to compartments A3P/A4A, and in the absence of *AbdB*, this continues to be the default pattern for all the more posterior compartments. The addition of *AbdB* is needed to specify parasegments 10-14.

The general model for the function of the *ANT-C* and *BX-C* complexes is to suppose that additional functions are added to define successive segments proceeding in the posterior direction. It functions by reliance on a *combinatorial pattern* in which the addition of successive gene products confers new specificities. This explains the rule that a loss-of-function mutation in one of the genes of the *ANT-C/BX-C* complexes generally allows the gene on the more anterior side of the mutated gene to determine phenotype, that is, loss-of-function results in homeotic transformation of posterior regions into more anterior phenotypes (884).

Expression of *Ubx* in a more anterior segment than usual should have the opposite effect to a loss-of-function; the segment develops a more anterior phenotype. When this is tested by arranging for *Ubx* to be expressed in the head, the anterior segments are converted to the phenotype of parasegment 6. So lack of expression of *Ubx* causes a homeotic transformation in which posterior segments acquire more anterior phenotypes; and overexpression of *Ubx* causes a homeotic transformation in which anterior segments acquire more posterior phenotypes.

This type of relationship is true generally for the cluster as a whole, and explains the properties of *cis*-acting mutations as well as those in the transcription units. These regulatory mutations cause loss of the protein in part of its domain of expression or

cause additional expression in new domains. So they may have either loss-of-function or gain-of-function phenotypes (or sometimes both). The most common is loss-of-function in an individual compartment. For example, *bx* specifically controls expression of *Ubx* in compartment T3A; a *bx* mutation loses expression of *Ubx* in that compartment, which is therefore transformed to the more anterior type of T2A. This example is typical of the general rule for individual *cis*-acting mutations in the complex; each converts a target compartment *so that it develops as though it were located at the corresponding position in the previous segment*. The order of the *cis*-acting sites of mutation on the chromosomes reflects the order of the compartments in which they function. So the expression of *Ubx* in parasegments 4, 5, 6 is controlled sequentially by *abx* (affects parasegment 5), *bx* (affects T3A), etc.

The presence of only 3 genes within the *BX-C* complex poses two major questions. First, how do the combinations of 3 proteins specify the identity of 10 parasegments? One possibility is that there are quantitative differences in the various regions, allowing for the same sort of varying responses in target genes that we described previously for the combinatorial functioning of the segmentation genes. Second, how do the proteins function in different tissue types? The pattern of expression described above refers generally to the epidermis; the development of other tissues is controlled in a way that is parallel, but not identical. For example, although *Ubx* is expressed in all posterior segments up to A8 in the epidermis, in mesoderm, it is repressed posterior of segment A7. The posterior boundary reflects repression by *abdA*, since in *abdA* mutants, *Ubx* expression extends posterior in the mesoderm.

Why are loci involved in regulating development of the adult insect from the embryonic larva different from genes coding for the everyday proteins of the organism? Is their enormous length necessary to generate the alternative products? Could it be connected with some timing mechanism, determined by how long it takes to transcribe the unit? At a typical rate of transcription, it would take ~100 minutes to transcribe *Antp*, which is a significant proportion of the 22 hour duration of *D. melanogaster* embryogenesis.

Proceeding from anterior to posterior along the embryo, we encounter the changing patterns of expression of the genes of the *ANT-C* and *BC-C* loci. What controls their transcription? As in the case of the segmentation loci, the homeotic loci are controlled *partially by the genes that were expressed at the previous stage of development, and partially by interactions among themselves*. For example, the expression of *Ubx* is changed by mutations in *bicoid*, *hunchback*, or *Kruppel*. The anterior boundary of expression respects the parasegment border defined by *ftz* and *eve*. The general principle is that all of these regulatory genes function by controlling transcription, either by activating it or by repressing it, and that the gene products may exert specific effects by both qualitative and quantitative combinations.

## GRADIENTS, CASCADES, AND SIGNALING PATHWAYS

### 6.31.22 The homeobox is a common coding motif in homeotic genes

---

#### Key Terms

The **homeobox** describes the conserved sequence that is part of the coding region of *D. melanogaster* homeotic genes; it is also found in amphibian and mammalian genes expressed in early embryonic development.

**Paralogs** are highly similar proteins that are coded by the same genome.

#### Key Concepts

- The homeobox codes for a 60 amino acid protein domain that is a DNA-binding motif.
- Many *Drosophila* homeotic and segmentation genes code for transcription factors that use a homeodomain to bind DNA.
- The homeodomain does not fully specify the target DNA site, which is influenced by protein-protein combinatorial interactions.
- Homeodomains are found in important regulators of development in a wide range of organisms.
- A vertebrate Hox cluster contains several genes that have homeoboxes, related to the genes in the ANT-C and BX-C fly loci.
- The Hox genes play roles in vertebrate development that are analogous to the roles of the fly genes.

---

The three groups of genes that control *D. melanogaster* development – maternal genes, segmentation genes, and homeotic genes – regulate one another and (presumably) target genes that code for structural proteins. Interactions between the regulator genes have been defined by analyses that show defects in expression of one gene in mutants of another. However, we have identified rather few of the structural targets on which these groups of genes act to cause differentiation of individual body parts.

Consistent with the idea that the segmentation genes code for proteins that regulate transcription, the genes of 3 gap loci (*hb*, *Kr*, *kni*) contain zinc finger motifs. As first identified in the transcription factors TFIID and Sp1 (see **Figure 22.13**), these motifs are responsible for making contacts with DNA. The products of other loci in the gap class also have DNA-binding motifs; *giant* encodes a protein with a basic zipper motif, and *tailless* encodes a protein that resembles the steroid receptors. This suggests that the general function of gap genes is to function as transcriptional regulators.

Conserved motifs are found in many of the homeotic and segmentation genes. The

most common of the conserved motifs is the **homeobox**, a 180 bp region located near the 3' end in several segmentation and homeotic genes. There are ~40 genes in *Drosophila* that contain a homeobox, and almost all are known to be involved in developmental regulation. (The homeobox was first identified by its predominance in the homeotic genes, from which it took its name.) The protein sequence coded by the homeobox is called the homeodomain; it is a DNA-binding motif in transcription factors (see **Figure 22.24** in *Molecular Biology 5.22.14 Homeodomains bind related targets in DNA*) (883).

The fly homeodomains fall into several groups. A major group in *Drosophila* consists of the homeotic genes in the *BX-C/ANT-C* complexes; they are called the *Antennapedia* group. Their homeodomains are 70-80% conserved, and usually occur at the C-terminal end of the protein (see **Figure 22.22**). A distinct homeodomain sequence is found in the related genes *engrailed* and *invected*; it has only 45% sequence conservation with the *Antennapedia* group (see **Figure 22.23**). Other types of homeodomain sequences are represented in 2-4 genes each (for review see 360).

Many of the *Drosophila* genes that contain homeoboxes are organized into clusters. Three of the homeotic genes in the *BX-C* cluster have homeoboxes, the *ANT-C* complex contains a group of 5 homeotic genes with homeoboxes, and 4 other genes at *ANT-C* also contain homeoboxes. The homeotic genes at *BX-C* and *ANT-C* are sometimes described under the general heading of *HOM-C* genes (for review see 356).

What is the basic function of the *HOM-C* genes in determining identity on the anterior-posterior axis? We assume that homeodomains with different amino acid sequences recognize different target sequences in DNA. Experiments in which regions have been swapped between different proteins suggest that a major part of the specificity of these proteins rests with the homeodomain. However, the ability to bind to a particular DNA target site may not account entirely for their properties. For example, some of these proteins can either activate or repress transcription in response to the context, that is, their actions depend on the set of other proteins that are bound, not just on recognition of the DNA-binding site (for review see 365).

The similarities between the homeodomains of the more closely related members of the group suggest that they could recognize overlapping patterns of target sites. This would open the way for combinatorial effects that could be based on quantitative as well as qualitative differences, that is, there could be competition between proteins with related homeodomains for the same sites. In some cases, different homeoproteins recognize the same target sites on DNA, which poses a puzzle with regard to defining their specificity of action; we assume that there are subtle differences in DNA-binding yet to be discovered, or there are other interactions, such as protein-protein interactions, that play a role.

The homeobox motif is extensively represented in evolution. A striking extension of the significance of homeoboxes is provided by the discovery that a DNA probe representing the homeobox hybridizes with the genomes of many eukaryotes. Genes containing homeoboxes have been characterized in detail in frog, mouse, and human DNA. The frog and mammalian genes are expressed in early embryogenesis, which strengthens the parallel with the fly genes, and suggests the possibility that genes containing homeoboxes are involved in regulation of embryogenesis in a variety of species.

Genes in mammals (and possibly all animals) that are related to the *HOM-C* group have a striking property: like those of the *BX-C/ANT-C* complexes, they are organized in clusters. The individual mammalian genes are called *Hox* genes. A cluster of *Hox* genes may extend 20-100 kb and contain up to 10 genes. Four *Hox* clusters of genes containing homeoboxes have been characterized in the mouse and human genomes. Their organization is compared with the two large fly clusters in **Figure 31.39** (889).

**Figure 31.39** Mouse and human genomes each contain 4 clusters of genes that have homeoboxes. The order of genes reflects the regions in which they are expressed on the anterior-posterior axis. The Hox genes are aligned with the fly genes according to homology, which is strong for groups 1, 2, 4, and 9. The genes are named according to the group and the cluster, e.g., HoxA1 is the most anterior gene in the HoxA group. All Hox genes are present in both man and mice except for some mouse genes missing from cluster C.

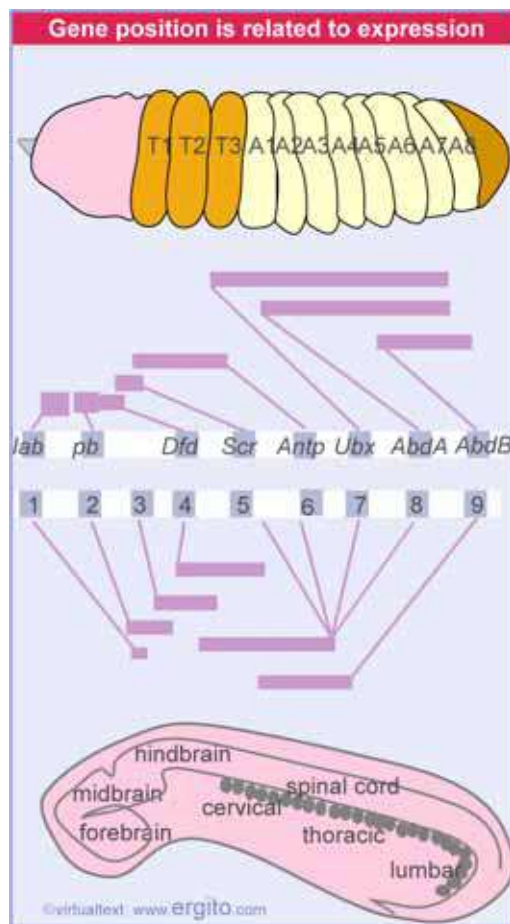

By comparing the sequences of the homeoboxes (and sometimes other short regions), the mammalian genes can be placed into groups that correspond with the fly genes. This is shown by vertical alignment in the figure. For example, *HoxA4* and *HoxB4* are best related to *Dfd*. When these relationships are defined for the cluster as a whole, it appears that within each cluster we can recognize a series of genes that are related to the genes in the *ANT-C* and *BX-C* clusters. Groups 1-9 in the mammalian loci are defined as corresponding to the genes of the *ANT-C* and *BX-C* loci organized end to end in anterior-posterior orientation. Groups 10-13 appear to have arisen by tandem duplications and divergence of group 9 (the *AbdB* homologue). The corresponding loci in each cluster are sometimes called **paralogs** (for example, *HoxA4* and *HoxB4* are paralogs).

This situation could have arisen if the fly and mammalian loci diverged at a point when there was only a single complex, containing all of the genes that define anterior-posterior polarity. The organism *Amphioxus*, which corresponds to a line of evolution parallel to the vertebrates, has a single *Hox* cluster containing one member of each paralogous group; this appears to be a direct representative of the original cluster. During evolution, the *Drosophila* genes broke into two separate clusters,

while the entire group of mammalian genes became duplicated, some individual members being lost from each complex after the duplication (891).

The parallel between the mouse and fly genes extends to their pattern of spatial expression. The genes within a *Hox* cluster are expressed in the embryo in a manner that matches their organization in the genome. Progressing from the left toward the right end of the cluster drawn in **Figure 31.39**, genes are expressed in the embryo in locations progressively more restricted to the posterior end. The patterns of expression for fly and mouse are compared schematically in **Figure 31.40**. The domain of expression extends strongly to the posterior boundary shown in the figure, and then tails off into more posterior segments (for review see 361; 364).

**Figure 31.40** A comparison of *ANT-C/BX-C* and *HoxB* expression patterns shows that the individual gene products share a progressive localization of expression towards the more posterior of the animal proceeding along the gene cluster from left to right. Expression patterns show the regions of transcription in the fly epidermis at 10 hours, and in the central nervous system of the mouse embryo at 12 days.

These results raise the extraordinary possibility that the clusters of genes not only share a common evolution, but also have maintained a common general function in which genome organization is related to spatial expression in fly and mouse, and

there is some correspondence between the homologous genes. The idea of such a relationship is strengthened by the observation that ectopic expression of mouse *HoxD4* or *HoxB6* in *Drosophila* cause homeotic transformations virtually identical to those caused by homeotic expression of *Dfd* or *Antp*, respectively! Since the homology between these mouse and fly proteins rests almost exclusively with their homeodomains, this reinforces the view that these domains determine specificity.

There are some differences in the apparent behavior of the vertebrate Hox clusters and the *ANT-C/BX-C* fly clusters:

- The *Hox* genes are small, and there is a greater number of protein-coding units. The mouse *HoxB* cluster is ~120 kb and contains 9 genes. The connection between genomic position and embryonic expression is analogous to that in *Drosophila*, but describes only the genes themselves; we have no information about *cis*-acting sites. Of course, this may be a consequence of the much greater difficulty in generating mutations in vertebrates. However, our present information identifies the control of *Hox* genes only by promoters and enhancers in the region upstream of the startpoint. It remains to be seen whether there is any counterpart to the very extensive and complex regulatory regions of the *Drosophila* homeotic genes.
- In *Drosophila*, each gene is unique; but in vertebrates, the duplication of the clusters enables multiple genes (paralogs) to have the same or very similar patterns of expression. If the paralogs have redundant or partially redundant functions, so that the absence of one product may be at least partially substituted by the corresponding protein of another cluster, the effects of mutations will be minimized.

Disruptions of *Hox* genes in mice often generate recessive lethals. In the examples of *HoxA1* and *HoxA3* various structures of the head and thorax are absent. Not all of the structures that usually express the mutant genes are missing, suggesting that there is indeed some functional redundancy, that is, other *Hox* genes of group 1 or group 3 can substitute in some but not all other tissues for the absence of the *HoxA* gene.

Homeotic transformations are less common with mutants in mice than in *Drosophila*, but sometimes occur. Loss of *HoxC8*, for example, causes some skeletal segments to show more anterior phenotypes. It remains to be seen whether this is a general rule.

Ectopic expression of *Hox* genes has been used successfully to demonstrate that gain-of-function can transform the identity of a segment towards the identity usually conferred by the gene. The most common type of effect in *Drosophila* is to transform a segment into a phenotype that is usually more posterior; in effect, the expression of the homeotic gene has added additional information that confers a more posterior identity on the segment. Similar effects are observed in some cases in the mouse. However, the pattern is not completely consistent (892).

Taken together, these results make it clear that the *Hox* genes resemble their counterparts in *Drosophila* in determining patterning along the anterior-posterior axis. It may be the case that there is a combinatorial code of *Hox* gene expression, or there may be differences in degree of functional redundancy between paralogs, but we cannot yet provide a systematic model for their role in determining pattern.

The most striking feature of organization of the *Hox* loci still defies explanation: why has the organization of the cluster, in which genomic position correlates with embryonic expression, been maintained in evolution? The obvious explanation is that there is some overall control of gene expression to ensure that it proceeds through the cluster, with the result that a gene could be properly expressed *only* when it is within the cluster. But this does not appear to be true, at least for those individual cases in which genes have been removed from the cluster. Analysis of promoter regions suggests that a *Hox* gene may be controlled by a series of promoter or enhancer elements that together ensure its overall pattern of expression. Usually these elements are in the region upstream of the startpoint. For example, *HoxB4* expression can be reconstructed as the sum of the properties of a series of such elements, tested by introducing appropriate constructs to make transgenic mice. But then why should there have been evolutionary pressure to retain genes in an ordered cluster? One possibility is that an enhancer for one gene might be embedded within another gene, in such a way that, even if an individual gene could function when translocated elsewhere, its removal would impede the expression of other gene(s). An indication that there may be something special about the organization of the region is given by the fact that it has an unusually high density of conserved noncoding sequences and an unusually low density of insertions such as transposons (1442). This suggests the existence of large scale regulatory elements that we have not yet identified.

## GRADIENTS, CASCADES, AND SIGNALING PATHWAYS

### 6.31.23 Summary

---

The development of segments in *Drosophila* occurs by the actions of segmentation genes that delineate successively smaller regions of the embryo. Asymmetry in the distribution of maternal gene products is established by interactions between the oocyte and surrounding cells. This leads to the expression of the gap genes, in 4 broad regions of the embryo. The gap genes in turn control the pair-rule genes, each of which is distributed in 7 stripes; and the pair-rule genes define the pattern of expression of the segment polarity genes, which delineate individual compartments. At each stage of expression, the relevant genes are controlled both by the products of genes that were expressed at the previous stage, and by interactions among themselves. The segmentation genes act upon the homeotic genes, which determine the identities of the individual compartments.

Each of the 4 maternal systems consists of a cascade which generates a locally distributed or locally active morphogen. The morphogen either is a transcription factor or causes the activation of a transcription factor. The transcription factor is the last component in each pathway.

The major anterior-posterior axis is determined by two systems: the anterior system establishes a gradient of bicoid from the anterior pole; and the posterior system produces nanos protein in the posterior half of the egg. These systems function to define a gradient of hunchback protein from the anterior end, with broad bands of knirps and giant in the posterior half. The terminal system acts to produce localized events at both termini. The dorsal-ventral system produces a gradient of nuclear localization of dorsal protein on the ventral side, which represses expression of *dpp* and *zen*; this leads to the ventral activation of *twist* and *snail*, and the dorsal-side activation of *dpp* and *zen*.

Each system is initiated by localization of a morphogen in the egg as a result of its interaction with the surrounding cells. For the anterior and posterior systems, this takes the form of localizing an RNA; *bicoid* mRNA is transported into and localized at the anterior end, and *nanos* mRNA is transported to the posterior end. For the dorsal-ventral system, the Toll receptor is located ubiquitously on the oocyte membrane, but the spatzle ligand is activated ventrally and therefore triggers the pathway on the ventral side. The pathway resembles the mammalian IL-1 signal transduction pathway and culminates in the phosphorylation of cactus, which regulates the dorsal transcription factor. On the dorsal side of the embryo, the morphogen Dpp is released; it is a member of the TGF  $\beta$  family that diffuses to interact with its receptor. A ligand-receptor interaction involving related members of the TGF  $\beta$ /receptor families is also employed in a comparable role in vertebrate development.

The early embryo consists of a syncytium, in which nuclei are exposed to common cytoplasm. It is this feature that allows all 4 maternal systems to control the function of a nucleus according to the coordinates of its position on the anterior-posterior and dorsal-ventral axes. At cellular blastoderm, zygotic RNAs are transcribed, and the developing embryo becomes dependent upon its own genes. Cells form at the

blastoderm stage, after which successive interactions involve a cascade of transcriptional regulators.

Three gap genes are zinc-finger proteins, and one is a basic zipper protein. Their concentrations control expression of the pair-rule genes, which are also transcription factors. In particular, the expression of *eve* and *ftz* controls the boundaries of compartments, functioning in every other segment. The segment polarity genes represent the first step in the developmental cascade that involves functions other than transcription factors. Interactions between the segmentation gene products define unique combinations of gene expression for each segment.

The segment polarity genes include proteins involved in cell-cell interactions as well as transcription factors. The basic circuitry that determines the anterior and posterior polarities of compartments is maintained by an autoregulatory interaction between the cells at the boundary. An anterior compartment secretes wingless protein, which acts upon the cell on the posterior side. This causes engrailed to be expressed in the posterior cell, which in turn causes secretion of hedgehog on the anterior side. Hedgehog causes the anterior cell to express wingless.

Homeotic genes impose the program that determines the unique differentiation of each segment. The complex loci *ANT-C* and *BX-C* each contain a cluster of functions, whose spatial expression on the anterior-posterior axis reflects genetic position in the cluster. Each cluster contains one exceedingly large transcription unit as well as other, shorter units. Many of the transcription units (including the largest genes, *Ubx* and *Antp*) have patterns of alternative splicing, but no significance has been attributed to this yet. Proceeding from left to right in each cluster, genes are expressed in more posterior tissues. The genes are expressed in overlapping patterns in such a way that addition of a function confers new features of posterior identity; thus loss of a function results in a homeotic transformation from posterior to more anterior phenotype. The genes are controlled in a complex manner by a series of regulatory sites that extend over large regions; mutations in these sites are *cis*-acting, and may cause either loss-of-function or gain-of-function. The *cis*-acting mutations tend to act on successive segments of the fly, by controlling expression of the homeotic proteins.

The genes of the *ANT-C* and *BX-C* loci, and many segmentation genes (including the maternal gene *bicoid* and most of the pair-rule genes) contain a conserved motif, the homeobox. Homeoboxes are also found in genes of other eukaryotes, including worms, frogs, and mammals. In each case, these genes are expressed during early embryogenesis. In mammals, the *Hox* genes (which specify homeodomains in the *Antennapedia* class) are organized in clusters. There are 4 *Hox* clusters in both man and mouse. These clusters can be aligned with the *ANT-C/BX-C* clusters in such a way as to recognize homologies between genes at corresponding positions. Proceeding towards the right in a *Hox* cluster, a gene is expressed more towards the posterior of the embryo. The *Hox* genes have roles in conferring identity on segments of the brain and skeleton (and other tissues). The analogous clusters represent regulators of embryogenesis in mammals and flies. *Hox* clusters may be a characteristic of all animals.

*Drosophila* genes containing homeoboxes form an intricate regulatory network, in which one gene may activate or repress another. The relationship between the sequence of the homeodomain, the DNA target it recognizes, and the regulatory

consequences, remains to be fully elucidated. Specificity in target choice appears to reside largely in the homeodomain; we have yet to explain the abilities of a particular homeoprotein to activate or to repress gene transcription at its various targets. The general principle is that segmentation and homeotic genes act in a transcriptional cascade, in which a series of hierarchical interactions between the regulatory proteins is succeeded by the activation of structural genes coding for body parts.

**SUPPLEMENTS****7.32.1 DNA reassociation kinetics**

---

**Key Terms**

A **Cot curve** is a plot of the extent of renaturation of DNA against time.

**Complexity** is the total length of different sequences of DNA present in a given preparation.

The **fast component** of a reassociation reaction is the first to renature and contains highly repetitive DNA.

**Intermediate component(s)** of a reassociation reaction are those reacting between the fast (satellite DNA) and slow (nonrepetitive DNA) components; contain moderately repetitive DNA.

The **slow component** of a reassociation reaction is the last to reassociate; usually consists of nonrepetitive DNA.

**Nonrepetitive DNA** shows reassociation kinetics expected of unique sequences.

**Repetitive DNA** behaves in a reassociation reaction as though many (related or identical) sequences are present in a component, allowing any pair of complementary sequences to reassociate.

The **repetition frequency** is the (integral) number of copies of a given sequence present in the haploid genome; equals 1 for nonrepetitive DNA, >2 for repetitive DNA.

**Highly repetitive DNA (Simple sequence DNA)** is the first component to reassociate and is equated with satellite DNA.

The **stringency** of a hybridization describes describes the effect of conditions on the degree of complementarity that is required for reaction. At the most stringent conditions, only exact complements can hybridize. As the stringency is lowered, an increasing number of mismatches can be tolerated between the two strands that are hybridizing.

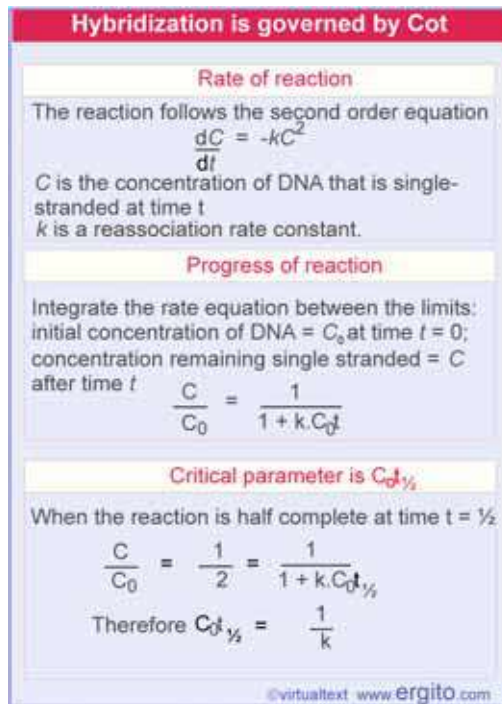

A **tracer** is a radioactively labeled nucleic acid component included in a reassociation reaction in amounts too small to influence the progress of reaction.

---

The general nature of the eukaryotic genome can be assessed by the kinetics of reassociation of denatured DNA. Reassociation between complementary sequences of DNA occurs by base pairing. This reverses the process of denaturation by which they were separated (see **Figure 1.17**). The kinetics of the reassociation reaction reflect the variety of sequences that are present; so the reaction can be used to quantitate genes and their RNA products.

**Figure S 1** describes the reaction. Renaturation of DNA depends on random collision of the complementary strands, and follows second-order kinetics. The reaction for any particular DNA can be characterized by conditions required for half-completion. This is the product of  $C_0 \times t_{1/2}$  and is called the **Cot**<sub>1/2</sub>. It is inversely proportional to the rate constant. Since the **Cot**<sub>1/2</sub> is the product of the concentration and time required

to proceed halfway, a greater  $Cot_{1/2}$  implies a slower reaction.

**Figure S 1** A DNA reassociation reaction is described by the  $Cot_{1/2}$ .

The reassociation of DNA usually is followed in the form of a **Cot curve**, which plots the fraction of DNA that has reassociated ( $1 - C/C_0$ ) against the log of the Cot. **Figure S 2** gives Cot curves for several simple genomes. The form of each curve is similar, with renaturation occurring over an ~100-fold range of Cot values between the points of 10% reaction and 90% reaction. But the  $Cot_{1/2}$  for each curve is different.

**Figure S 2** Rate of reassociation is inversely proportional to the length of the reassociating DNA.

The genomes in **Figure S 2** represent a series of DNAs. Each is unique in sequence,

and they become progressively longer. The  $Cot_{1/2}$  is directly related to the amount of DNA in the genome. This reflects a situation in which, as the genome becomes more complex, there are fewer copies of any particular sequence within a given mass of DNA. For example, if the  $C_0$  of DNA is 12 pg, it will contain 3000 copies of each sequence in a bacterial genome whose size is 0.004 pg, but will contain only 4 copies of each sequence present in a eukaryotic genome of size 3 pg. So the same absolute concentration of DNA measured in moles of nucleotides per liter (the  $C_0$ ) will provide a concentration of each eukaryotic sequence that is  $3000/4 = 750\times$  less than that of each bacterial sequence.

Since the rate of reassociation depends on the concentration of complementary sequences, for the eukaryotic sequences to be present at the same relative concentration as the bacterial sequences, it is necessary to have  $750\times$  more DNA (or to incubate the same amount of DNA for 750 times longer). So the  $Cot_{1/2}$  of the eukaryotic reaction is  $750\times$  the  $Cot_{1/2}$  of the bacterial reaction.

The  $Cot_{1/2}$  of a reaction therefore indicates the total length of different sequences that are present. This is described as the **complexity**, usually given in base pairs. The  $Cot_{1/2}$  for the renaturation of the DNA of any genome (or part of a genome) is proportional to its complexity. The complexity of any DNA can be determined by comparing its  $Cot_{1/2}$  with that of a standard DNA of known complexity. Usually *E. coli* DNA is used as a standard. Assuming that the *E. coli* genome of  $4.2 \times 10^6$  bp consists of unique sequences:

$$\frac{Cot_{1/2} \text{ (DNA of any genome)}}{Cot_{1/2} \text{ (} E. coli \text{ DNA)}} = \frac{\text{Complexity of any genome}}{4.2 \times 10^6 \text{ bp}}$$

When the DNA of a eukaryotic genome is characterized by reassociation kinetics, usually the reaction occurs over a range of  $Cot$  values spanning up to eight orders of magnitude. This is much broader than the 100-fold range expected from the examples of **Figure S 2**. The reason is that each of these curves follows the equation that describes the kinetics of reassociation for a single component. A eukaryotic genome actually includes several such components, each reassociating with its own characteristic kinetics. The  $Cot$  curve reveals a crucial difference between bacterial and eukaryotic genomes: bacterial genomes essentially consist of a single kinetic component, but eukaryotic genomes are much more complex.

**Figure S 3** shows the reassociation of a (hypothetical) eukaryotic genome, starting at a  $Cot$  of  $10^{-4}$  and terminating at a  $Cot$  of  $10^4$ . The reaction falls into three distinct phases, outlined by the shaded boxes. Each of these phases represents a different kinetic component of the genome:

**Figure S 3** The reassociation kinetics of eukaryotic DNA show three types of component (indicated by the shaded areas). The arrows identify the  $Cot_{1/2}$  values for each component.

- The **fast component** is the first fraction to reassociate. In this case, it represents 25% of the total DNA, renaturing between  $Cot$  values of  $10^{-4}$  and  $\sim 2 \times 10^{-2}$ , with a  $Cot_{1/2}$  value of 0.0013.
- The next fraction is called the **intermediate component**. This represents 30% of the DNA. It renatures between  $Cot$  values of  $\sim 0.2$  and 100, with a  $Cot_{1/2}$  value of 1.9.
- The **slow component** is the last fraction to renature. This is 45% of the total DNA; it extends over a  $Cot$  range from  $\sim 100$  to  $\sim 10,000$ , with a  $Cot_{1/2}$  of 630.

To calculate the complexities of these fractions, each must be treated as an independent kinetic component whose reassociation is compared with a standard DNA. The slow component represents 45% of the total DNA, so its concentration in the reassociation reaction is 0.45 of the measured  $C_0$  (which refers to the total amount of DNA present). The  $Cot_{1/2}$  applying to the slow fraction alone is  $0.45 \times 630 = 283$ .

Suppose that under these conditions, *E. coli* DNA reassociates with a  $Cot_{1/2}$  of 4.0. This corresponds to a complexity for the slow fraction of  $3.0 \times 10^8$  bp ( $= 4.2 \times 10^6 \times 283 / 4$ ). Treating the other components in a similar way shows that the intermediate component has a complexity of  $6 \times 10^5$  bp, and the fast component has a complexity of only 340 bp. This provides a quantitative basis for our statement that, the faster a component reassociates, the lower is its complexity.

Reversing the argument, suppose we took three DNA preparations, each containing a unique sequence of the appropriate length ( $340$  bp,  $6 \times 10^5$  bp, and  $3 \times 10^8$  bp, respectively) and mixed them in the proportions of mass 25:30:45. Each would renature as though it were a single component. Together the mixture would display the same kinetics as those determined for the whole genome of **Figure S 3**.

*The complexity of the slow component corresponds with its physical size.* Suppose that the genome reassociating in **Figure S 3** has a haploid DNA content of  $7.0 \times 10^8$  bp, determined by chemical analysis. Then 45% of it is  $3.15 \times 10^8$  bp, which is the same (within experimental error) as the value of  $3.0 \times 10^8$  bp measured by the kinetics of reassociation. The complexity of the slow component corresponds to its physical length.

The slow component comprises sequences that are unique in the genome: on denaturation, *each single-stranded sequence is able to renature only with the corresponding complementary sequence.* This part of the genome is the sole component of prokaryotic DNA and is usually a major component in eukaryotes. It is called **nonrepetitive DNA**.

What is the nature of the components that renature more rapidly than the nonrepetitive (slow) DNA? In the example of **Figure S 2**, the intermediate component occupies 30% of the genome. Its chemical complexity is  $0.3 \times 7 \times 10^8 = 2.1 \times 10^8$  bp. But its kinetic complexity is only  $6 \times 10^5$  bp.

*The unique length of DNA that corresponds to the  $Cot_{1/2}$  for reassociation is much shorter than the total length of the DNA chemically occupied by this component in the genome.* In other words, the intermediate component behaves as though consisting of a sequence of  $6 \times 10^5$  bp that is present in 350 copies in every genome (because  $350 \times 6 \times 10^5 = 2.1 \times 10^8$ ). Following denaturation, *the single strands generated from any one of these copies are able to renature with their complements from any one of the 350 copies.* This effectively raises the concentration of reacting sequences in the reassociation reaction, explaining why the component renatures at a lower  $Cot_{1/2}$ .

Sequences that are present in more than one copy in each genome are called **repetitive DNA**. The number of copies present per genome is called the **repetition frequency** ( $f$ ).

Repetitive DNA is often classed into two general types, corresponding approximately to the intermediate and fast components of **Figure S 3**:

- **Moderately repetitive DNA** occupies the intermediate fraction, usually reassociating in a range between a  $Cot$  of  $10^{-2}$  and that of nonrepetitive DNA.
- **Highly repetitive DNA** occupies the fast fraction, reassociating before a  $Cot$  of  $10^{-2}$  is reached.

*The behavior of a repetitive DNA component represents only an average that is useful for describing its sequences.* The relevant parameters do not necessarily represent the properties of any particular sequence.

The moderately repetitive component of **Figure S 3** includes a total length of  $6 \times 10^5$  bp of DNA, repeated  $\sim 350\times$  per genome. But this does not correspond to a single, identifiable, continuous length of DNA. *Instead, it is made up of a variety of individual sequences, each much shorter*, whose total length together comes to  $6 \times 10^5$  bp. These individual sequences are dispersed about the genome. Their average repetition is 350, but some will be present in more copies than this and some in fewer.

When a eukaryotic genome is analyzed by reassociation kinetics, the individual sequence components are rarely so well separated as shown in **Figure S 3**. In fact, they often overlap extensively, so that in reality there is probably a continuum of repetitive components, reassociating over a range from  $>10\times$  to  $>20,000\times$  that of the nonrepetitive component.

The different components of eukaryotic DNA can be isolated in the form of the DNA that becomes double-stranded after renaturation to a particular Cot value. The properties of renatured nonrepetitive and repetitive DNA differ significantly.

Nonrepetitive DNA forms duplex material that behaves very much like the original preparation of DNA before its denaturation. When denatured again, the duplex molecules melt sharply at a  $T_m$  only slightly below that of the original native DNA. This shows that strand reassociation has been accurate: each unique sequence has annealed with its exact complement.

Different behavior is shown by renatured repetitive DNA. The reassociated double strands tend to melt gradually over rather a wide temperature range, as shown in **Figure S 4**. This means that they do not consist of exactly paired molecules. Instead, they must contain appreciable mispairing. The more mispairing in a particular molecule, the fewer hydrogen bonds need to be broken to melt it, and thus the lower the  $T_m$ .

**Figure S 4** The denaturation of reassociated nonrepetitive DNA takes place over a narrow temperature range close to that of native DNA, but reassociated repetitive DNA melts over a wide temperature range.

The breadth of the melting curve shows that renatured repetitive DNA contains a spectrum of sequences, ranging from those that have been formed by reassociation between sequences that are only partially complementary, to those formed by reassociation between sequences that are very nearly or even exactly complementary. How can this happen?

*Repetitive DNA components consist of families of sequences that are not exactly the same, but are related.* The members of each family consist of a set of nucleotide sequences that are sufficiently similar to renature with one another. The differences between the individual members are the result of base substitutions, insertions, and deletions, all creating points within the related sequences at which the complementary strands cannot base pair. The proportion of these changes establishes the relationship between any two sequences. When two closely related members of the family renature, they form a duplex with high  $T_m$ . When two more distantly related members associate, they form a duplex with a lower  $T_m$ . Overall, we see the broad range represented in the figure.

The ability of related but not identical complementary sequences to recognize each other can be controlled by the **stringency** of the conditions imposed for reassociation. A higher stringency is imposed by (for example) an increase in temperature, which requires a greater degree of complementarity to allow base pairing. So by performing the hybridization reaction at high temperatures, reassociation is restricted to rather closely related members of a family; at lower temperatures, more distantly related members may anneal. The measured size of a repetitive family is arbitrary, since it is determined by the hybridization conditions.

Moderately repetitive DNA is dispersed throughout the genome, usually in the form of relatively short individual sequences. It is responsible for the high degree of secondary structure formation in pre-mRNA, when (inverted) repeats in the introns pair to form duplex regions. Highly repetitive DNA often forms discrete clusters (see *Molecular Biology 1.4 Clusters and repeats*). Neither class represents protein.

The genome sequence components represented in mRNA can be determined by using the RNA as a **tracer** in a reassociation experiment. A very small amount of radioactively labeled RNA (or cDNA) is included together with a much larger amount of cellular DNA. The tracer RNA (or cDNA) participates in the reaction as though it were just another member of the sequence component from which it was transcribed. The  $Cot$  values at which the labeled RNA hybridizes identify the repetition frequencies of the corresponding genomic sequences.

**Figure S 5** shows a typical result for a population of mRNAs. A small proportion of the RNA, generally 10% or less, hybridizes with a  $Cot_{1/2}$  corresponding to moderately repetitive sequences. The major component hybridizes with nonrepetitive DNA.

**Figure S 5** The hybridization of an mRNA tracer preparation in a reassociation curve shows that most mRNA sequences are derived from nonrepetitive DNA, the remainder from moderately repetitive DNA, and none from highly repetitive DNA.

Reassociation analysis can be also used to measure the complexity of an RNA population. One method is to hybridize nonrepetitive DNA with an excess of RNA; the proportion of the DNA that is bound at saturation identifies the complexity of the RNA population. Another method is to follow the kinetics of hybridization between an excess of an RNA population and a DNA copy prepared from it. This is exactly analogous to reassociation analysis of genomic DNA. The reaction is described in terms of the  $Rot_{1/2}$  (where  $R_0$  is the starting concentration of RNA).

In looking at the DNA that hybridizes with mRNA, we are basically examining the exons in the genome. The conclusion therefore is that most exons are present at low repetition frequency – depending on the stringency of hybridization, they may be

unique or present in a small number of copies.

**SUPPLEMENTS****7.32.2 Mendel's laws and dominance**

---

**Key Terms**

An **allele** is one of several alternative forms of a gene occupying a given locus on a chromosome.

An individual is said to be **homozygous** when it has identical alleles of a given gene.

An individual is said to be **heterozygous** when it has different alleles of a given gene on each of its homologous chromosomes.

**Complete dominance** is the state in which the phenotype is the same when the dominant allele is homozygous or heterozygous.

A **dominant** allele determines the phenotype displayed in a heterozygote with another (recessive) allele.

A **recessive** allele is obscured in the phenotype of a heterozygote by the dominant allele, often due to inactivity or absence of the product of the recessive allele.

**Incomplete dominance** is a state in which the heterozygote has a phenotype in between that of each of the homozygotes.

Two alleles are said to be **codominant** when they are each equally evident in the phenotype of the heterozygote.

Mendel's law of **independent assortment** states that the assortment of one gene does not influence the assortment of another.

A **parental genotype** is one that is identical to the genotype of one of the contributing parents.

**Recombinant** progeny have a different genotype from that of either parent.

---

The essential attributes of the gene were defined by Mendel more than a century ago. As he concluded in his analysis of pea genetics in 1865: "The law of combination of different characters, which governs the development of the hybrids, finds therefore its explanation in the principle enunciated, that the hybrids produce egg cells and pollen cells, which in equal numbers, represent all constant forms which result from combinations of the characters brought together in fertilization." *Summarized in his two laws, the gene was recognized as a "particulate factor" that passes unchanged from parent to progeny.*

A gene may exist in alternative forms that determine the expression of some particular characteristic. For example, the color of a flower may be red or white. The forms of the gene are called **alleles**. Mendel's first law describes the *segregation of alleles: alleles have no permanent effect on one another when present in the same plant, but segregate unchanged by passing into different gametes.*

When an organism has two identical alleles of a gene, it is said to be **homozygous** (or true-breeding) for the trait conveyed by that gene. If the alleles are different, the organism is **heterozygous** (or hybrid). *The phenotype of a homozygote directly*

reflects the genotype of the (single type of) allele, but the phenotype of a heterozygote depends on the relationship between the types of alleles that are present.

Mendel's first law recognizes that the genotype of a heterozygote includes both alleles, irrespective of the phenotype that is displayed. When a homozygote for one allele is crossed with a homozygote for another allele, all the progeny in the first (F1) generation are heterozygotes with the same phenotype. But when the heterozygotes are crossed with one another to generate a second (F2) generation, the genotypes of the original parents reappear. The critical point is that the alleles must consist of discrete physical entities that contribute independently (or fail to contribute) to the phenotype.

**Figure S 6** shows how the results of such crosses differ according to the type of relationship between alleles:

**Figure S 6** Mendel's first law: alleles segregate each generation.

- The case analyzed by Mendel corresponds to **complete dominance**, and is shown in the first column of results. When one allele is **dominant** and the other is **recessive**, the phenotype of a heterozygote is determined by the dominant allele. The recessive allele makes no contribution. The single dominant allele produces the same phenotype that is seen in a wild-type homozygote. The appearance of the heterozygote is indistinguishable from that of the homozygous

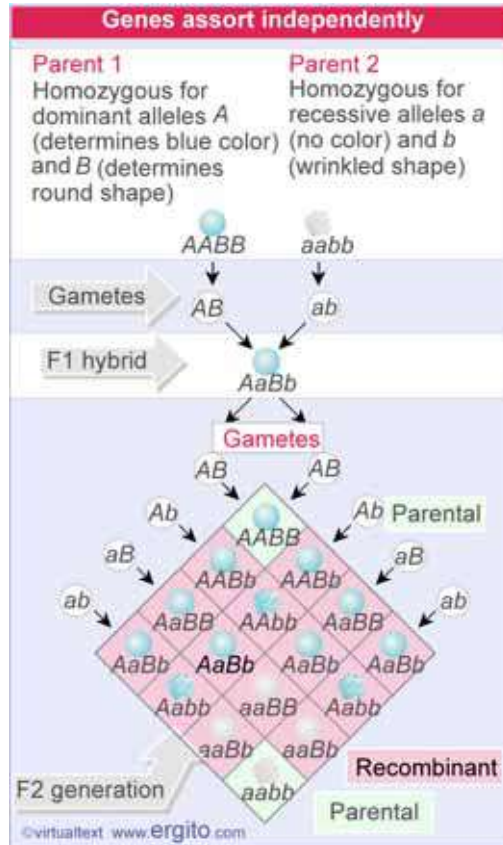

dominant parent. The F1 resembles the dominant parent. Complete dominance generates the classic 3:1 ratio of dominant to recessive phenotypes in the F2.

- Some alleles exhibit **incomplete dominance** (or partial dominance), as shown in the middle column. The phenotype of the heterozygote is intermediate between that of the two homozygotes. In the snapdragon, for example, a cross between red and white generates heterozygotes with pink flowers. However, the same rule is observed that the first hybrid (F1) generation is uniform in phenotype; and the same ratios are generated in the second (F2) generation, except that three phenotypes can be distinguished instead of two ( $AA$  is red,  $2 Aa$  are pink,  $aa$  is white). This type of situation arises through quantitative effects; the single red allele in the heterozygote produces half as much pigment as the two red alleles in a homozygote.
- Alleles are said to be **codominant** when they contribute equally to the phenotype, as shown in the final column. In human blood groups, the  $AA$  and  $BB$  combinations are homozygous, and  $AB$  is a codominant heterozygote in which the  $A$  and  $B$  groups are equally expressed. The result is that each genotypic class produces a different phenotype. The F1 has the properties of both parents, and the F2 has the phenotypes A: 2 AB: B.

Mendel's second law summarizes the **independent assortment** of different genes. When a homozygote that is dominant for *two different characters* is crossed with a homozygote that is recessive for both characters, as before the F1 consists of plants whose phenotype is the same as the dominant parent. But in the next (F2) generation, two general classes of progeny are found:

- One class consists of the two **parental genotypes**.
- The other class consists of *new* phenotypes, representing plants with the dominant feature of one parent and the recessive feature of the other. These are called **recombinant** types; and they occur in both possible (*reciprocal*) combinations.

**Figure S 7** shows that the ratios of the four phenotypes comprising the F2 can be explained by supposing that gamete formation involves an entirely random association between one of the two alleles for the first character and one of the two alleles for the second character. All four possible types of gamete are formed in equal proportion; and then they associate at random to form the zygotes of the next generation. Once again, the phenotypes conceal a greater variety of genotypes.

**Figure S 7** Mendel's second law: different genes assort independently in genetic crosses.

The law of independent assortment establishes the principle that the behavior of any pair (or greater number) of genes can be predicted overall by the rules of mathematical combination. *The assortment of one gene does not influence the assortment of another.* Implicit in this concept is the view that assortment is a matter of *statistical probability* and not an exact result. The ratio of progeny types will approximate increasingly closely to the predicted proportions as the number of crosses is increased.

Appreciation of Mendel's discoveries was inhibited by the lack of any known physical basis for the postulated factors (genes). When the chromosomal theory of inheritance was subsequently proposed, however, it was realized that the behavior of chromosomes at meiosis and fertilization corresponds precisely with the properties of Mendel's particulate units of inheritance.

There is an exact parallel between the behavior of chromosomes and Mendel's units of inheritance:

- Genes occur in allelic pairs. One member of each pair is contributed by each parent; so the diploid set of chromosomes results from the contribution of a haploid set by each parent.

- The assortment of nonallelic genes into gametes is independent of (parental) origin; correspondingly, nonhomologous chromosomes undergo independent segregation at meiosis.

*The critical proviso is that each gamete obtains a complete haploid set, and this condition is fulfilled whether viewed in terms of Mendel's factors or chromosomes.*

**SUPPLEMENTS****7.32.3 Linkage and mapping**

---

**Key Terms**

A **recombinant genotype** is one that consists of a new combination of genes produced by crossing over.

A **parental genotype** is one that is identical to the genotype of one of the contributing parents.

**Linkage** describes the tendency of genes to be inherited together as a result of their location on the same chromosome; measured by percent recombination between loci.

A **linkage map** is a map showing the linear order of genes on a chromosome and the relative distances between them in recombinational units.

An **allele** is one of several alternative forms of a gene occupying a given locus on a chromosome.

A **backcross** describes a genetic cross in which a hybrid strain is crossed to one of its two parental strains.

**Crossing-over** describes the reciprocal exchange of material between chromosomes that occurs during prophase I of meiosis and is responsible for genetic recombination.

A **chiasma** (*pl.* chiasmata) is a site at which two homologous chromosomes appear to have exchanged material during meiosis.

**Breakage and reunion** describes the mode of genetic recombination, in which two DNA duplex molecules are broken at corresponding points and then rejoined crosswise (involving formation of a length of heteroduplex DNA around the site of joining).

**Map distance** is measured as cM (centimorgans) = percent recombination (sometimes subject to adjustments).

A **map unit** is the distance between two genes that recombine with a frequency of 1%.

A **locus** is the position on a chromosome at which the gene for a particular trait resides; a locus may be occupied by any one of the alleles for the gene.

A **linkage group** includes all loci that can be connected (directly or indirectly) by linkage relationships; equivalent to a chromosome.

A **marker** is an identifiable and inheritable difference that can be mapped to a location on a chromosome. A genetic marker is an allele that is identified with its genetic trait. A molecular marker is a DNA sequence difference that can be identified by molecular methods.

**Phage T4** is a virus that infects *E. coli* causing lysis of the bacterium.

**Rapid lysis** (*r*) mutants display a change in the pattern of lysis of *E. coli* at the end of an infection by a T-even phage.

---

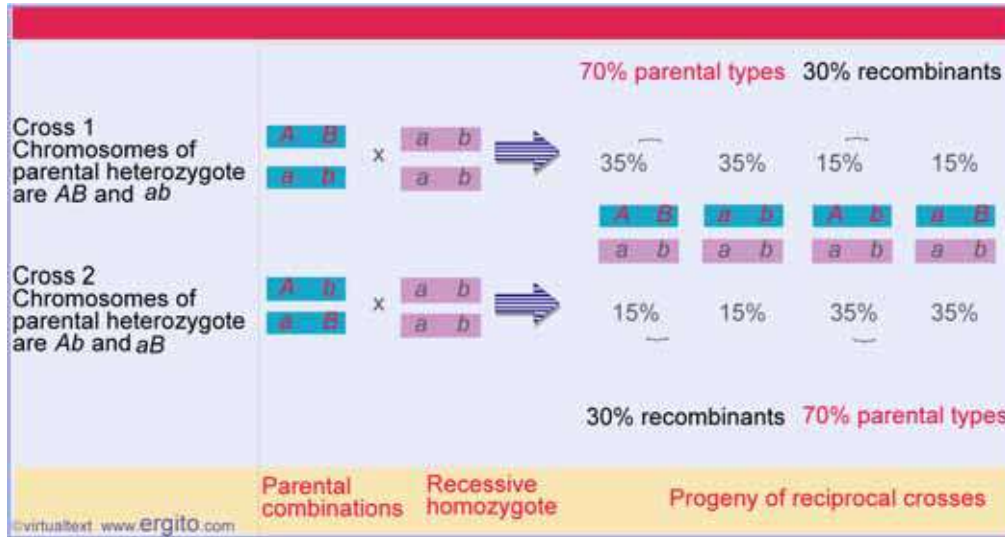

Mendel's laws predict that genes carried on different chromosomes will segregate independently (for additional description see *Molecular Biology Supplement 32.2 Mendel's laws and dominance*). However, genes that are on the same chromosome show *linked inheritance*. The basic observation is that genes on different chromosomes *recombine* at random from one generation to the next, whereas genes that are linked show a *reduction in recombination*, that is, they tend to stay together.

The results of a genetic cross are analyzed by determining the proportions of **recombinant genotypes** (where an allele of one parent is found with an allele of the other parent) and **parental genotypes** (which have the same combination of alleles as either parent). Genes on different chromosomes segregate independently, as predicted by Mendel, to give 50% parental and 50% recombinant progeny. Genes on the same chromosome behave differently, because they are present on the same (very long) molecule of DNA. Instead of generating the proportions depicted by independent assortment, the proportion of parental genotypes is greater than expected, *because there is a reduction in the formation of recombinant genotypes*. The propensity of some characters to remain associated instead of assorting independently is called **linkage**.

Linkage is measured by the per cent recombination between two loci (in formal terms a *map distance of 1 centimorgan = 1% recombination*). When pairwise combinations of loci on the same chromosome are tested in genetic crosses, loci close to one another are linked, as defined by a map distance <50 cM. Loci that are farther apart recombine at the limit of 50%. But a **linkage map** corresponding to the chromosome can be generated by extending a series of genetic crosses in which in effect two loci >50 cM apart are connected because they show linkage to a locus between them. This genetic map corresponds to the physical existence of the chromosome.

A crucial concept in the construction of a genetic map is that the distance between genes does not depend on the particular **alleles** that are used, but only on the genetic *loci*. The **locus** defines the position occupied on the chromosome by the gene representing a particular trait. The various alternative forms of a gene – that is, the alleles used in mapping – all reside at the same location on its particular chromosome. So genetic mapping is concerned with identifying the positions of genetic loci, which are fixed and lie in a linear order. In a mapping experiment, the same result is obtained irrespective of the particular combination of alleles.

**Figure S 8** shows how a **backcross** to a recessive homozygote is used to measure linkage. The alleles of the recessive parent make no contribution to the phenotype of the progeny. As a result, the backcross essentially makes it possible to examine directly the genotype of the organism being investigated. In each cross the progeny show an increase in the proportion of parental types (70%) and a decrease in the proportion of recombinant types (30%), compared with the 50% of each type that is expected from independent assortment. The linkage between A and B is measured as 30%.

**Figure S 8** Linkage can be measured by a backcross with a double recessive homozygote.

The smaller the proportion of recombinants in the progeny, the tighter the linkage. A crucial characteristic is that the *same proportion of recombinants is obtained irrespective of the arrangement of parental alleles ( $AB/ab$  or  $Ab/aB$ )*. And in each case, both of the (reciprocal) recombinant types are present in the same proportions..

Morgan proposed that genetic linkage is the "simple mechanical result of the location of the (genes) in the chromosomes." He suggested that the production of recombinant classes can be equated with the process of **crossing-over** that is visible during meiosis. Early in meiosis, at the stage when all four copies of each chromosome are organized in a bivalent, pairwise exchanges of material occur between the closely associated (synapsed) chromatids.

The visible result of a crossing-over event is called a **chiasma**, and is illustrated diagrammatically in **Figure S 9**. A chiasma represents a site at which two of the chromatids in a bivalent have been broken at corresponding points. The broken ends have been rejoined crosswise, generating new chromatids. Each new chromatid consists of material derived from one chromatid on one side of the junction point, with material from the other chromatid on the opposite side. The two recombinant chromatids have reciprocal structures. The event is described as a **breakage and reunion**.

**Figure S 9** Chiasma formation is responsible for generating recombinants.

If the likelihood that a chiasma will form between two points on a chromosome depends on their distance apart, genes located near each other will tend to remain together. As the distance decreases, the probability of crossing-over between them will decrease. If crossing-over is responsible for recombination, the closer genes lie to one another, the more tightly they will be linked. Reversing the argument, genetic linkage can be taken to be a measure of physical distance.

The extent of recombination between two genes on the same chromosome can be used as a **map distance** to measure their relative locations. The formula to measure genetic distance is:

$$\text{Map distance} = \frac{\text{Number of recombinants} \times 100}{\text{Total number of progeny}}$$

**Map units** are defined as 1 unit (or centiMorgan, abbreviated cM) equals 1% crossover. For short distances (<10%), map units are given directly by the percent recombinants. However, when two crossovers occur near one another, they restore the parental arrangement of the loci on either side. This reduces the number of recombinants, so that recombination frequency underestimates the map distance.

A critical feature is observed when multiple characters are followed together. For genes carried on the same chromosome, *individual map distances are (approximately) additive*. If two genes *A* and *B* are 10 units apart, and gene *C* lies a further 5 units beyond *B*, the direct measure of distance between *A* and *C* will be close to 15 units. The genes can therefore be placed in a *linear order*.

A crucial concept in the construction of a genetic map is that the distance between genes does not depend on the particular *alleles* that are used, but only on the genetic

loci>. The **locus** defines the position occupied on the chromosome by the gene representing a particular trait. The various alternative forms of a gene – that is, the alleles used in mapping – all reside at the same location on its particular chromosome.

So genetic mapping is concerned with identifying the positions of genetic loci, which are fixed and lie in a linear order. In a mapping experiment, the same result is obtained irrespective of the particular combination of alleles (see **Figure S 8**, where in either combination, there are 70% parental and 30% recombinant types).

Linkage is not displayed between all pairs of genes located on a single chromosome. The maximum recombination between two loci is the 50% corresponding to the independent segregation predicted by Mendel's second law. (Although there is a high probability that recombination will occur between two genes lying far apart on a chromosome, each individual recombination event involves only two of the four associated chromatids, so there is a limit of 50% recombination between the genes.)

In spite of their presence on the same chromosome, genes that are far apart therefore assort independently. But although they show no direct linkage, each can be linked to genes that lie between them. This allows the genetic map to be extended beyond the limit of 50% recombination that can be measured directly between any pair of genes. A genetic map is usually based on measurements involving genes that are fairly close together (and is subject to corrections from the simple percent recombination).

A **linkage group** includes all those genes that can be connected either directly or indirectly by linkage relationships. Genes lying close together show direct linkage; those >50 cM apart assort independently. As linkage relationships are extended, the genes of any organism fall into a discrete number of linkage groups. Each gene identified in the organism can be placed into one of the linkage groups. Genes in one linkage group always show independent assortment with regard to genes located in other linkage groups.

*The number of linkage groups is the same as the (haploid) number of chromosomes. The relative lengths of the linkage groups are similar to the relative sizes of the chromosomes.*

Mendel's concept of the gene as a discrete particulate factor can therefore be extended into the concept that *the chromosome constitutes a linkage group, divided into many genes, whose physical arrangement underlies their genetic behavior*. We sometimes use the term genetic marker to describe a gene of interest, for example, one being used in a mapping experiment or identifying a particular region. Thus a chromosome may be said to carry a particular set of **markers**, that is, alleles.

On the genetic maps of higher organisms established during the first half of this century, the genes are arranged like beads on a string. They occur in a fixed order, and genetic recombination involves transfer of corresponding portions of the string between homologous chromosomes. The gene is to all intents and purposes a mysterious object (the bead), whose relationship to its surroundings (the string) is unclear.

The resolution of the recombination map of a higher eukaryote is restricted by the

small number of progeny that can be obtained from each mating. Recombination occurs so infrequently between nearby points that it is rarely observed between different mutations in the same gene. This forces the questions: does recombination occur within a gene; and can its frequency at these close quarters be used to arrange sites of mutation in a linear order?

To answer these questions by conventional genetic means requires a microbial system in which a very large number of progeny can be obtained from each genetic cross. A suitable system is provided by **phage T4**, a virus that infects the bacterium *E. coli*. Infection of a single bacterium leads to the production of ~100 progeny phages in less than 30 minutes.

The constitution of an individual locus was investigated by Benzer in a series of intensive studies of the *rII* genes of the phage, which are responsible for a change in the pattern of bacterial killing known as **rapid lysis**. When two different *rII* mutant phages are used to infect a bacterium simultaneously, the conditions can be arranged so that progeny phages will be produced *only* if recombination has occurred between the two mutations to generate a wild-type recombinant. The frequency of recombination depends on the distance between sites, just as in the eukaryotic chromosome.

The selective power of this technique in distinguishing recombinants of the desired type allows even the rarest recombination events to be quantitated, so that the map distance between *any* pair of mutations can be measured. About 2400 mutations fall into 304 different mutant sites. (When two mutations fail to recombine, they are assumed to represent independent and spontaneous occurrences at the *same* genetic site.)

The mutations can be arranged into a linear order, showing that *the gene itself has the same linear construction as the array of genes on a chromosome*. So the genetic map is linear within as well as between loci: it consists of an unbroken sequence within which the genes reside. This conclusion has of course now been extended in molecular terms to all known genetic systems.

**SUPPLEMENTS****7.32.4 Protein folding**

---

**Key Terms**

A **cofactor** is a small inorganic component (often a metal ion) that is required for the proper structure or function of an enzyme.

**Chaperones** are a class of proteins which bind to incompletely folded or assembled proteins in order to assist their folding or prevent them from aggregating.

A **domain** of a protein is a discrete continuous part of the amino acid sequence that can be equated with a particular function.

---

We can consider two principles that might control the folding of a protein into the correct higher-order structure.

- *Folding is an intrinsic feature of the primary sequence.* In this case, the final structure must always be the most stable thermodynamically and can be generated at any time after synthesis of the polypeptide chain is complete.
- *The correct structure can be generated only during the synthesis of the polypeptide.* Then it becomes possible that an intrinsically less stable structure could prevail because the protein becomes "trapped" in it during synthesis.

The relationship between higher-order structures and the primary structure may be revealed when a protein is *denatured* by heating or by chemical treatments that disrupt protein conformation. Most denaturing events involve the breakage of hydrogen and other noncovalent bonds. An exception is the disruption of S–S bridges that results from treatment with reducing agents. However, all of these changes affect the *conformation*; the primary sequence of amino acids in the polypeptide chain remains unaltered.

In some cases, the higher-order structure follows ineluctably from the primary sequence. The enzyme ribonuclease is the classic example (1115). After the protein has been denatured, its active conformation can be regained by reversing the denaturing procedure. *All the information necessary to form the secondary structure resides in the primary sequence.* Thus the production of active ribonuclease is an inevitable event whenever the intact primary chain is placed in the appropriate conditions.

In other cases, proteins can be irreversibly denatured. Thus under certain (nonphysiological) conditions, a protein may have alternative stable conformations. In some cases the correct conformation probably can be attained *only* during synthesis of the protein. The conformation could depend on specific interactions between regions of the protein that can occur only in the absence of other regions (that is, those that have not yet been synthesized). This is probably the more common situation.

In some instances, a **cofactor** that is part of the active protein (such as the iron-binding heme group of the cytochromes) must be present in order for the polypeptide chain to take up its proper conformation. In the case of multimeric proteins, it may be necessary for one subunit to be present in order for another to acquire the proper conformation.

Protein folding is usually rapid *in vivo*, occurring within seconds or less. It begins even before a protein has been completely synthesized. Probably it involves a *sequential folding* mechanism, in which the reaction passes through discrete (although highly transient) intermediates. The process is initiated by the collapse of hydrophobic side chains into the "core" of the protein; this occurs within milliseconds. Units of secondary structure, largely  $\alpha$ -helices and  $\beta$ -sheets, form on the same time scale. The transition from this structure to the final tertiary structure is slower. The process appears to be cooperative, so that formation of one region of secondary structure enhances formation of the next region, and so on (for review see 2389)

The acquisition of structure when a protein is synthesized is not a spontaneous process, but may require assistance. More precisely, we should say that spontaneous folding is a slow reaction, which under normal cellular conditions is a rate-limiting step. The rate is significantly increased by several types of additional functions. These are summarized in **Figure S 10**. They fall into two groups: enzymes that catalyze specific isomerization steps; and factors that act stoichiometrically to influence folding directly.

Protein Activity	Families	Function	Effect
<b>Catalytic</b>			
Protein disulfide isomerase	Thioredoxin	Formation of S-S bonds	Increases rate of folding
Peptidyl prolyl isomerase	Cyclophilin PPI FKBP PPI	<i>cis/trans</i> bond conversion "	
<b>Stoichiometric</b>			
Chaperones	Hsp-70 (DnaK) Hsp-60 (GroEL) Hsp-90	Binds improperly folded protein	Inhibits wrong folding pathway

©virtualtext www.ergito.com

**Figure S 10** Both catalytic and stoichiometric functions are required to assist protein folding

The formation of disulfide bonds is shown in **Figure S 11**. The animation shows that formation of a disulfide bond may have a major effect on the conformation of the protein. It is influenced by both environment and specific accessory proteins. Disulfide bonds are rare in cytoplasmic proteins, but common in exported proteins. This is related to a difference in the thiol/disulfide redox state between internal and external conditions. It may help to prevent bond formation in a bacterium, but helps to drive it in the periplasm (the layer surrounding the bacterial cell).

**Figure S 11** Formation of a disulfide bridge between the sulfhydryl groups of two cysteines may connect different parts of a polypeptide chain.

Disulfide bond formation can occur spontaneously *in vitro*, but the rate is slow. It has a  $t_{1/2} > 15$  min, compared with the ability to form disulfide bonds correctly within a few seconds *in vivo*. The process is catalyzed *in vivo* by an enzyme, protein disulfide isomerase (PDI). This is a curious protein, which participates in a variety of functions concerned with protein-modification, in addition to its sponsorship of disulfide bridge formation. It is not entirely clear whether it simply helps the initial formation of disulfide bonds or whether it also catalyzes rearrangement of disulfide bonds that have formed incorrectly (for review see 3443)

Proline has a major effect upon protein structure because of the restrictions imposed by its ring structure. Proline introduces a bend in a polypeptide chain, because the nitrogen atom is restrained by the ring structure. The existence (and interconversion) of two stereochemical forms of the peptidyl-proline link is an important feature of protein structure. The direction of the bend is determined by whether the proline is in the *cis* or *trans* configuration, as shown in **Figure S 12**.

**Figure S 12** The configuration of proline has an important effect on protein conformation.

Proteins containing proline fold slowly because the peptidyl-proline link does not necessarily form in correct stereochemical conformation. The enzyme peptidyl-prolyl isomerase (PPI) catalyzes the *cis-trans* conversion, and by this means significantly accelerates the folding reaction. Enzymes with PPI activity fall into two major groups, named for their abilities to bind certain drugs: cyclophilin PPI binds the drug cyclosporin A, and FKBP PPI binds the drug FK506. Members of the cyclophilin class are better characterized, and they vary in their specificity of action from those that appear to be generic (able to act on any protein) to those that appear to work only with specific proteins. This makes the point that, although control of proline isomerization is a general feature of many proteins, it can also be used to control specifically the maturation of an individual protein.

Proteins that act stoichiometrically on the folding of other proteins are called molecular **chaperones**. A chaperone forms a complex with a protein during folding, *but is required only during assembly, and is not part of the mature structure*. The major role of a chaperone is to prevent the formation of incorrectly folded structures, in which the substrate protein might otherwise become trapped during folding (see **Figure 8.8** in *Molecular Biology 2.8.4 Chaperones may be required for protein folding*).

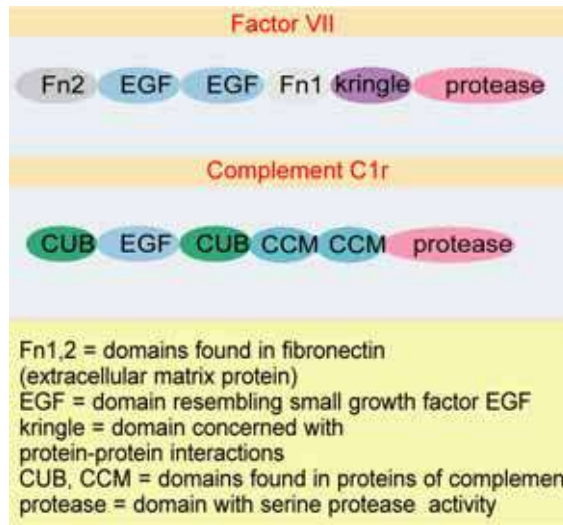

Protein folding is an intricate process. The primary sequence of a protein is a crucial

determinant of its higher-order structures. Sometimes it is the sole determinant, but in most cases additional interactions are involved in acquiring the final conformation. In each case, however, if the primary sequence is synthesized within the appropriate environment, it will acquire the proper higher-order structures.

Although higher-order structure follows from primary sequence, the same general tertiary structure can be determined by different primary sequences. For example, the globin (red blood cell) proteins of different species vary substantially in sequence, but have the same general tertiary structure.

An important concept is that a protein may consist of **domains**. A domain is a (relatively) independent region of the protein. In some cases its conformation can be acquired independently by the relevant fragment of the polypeptide chain. Some globular proteins consist of discrete domains connected by "clefs." Sometimes a substrate binds to the cleft between domains.

A domain may represent a functional unit that is identified with a particular activity of the protein, for example, its ability to perform a certain catalytic activity, to bind a certain ligand, or to interact specifically with other types of domains. The lengths of recognized domains vary from 30–300 amino acid residues. Certain types of domains may be found in proteins with particular locations; for example, on the exterior of the cell. A domain may represent an evolutionary unit. It may have arisen as a functional polypeptide or region of a polypeptide and later have associated with other domains to generate a new protein with additional abilities. The occurrence of closely related domains in different proteins is common; **Figure S 13** compares the use of domains in two blood cell proteins.

**Figure S 13** Overlapping arrangements of discrete domains are found in proteins.

**SUPPLEMENTS****7.32.5 Membranes and membrane proteins**

---

**Key Terms**

**Amphipathic** structures have two surfaces, one hydrophilic and one hydrophobic.

Lipids are amphipathic; and some protein regions may form amphipathic helices, with one charged face and one neutral face.

A **saturated** fatty acid only has single carbon-carbon bonds in its backbone.

An **unsaturated** fatty acid has some double carbon-carbon bonds in its backbone.

A **phospholipid** is a lipid that has a positively charged head that is linked by a phosphate group to the fatty acid tails.

A **glycolipid** has a head consisting of an oligosaccharide, linked to a fatty acid tail.

A **sterol** is a compound containing a planar steroid ring.

A **lipid bilayer** is a structure formed by phospholipids in an aqueous solution. The structure consists of two sheets of phospholipids, in which the hydrophilic phosphate groups face the aqueous solution and the hydrophobic tails face each other.

**Fluidity** is a property of membranes; it indicates the ability of lipids to move laterally within their particular monolayer.

A **transmembrane protein (Integral membrane protein)** extends across a lipid bilayer. A hydrophobic region (typically consisting of a stretch of 20-25 hydrophobic and/or uncharged amino acids) or regions of the protein resides in the membrane. Hydrophilic regions are exposed on one or both sides of the membrane.

The **transmembrane region (transmembrane domain)** is the part of a protein that spans the membrane bilayer. It is hydrophobic and in many cases contains approximately 20 amino acids that form an  $\alpha$ -helix. It is also called the transmembrane domain.

A **hydropathy plot** is a measure of the hydrophobicity of a protein region and therefore of the likelihood that it will reside in a membrane.

The side of the plasma membrane, or of the membrane of an organelle, which faces the cytoplasm is its **cytoplasmic face**.

The **extracellular matrix (ECM)** is a relatively rigid layer of insoluble glycoproteins that fill the spaces between cells in multicellular organisms. These glycoproteins connect to plasma membrane proteins.

---

The characteristic properties of membranes result from their high contents of lipids. A crucial feature of lipids creates the membranous environment: they are **amphipathic**. One end of the molecule consists of a polar "head," while the other end consists of a hydrophobic "tail."

The major bulk of a lipid is provided by its hydrophobic tails, which differ in overall

length and in the nature of the carbon-carbon bonds. One type of fatty acid tail is **saturated**: all the carbon-carbon links are single bonds. The other type of tail is **unsaturated**: one or more carbon-carbon links consist of double bonds. Because rotation is restricted around the double bond, the unsaturated tail has a bend, while the saturated tail can extend freely. Fatty acid tails are usually ~20 residues long. Distinguished by their polar heads, membranes contain the three principal types of lipids illustrated in **Figure S 14**:

**Figure S 14** A lipid has a polar head and a hydrophobic tail.

- In **phospholipids** the head has a positively charged group linked via a negatively charged phosphate group to the rest of the molecule. The example of **Figure S 14** has a head consisting of choline-phosphate-glycerol, attached to two hydrophobic tails. Lipids based on glycerol have one saturated and one unsaturated fatty acid tail.
- **Glycolipids** are characterized by the presence of oligosaccharide. The chain of sugars typically consists of 1-15 residues. In animal cells, the connection between the saccharide head and the fatty acid tail is sphingosine (a long amino alcohol). Lipids based on sphingosine have a fatty acid chain in addition to the long hydrocarbon chain of sphingosine itself. In plants and bacteria, glycerol connects the head and tail.
- **Sterols** contain a steroid ring. They lend rigidity to a membrane because the steroid ring is planar. Cholesterol, a prominent component of animal cell

membranes, has a polar hydroxyl group at the terminus.

In an aqueous environment, a lipid is happy to have its polar head exposed, but tries to bury its hydrophobic tail away from the water. **Figure S 15** illustrates how this is accomplished in the cell. Two lipid monolayers are juxtaposed to form a **lipid bilayer**, a sheet in which the polar heads of the lipids face out toward the aqueous environment on either side, while the hydrophobic tails face in to create a hydrophobic environment.

**Figure S 15** A lipid bilayer forms in an aqueous environment when the the polar heads are immersed in the water and the hydrophobic tails of the lipids segregate away from water.

Although a membrane consists of a specific type of structure, the lipid bilayer, there is variety in the constitution of different membranes. Overall lipid compositions of membranes vary considerably, with regard to both the ratio of protein to lipid and the types of lipids. These differences mean that different membranes have different biophysical properties.

One of the important properties of a membrane is the ability of the constituent lipids to move within it. Lipid molecules rarely move from one monolayer to the other in a bilayer, but frequently move laterally to exchange places with their neighbors within the monolayer. The property of movement is called **fluidity**; and a membrane is often regarded as a "two dimensional fluid" (1023).

The more readily the tails of adjacent lipids can pack together, the more crystalline the membrane structure can become, and the less fluid. The major determinants of membrane fluidity are therefore the types and lengths of the lipid tails. The proportion of saturated versus unsaturated residues in the tails has a major effect on fluidity; unsaturated chains are more difficult to pack, and therefore give a more fluid structure.

A protein that resides in a membrane is called a **transmembrane protein**. The structure of such a protein is illustrated in **Figure S 16**. A typical transmembrane protein resides in the membrane by means of a specific region called the **transmembrane domain**. This consists of a stretch of ~21 amino acids with

sufficient hydrophobicity to be comfortable in the environment of the lipid bilayer. It forms an  $\alpha$ -helix that just spans the membrane. The transmembrane domain is flanked by regions that protrude into the interior of the cell or out into the surrounding environment. These regions are generally hydrophilic, like any protein that resides in the cytosol. A protein may have several transmembrane domains, in which case the parts of the polypeptide chain connecting them can be viewed as "looping out" into the cytoplasm or the exterior.

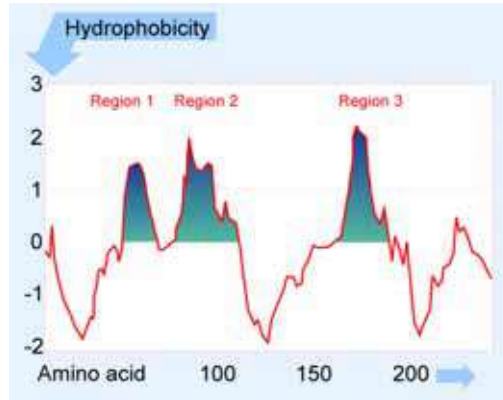

**Figure S 16** A transmembrane protein crosses the lipid bilayer. The hydrophobic transmembrane region spans the bilayer, and hydrophilic regions are exposed on either side.

Within the lipid bilayer, water is effectively excluded. As a result, the regions of the proteins located within the bilayer are not subjected to the aqueous environment of the cytosol. The lipid "solvent" does not form hydrogen bonds with the protein, and therefore solvates neither the groups of the peptide backbone nor polar side chains. Hydrogen bonding occurs solely between groups within the protein itself, and functions to form  $\alpha$ -helices and (to a lesser degree)  $\beta$ -sheets. This allows the protein to acquire a different conformation from what would be reached in an aqueous environment. Indeed, it is possible that membrane proteins can attain their natural conformation *only* in the hydrophobic environment.

The hydrophobicity of a sequence of amino acids can be used to predict (although not perfectly) whether it is likely to reside in a membrane. A **hydropathy plot** shows the sequence of a protein in terms of the hydrophobicity of overlapping segments. There are various means of measuring hydrophobicity, but whichever scale is used, it is conventional to assess hydrophobicity as a positive score and hydrophilicity as a negative score. Most of the scales utilize the energy required in kcal/mol to transfer from a hydrophobic to a hydrophilic phase.

In the example of **Figure S 17**, the hydrophobicity is calculated for each position in the protein by summing the scores of the individual amino acids in the next 21 positions. A region with a positive score is therefore a candidate to provide a transmembrane domain that resides in a membrane.

**Figure S 17** A hydropathy plot identifies potential membrane-spanning regions as the most hydrophobic sequences of a protein.

Proteins may also be associated with a membrane by means of covalent linkage to a fatty acid that is incorporated into the lipid bilayer. **Figure S 18** depicts four forms of such association. In each case, a fatty acid or lipid is attached to an amino acid near to or at one terminus of the protein, with the result that the entire polypeptide chain resides on one side of the membrane, but is attached to it.

**Figure S 18** Proteins may be associated with one face of a membrane by acyl linkages to fatty acids.

Prenylation is used to attach proteins to both the plasma membrane and internal membranes. Two types of prenyl groups have been identified: farnesyl is a 15 carbon

isoprenoid (shown in the figure), and geranylgeranyl is a 20 carbon chain. They are added to cysteine residues by a thioester linkage; the cysteine is always located at the fourth position from the C terminus, as part of the sequence CAAX, where A represents aliphatic amino acids and X is methionine or serine for farnesylation, and leucine for geranylgeranylation. The usefulness of the prenyl groups for assisting attachment to the membrane is obvious, but we do not yet know how specificity is conferred with regard to the choice of membrane.

Two fatty acids are used to anchor proteins on the cytoplasmic side of the plasma membrane. Palmitic acid, a 16 carbon-chain saturated fatty acid, is linked through a sulfide bond to a cysteine residue located close to the terminus (usually the C-terminus, but sometimes the N-terminus). Myristic acid, a 14 carbon-chain saturated fatty acid, is linked to the amino group of N-terminal glycine. Myristoylated proteins are often, but not always, associated with a membrane.

The more complex structure of a glycosyl-phosphatidyl-inositol (GPI) anchor is linked to the carboxyl group of the C-terminal amino acid of protein exposed on the extracellular side of the membrane. Addition of the GPI anchor actually involves cleavage of the original polypeptide chain near the C-terminus, generating a new C-terminus that is linked to the anchor. Enzymes exist that can cleave the GPI anchor from the protein, releasing the protein into the extracellular medium.

The membranes bounding different cellular compartments are different not only in their overall composition, but also in the particular proteins that reside within them. The proteins in each type of membrane serve, for example, to control transport into or out of the particular compartment, and are therefore designed to recognize the particular molecules or macromolecules that travel this route.

Each membrane has two "faces," as indicated in **Figure S 19**. In all membranes, the **cytoplasmic face** is defined as the surface that contacts the general cytosol. The noncytoplasmic face is given various names, depending on the membrane. On a plasma membrane, it provides the outside surface of the cell. In a membrane within the cell, it provides a limit for an interior compartment, comprising the surface that separates the lumen of the compartment from the cytosol.

**Figure S 19** The asymmetry of the membrane bilayer distinguishes the cytoplasmic face from the exterior face.

A major feature of the lipid bilayer is an asymmetry created by biochemical differences between the two faces of the membrane. Three components of the plasma membrane are unevenly distributed:

- Different lipids are concentrated in the cytoplasmic and extracellular monolayers. This affects both the polar heads and the hydrophobic tails. Lipids on the cytoplasmic face are more highly charged and tend to be unsaturated. How is the difference between the monolayers established? Lipids are synthesized within the cell, and initially inserted into the cytoplasmic surface of the membrane. A specific protein, a "flippase," may be responsible for transporting a lipid from one monolayer to the other. The existence of specific flippases for different lipids could be responsible for creating some of the asymmetries in lipid distribution between the bilayers.
- Proteins are oriented so that different sequences (or even entire proteins) are present on each face. The location of a protein is determined by its sequence, which contains signals that cause it to be inserted in the membrane in a particular orientation. This is discussed in detail in *Molecular Biology 2.8.15 Anchor sequences determine protein orientation*.
- Carbohydrate groups (on glycolipids or glycoproteins) are found exclusively on the extracellular face. The consequence of this organization for the plasma membrane is that the exterior of the cell has a surface rich in oligosaccharides.

The plasma membrane circumscribes a cell. It marks the boundary between the cellular milieu inside and the environment outside. In the case of a unicellular organism, the surroundings constitute the environment in which the organism lives. In a multicellular organism, the environment for any one cell is created by other cells. In some cases, the plasma membrane is extended by the presence of additional glycoproteins, connected to those actually included in the membrane. This type of arrangement may form a cell coat. In some cases, the cell coat is extended into an **extracellular matrix**, rich in glycoproteins, and providing a thicker layer at the cell surface.

The role of the plasma membrane extends beyond providing a mere barrier to the outside. It controls ingress and egress for molecules both small and large. Within the membrane reside specific transport systems that pump ions in or out, that allow proteins to be secreted from the cell into the environment (see *Molecular Biology 6.27 Protein trafficking*), and that recognize molecules outside and as a result transmit messages to the interior (see *Molecular Biology 6.28 Signal transduction*).

Plasma membranes of animal cells contain relatively large amounts of cholesterol, which increases mechanical stability because of the steroid rings near its polar head. (Plant cells lack cholesterol, but have other sterols instead.) Plasma membranes also are the only membranes to contain significant amounts of glycolipids.

A plasma membrane contains about equal masses of lipid and protein. Internal membranes, such as those surrounding mitochondria, have a greater proportion of protein. The mass of an individual protein molecule is much larger than any lipid, so there are 10–100× more lipid molecules than protein molecules. We might view the basic structure of a membrane as consisting of a lipid bilayer that provides a residence for relatively large protein molecules.

Protein components of the membrane can move laterally within the lipid bilayer, although they diffuse much more slowly than the lipid components. As the result of a stimulus, proteins can be "internalized," when they are removed to the interior of the cell. Other proteins are secreted from the interior of the cell to the exterior by passing through the membrane. The lipid bilayer itself, and the proteins associated with it, therefore comprises a dynamic structure.

**SUPPLEMENTS****7.32.6 ER and Golgi**

---

**Key Terms**

The **endoplasmic reticulum (ER)** is an organelle involved in the synthesis of lipids, membrane proteins, and secretory proteins. It is a single compartment that extends from the outer layer of the nuclear envelope into the cytoplasm. It has subdomains, such as the rough ER and smooth ER.

The **lumen** describes the interior of a compartment bounded by a membrane, usually the endoplasmic reticulum or the Golgi apparatus.

**Rough endoplasmic reticulum (rough ER)** refers to the region of the endoplasmic reticulum to which ribosomes are bound. It is the site of synthesis of membrane proteins and secretory proteins.

**Smooth ER** consists of a regions of endoplasmic reticulum devoid of ribosomes.

The **ribosome** is a large assembly of RNA and proteins that synthesizes proteins under direction from an mRNA template. Bacterial ribosomes sediment at 70S, eukaryotic ribosomes at 80S. A ribosome can be dissociated into two subunits.

The **Golgi apparatus** is an organelle that receives newly-synthesized proteins from the endoplasmic reticulum and processes them for subsequent delivery to other destinations. It is composed of several flattened membrane disks arranged in a stack.

The **cisternae** of the Golgi apparatus are the successive stacks, each bounded by a membrane, that make up individual compartments.

The **cis face** of the Golgi is the side juxtaposed to the nucleus.

The **trans face** of the Golgi is juxtaposed to the plasma membrane.

**Lipid trafficking** is the movement of lipids among the various membranes of a eukaryotic cell.

An **endosome** is an organelle that functions to sort endocytosed molecules and molecules delivered from the trans-Golgi network and deliver them to other compartments, such as lysosomes. It consists of membrane-bounded tubules and vesicles.

A **lysosome** is an organelle that contains hydrolytic enzymes and has an acidic lumen (pH as low as 4.5). Its primary function is the degradation of endocytosed material.

The **peroxisome** is an organelle in the cytoplasm enclosed by a single membrane. It contains oxidizing enzymes.

---

Membranes occupy a major part of the eukaryotic cell. In addition to surrounding individual organelles, large sheets of membranes are a prominent feature of many cells (especially those involved in secreting proteins). The electron micrograph in **Figure 8.19** shows an extensive sheet of membranes that extends from the nucleus. This is the **endoplasmic reticulum**, a highly convoluted sheet of membranes

representing 30–60% of total membrane. The interior space comprises the **lumen**.

Visualized in the electron micrograph, the endoplasmic reticulum can be divided into two types: **rough ER** and **smooth ER**. They are part of the same membrane sheet. The characteristic appearance of the rough ER results from the presence of **ribosomes** on its cytoplasmic surface. The ribosomes are small particles concerned with the synthesis of proteins. Their presence is an indication that proteins are being synthesized at the cytoplasmic surface of the endoplasmic reticulum, which then processes them for assignment to various cell compartments.

Between the endoplasmic reticulum and the plasma membrane lies the **Golgi apparatus**. The electron micrograph in **Figure S 20** shows the Golgi as a series of individual membrane sheets, tightly packed together.

**Figure S 20** The Golgi apparatus consists of a series of individual membrane stacks. Photograph kindly provided by Alain Rambourg.

The relationship between the ER and Golgi is depicted diagrammatically in **Figure S 21**. The ER is shown as a sheet made from the folding of a single lipid bilayer that extends from the outer membrane surrounding the nucleus. The Golgi consists of a "stack" of flat **cisternae**, like a pile of discs. Each cisterna consists of a closed structure bounded by a single continuous membrane. A stack usually consists of <10 cisternae, but the number of stacks varies considerably among different types of cell. The cisternae appear to be separate structures, each contained by its own membrane.

**Figure S 21** The endoplasmic reticulum consists of a continuous sheet of highly folded membranes extending from the outer nuclear membrane. The Golgi consists of stacks of separate cisternae.

The Golgi apparatus is polarized. In secretory cells, the **cis face** is associated with the endoplasmic reticulum. The **trans face** lies toward the plasma membrane. Proteins that are moving through the system are transported from the ER to enter the Golgi at the **cis face**, pass through the stacks as they are transported to the **trans face**, and then exit at the TGN (*trans* Golgi network). The Golgi stacks have different biochemical constitutions, and can be fractionated on this basis to give preparations that represent the different enzymatic activities associated with progression across the Golgi.

Most lipids are synthesized in the endoplasmic reticulum. Other membranes presumably gain their lipid components by transport from the ER, although little is known about this process of **lipid trafficking**. The lipid transport system must be responsible for the differences in lipid composition between different cellular membranes.

Some small membrane-bound organelles are associated with the ER-Golgi system. In particular, **endosomes** are also involved in protein trafficking. They are small bodies located in the vicinity of the *trans*-Golgi and plasma membrane, and they undergo a process of active interchange with the Golgi and plasma membrane.

**Lysosomes** are rather small, spherical membrane-enclosed bodies that contain hydrolytic enzymes. They are formed by budding these bags of enzymes from the

Golgi apparatus. Lysosomes are heterogeneous; different vesicles contain different enzymes. Their properties depend on the particular hydrolytic activities of the particular enzymes.

An organelle of rather similar size is the **peroxisome**, another membrane-enclosed body, which contains the enzyme catalase. Together with other enzymes, it is responsible for a series of oxidizing reactions.

*This content is available online at <http://www.ergito.com/main.jsp?bcs=MBIO.7.32.6>*

## SUPPLEMENTS

## 7.32.7 Allostery

## Key Terms

**Allosteric** regulation describes the ability of a protein to change its conformation (and therefore activity) at one site as the result of binding a small molecule to a second site located elsewhere on the protein.

The **effector site** is the site that is bound by a small molecule on an allosteric protein. The result of binding is to change the activity of the active site, which is located elsewhere on the protein.

An **active site** is the restricted part of an enzyme to which a substrate binds.

**Feedback inhibition** describes the ability of a small molecule product of a metabolic pathway to inhibit the activity of an enzyme that catalyzes an earlier step in the pathway.

**Allosteric** proteins exist in alternative conformations and have different biological properties in each conformation. The transition between conformations is influenced by the interaction of the protein with a cofactor or with another protein.

**Figure S 22** illustrates the consequences of an allosteric transition. The crucial feature in allostery is the ability of a small molecule to bind to one site on the protein (the **effector site**) to trigger a change in conformation that alters the structure and activity of another site (the substrate-binding or **active site**). Allosteric transitions affect *only* the conformation – they do not change the primary sequence – and they rely heavily on making and breaking hydrogen bonds.

**Figure S 22** When a small molecule binds to an effector site, an allosteric protein changes conformation so that the function of the substrate-binding site is altered.

*This is a static version of an interactive figure; see*

*<http://www.ergito.com/main.jsp?bcs=MBIO.7.32.7> to view properly.*

Allosteric proteins play an important role in both metabolic and genetic regulation. Often the product of a metabolic pathway can bind to an enzyme catalyzing an early step in the pathway to prevent it from sending further small molecules through the pathway. This interaction is called **feedback inhibition**. It is illustrated in **Figure S 23**. The equivalent interaction in genetic regulation occurs when the product of a pathway binds to a protein that turns off expression of the genes coding for the enzymes of the pathway.

**Figure S 23** Feedback inhibition results when an effector that inhibits an enzyme's activity is itself the product of the pathway in which the enzyme functions.

Allosteric proteins are often multimeric. In such cases, the conformation of one subunit can influence the conformation of the other subunit(s). One common form of interaction occurs when the protein consists of two different types of subunit, one bearing the regulatory (effector) site, and the other bearing the catalytic (substrate-binding) site. When we redraw the interaction of **Figure S 22** in terms of a dimer, we see the result illustrated in **Figure S 24**: binding of the effector molecule to the regulatory subunit causes a change in the structure of the substrate site on the catalytic subunit. Such a change may in principle be responsible either for activating or for inhibiting the catalytic activity.

**Figure S 24** Effector binding to a regulatory subunit can control the activity of the catalytic subunit of an allosteric protein.

Another interesting interaction occurs when an allosteric protein consists of identical subunits. Binding of an effector molecule to one subunit makes it become much easier for the other subunits to bind the effector. As illustrated in **Figure S 25**, this effect amplifies the effect of binding the first small molecule in such a way that the protein characteristically flips very rapidly from one state to another. This is an important ability in a regulatory protein.

**Figure S 25** Effector binding to one subunit of an allosteric protein may cause a structural change that enhances binding at the other subunits.

SUPPLEMENTS

7.32.8 tRNA sequences

Key Terms

The **extra arm** of tRNA lies between the T $\Psi$ C and anticodon arms. It is the most variable in length in tRNA, from 3-21 bases. tRNAs are called class 1 if they lack it, and class 2 if they have it.

Figure S 26 shows the numbering of tRNA base positions in more detail.

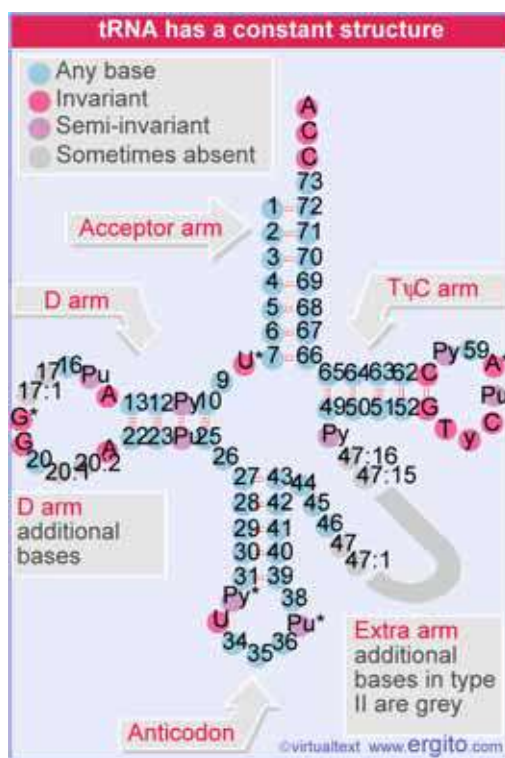

Figure S 26 tRNAs vary in length according to the sizes of the D and T $\Psi$ C arms.

As tRNAs were sequenced, positions that seemed entirely invariant did display occasional exceptions. So for practical purposes, the description of any position as invariant means that the specified base is present in >90-95% of tRNAs. Sometimes the exceptions are individual; sometimes they fall into groups representing some peculiarity of a particular cell.

The length of the D loop varies by up to 4 residues. The extra nucleotides relative to the most common structure are denoted 17:1 (lying between 17 and 18) and 20:1 and 20:2 (lying between 20 and 21). However, in the smallest D loops, residue 17 as well as these three is absent.

The most variable feature of tRNA is the so-called **extra arm**. Depending on the nature of the extra arm, tRNAs can be divided into two classes. *Class 1 tRNAs* have a small extra arm, consisting of only 3-5 bases. They represent ~75% of all tRNAs. *Class 2 tRNAs* have a large extra arm – it may even be the longest in the tRNA – with 13–21 bases, and ~5 base pairs in the stem. The additional bases are numbered from 47:1 through 47:18. The functional significance of the extra arm is unknown.

## SUPPLEMENTS

## 7.32.9 Complementation

## Key Terms

**Interallelic complementation (intragenic complementation)** describes the change in the properties of a heteromultimeric protein brought about by the interaction of subunits coded by two different mutant alleles; the mixed protein may be more or less active than the protein consisting of subunits only of one or the other type.

**Negative complementation** occurs when interallelic complementation allows a mutant subunit to suppress the activity of a wild-type subunit in a multimeric protein.

A **dominant negative** mutation results in a mutant gene product that prevents the function of the wild-type gene product, causing loss or reduction of gene activity in cells containing both the mutant and wild-type alleles. The effect may result from the titration of another factor that interacts with the gene product or by an inhibiting interaction of the mutant subunit on the multimer.

Complementation was originally developed as a test to determine whether two mutations lie in different genes. It consists of comparing the phenotypes when both mutations are the same piece of DNA (called the *cis* configuration) and when they are on different pieces of DNA (called the *trans* configuration).

**Figure S 27** shows that, if the mutations are in the same gene, the *trans* configuration has a mutant phenotype. Both copies of the gene are mutated (each copy has one of the mutations). The *cis* configuration has wild phenotype, however, because one copy of the gene has both mutations, and the other has no mutations.

**Figure S 27** When mutations are in the same gene, each allele has a different mutation, so only mutant protein is produced in the *trans* configuration.

**Figure S 28** shows that, if the mutations are in different genes, the configuration does not matter. There is always one mutant copy of each gene and one wild-type copy of each gene.

**Figure S 28** When mutations are in different genes, one allele has two mutations, but the other has none, and so produces wild-type protein.

The practical form of the test, therefore, is to use the *cis* configuration as a control (it is always wild-type) and to determine whether the *trans* configuration is mutant (mutations are in the same gene) or wild-type (mutations are in different genes).

The complementation test applies to genes whose products function as independent proteins. When the gene product is a subunit of a multimeric protein, interactions between the subunits can either allow complementation between alleles or cause one allele to suppress the effect of the other.

An exception to the rule that only different genes can complement is sometimes found when a gene represents a polypeptide that is the subunit of a homomultimeric protein. In the wild-type cell, the active protein consists of several *identical* subunits. In a cell containing two mutant alleles, however, their products can mix to form multimeric proteins that contain *both types* of subunit. **Figure S 29** shows that if the two mutations compensate, the mixed-subunit protein is active, even though the proteins consisting solely of either type of mutant subunit are inactive. This effect is called **interallelic complementation**.

**Figure S 29** Interallelic complementation occurs when different mutations in the subunits of a multimeric protein can compensate to make an active protein even though each separate subunit can only form inactive multimers.

In the reverse type of interaction, a defective subunit produced by one allele inhibits the active subunits produced by another allele. This is called **negative complementation**. **Figure S 30** shows that in effect the "bad" subunit poisons the multimeric protein so that the "good" subunits cannot function. An allele that is able to prevent other alleles from functioning is called a **dominant negative**.

**Figure S 30** Negative complementation occurs when a mutant subunit prevents the wild-type subunit from functioning.

Dominant negatives can be constructed by targeting mutagenesis at an active site in the protein. **Figure S 31** shows that one common use for this technique is to delete the DNA-binding site from a protein that is a subunit in a DNA-binding factor. When the gene for the mutant protein is introduced into the cell, the defective subunit overwhelms the normal subunits, and prevents them from forming multimers with sufficient activity to bind DNA. The same principle can be applied to any situation in which a protein forms a subunit of a multimeric protein. The subunits do not have to be identical. In **Figure S 31**, one subunit could bind DNA, while the other might interact with other proteins. The function of the second protein would be prevented by a dominant-negative subunit without a DNA-binding site.

**Figure S 31** A dominant negative mutant can be constructed by removing the DNA-binding site from a subunit of a DNA-binding protein.

The same technique can be used to target any active site, for example, the kinase site of a multimeric protein kinase enzyme. It is enormously useful because it can be used in circumstances where it is impossible to mutate the endogenous protein. This allows the function of the protein to be tested directly by introducing the mutant allele.

---

**SUPPLEMENTS****7.32.10 G proteins**

---

**Key Terms**

A **serpentine** receptor has 7 transmembrane segments. Typically it activates a trimeric G protein.

A **second messenger** is a small molecule that is generated when a signal transduction pathway is activated. The classic second messenger is cyclic AMP, which is generated when adenylate cyclase is activated by a G protein (when the G protein itself was activated by a transmembrane receptor).

---

There are two types of G proteins. The name reflects the ability to bind a guanine nucleotide. The guanine nucleotide can alternate between GDP and GTP, and controls the activity of the protein. Both types of G protein work on the same principle that the GDP-bound form is inactive, and the GTP-bound form is active.

*Trimeric G proteins* are associated with the cytosolic face of the membrane. They are involved in the initial stages of signal transduction. They are activated by transmembrane receptors, most typically by **serpentine** receptors (7-membrane pass proteins). The three subunits are called  $\alpha$ ,  $\beta$ , and  $\gamma$ . The  $\alpha$  subunit binds the guanine nucleotide.

The inactive form of the G protein is bound to GDP. In this form, the G protein is constitutively associated with a membrane receptor. When the receptor is activated (usually by binding ligand) it causes GDP to be displaced from the G protein. Because the concentration of GTP in the cytosol is much greater than that of GDP, the vacant nucleotide binding site is filled with GTP.

**Figure S 32** shows how trimeric G proteins are activated. Binding of GTP causes the G protein to dissociate into a free  $\alpha$  subunit and free  $\beta \gamma$  dimer. Depending on the individual G protein, it can be either the  $\alpha$  subunit or the  $\beta \gamma$  dimer that transmits the signal to the next stage in the pathway. Whichever is the active component (and sometimes both are active) may either activate or repress the activity of a target protein.

**Figure S 32** When a receptor is activated by hormone binding, it causes GTP to replace GDP on a  $G_{\alpha}$  subunit. The  $G_{\alpha}$  subunit dissociates from the  $\beta\gamma$  dimer, and activates an effector such as adenylyl cyclase.

*This is a static version of an interactive figure; see*

*<http://www.ergito.com/main.jsp?bcs=MBIO.7.32.10> to view properly.*

The target protein often is also associated with the membrane. This chain of events often stimulates the production of **second messengers**. In one classic example, when the protein G is activated, the  $\alpha$  subunit then activates adenylyl cyclase, which generates cyclic AMP.

How long the G protein remains active is controlled by the  $\alpha$  subunit. All  $\alpha$  subunits are GTPases. When the GTP is hydrolyzed to GDP, the  $\alpha$  subunit reassociates with the  $\beta \gamma$  dimer to reconstitute the trimeric G protein. By removing the individual subunits, the hydrolysis of GTP terminates the physiological response.

Each  $\alpha$  subunit hydrolyzes its GTP *in vitro* at a characteristic (slow) rate, typically with a half-life  $\sim 15$  secs. But some of the physiological reactions are much shorter lived. For example, in the classic system of vision, a light response terminates in  $\sim 100$  msec. The rate of GTP hydrolysis can be accelerated *in vivo* by interaction with another component of the system. This type of interaction was originally discovered for monomeric G proteins (see below), where the relevant component is called a GAP. A common type of protein with GAP function for the  $\alpha$  subunits of trimeric G proteins is the RGS (G protein signaling) class (for review see 2276). An RGS acts indirectly by affecting the conformation of the  $\alpha$  subunit so that it becomes a more effective GTPase.

Monomeric G proteins are cytosolic and are often used as binary switches in signalling or other pathways. They work on the same principle as the  $\alpha$  subunit of a trimeric G protein. A monomeric G protein is a GTPase that hydrolyzes its bound GTP. This converts it from an active state to an inactive state.

**Figure S 33** shows that three types of ancillary proteins influence the balance between the GDP- and GTP-bound forms of a monomeric G protein.

**Figure S 33** Monomeric G proteins are active when bound to GTP and inactive when bound to GDP. Their activity is controlled by other proteins.

*This is a static version of an interactive figure; see <http://www.ergito.com/main.jsp?bcs=MBIO.7.32.10> to view properly.*

- A GAP (GTPase activating protein) stimulates the GTPase activity. This is needed for a fast reaction time, because the intrinsic rate of GTP hydrolysis is slow. Thus GAP activity inactivates the G protein. Different GAPs have

specificities for different GTP-binding proteins; they are typically named as *Protein-GAP*, where Protein is the monomeric G-protein on which they act.

- A GEF (guanine nucleotide exchange factor) displaces the GDP bound to an inactive G protein. The principle of replacement is the same as for the trimeric  $\alpha$  subunit. Release of the GDP creates an empty site. The concentration of GTP in the cytosol is greater than that of GDP, so the site is then filled with GTP. This activates the protein. GEFs have the same sort of specificity as GAPs, and similarly are named in the form *Protein-GEF* (for review see 3217).
- A GDI (guanine nucleotide dissociation inhibitor) can block the displacement reaction. This maintains the G protein in the inactive state.

Examples of specific monomeric G proteins are EF-Tu (see *Molecular Biology* 2.6.10 *Elongation factor Tu loads aminoacyl-tRNA into the A site*), Ran (see *Molecular Biology* 2.8.28 *Transport receptors carry cargo proteins through the pore*), ARF and Rab (see *Molecular Biology* 6.27.7 *Vesicles can bud and fuse with membranes*), and Ras and the Rho family (see *Molecular Biology* 6.28.15 *The activation of Ras is controlled by GTP*).

**SUPPLEMENTS****7.32.11 Restriction mapping**

---

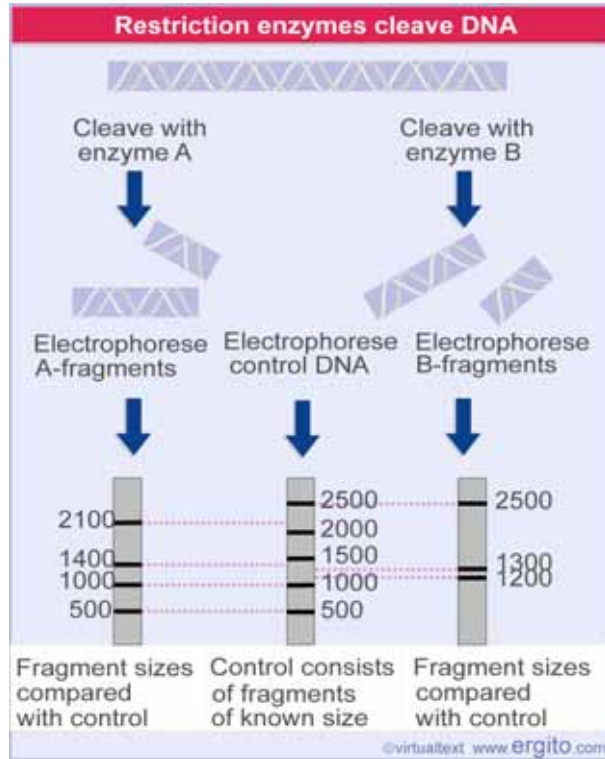

**Key Terms**

**End labeling** describes the addition of a radioactively labeled group to one end (5' or 3') of a DNA strand.

---

The principle of restriction mapping is to break a piece of DNA into several fragments that overlap, and then to place these fragments in order by making use of the overlap. One way of generating overlapping fragments is to use enzymes that cleave at different target sites. Another is to use partial cleavage, so that an enzyme attacks any individual target site with less than 100% efficiency.

**Figure S 34** shows an example of cleavage by different enzymes. A DNA molecule of length 5000 bp is incubated separately with two restriction enzymes, A and B. After cleavage the DNA is electrophoresed. The sizes of the individual fragments generated by enzyme A (left) or enzyme B (right) are determined by comparison with the positions of fragments of known size, such as the control shown in the center. This demonstrates that enzyme A has cut the substrate DNA into four fragments (lengths 2100, 1400, 1000, and 500 bp), while enzyme B has generated three fragments (lengths 2500, 1300, and 1200 bp).

**Figure S 34** DNA can be cleaved by restriction enzymes into fragments that can be separated by gel electrophoresis.

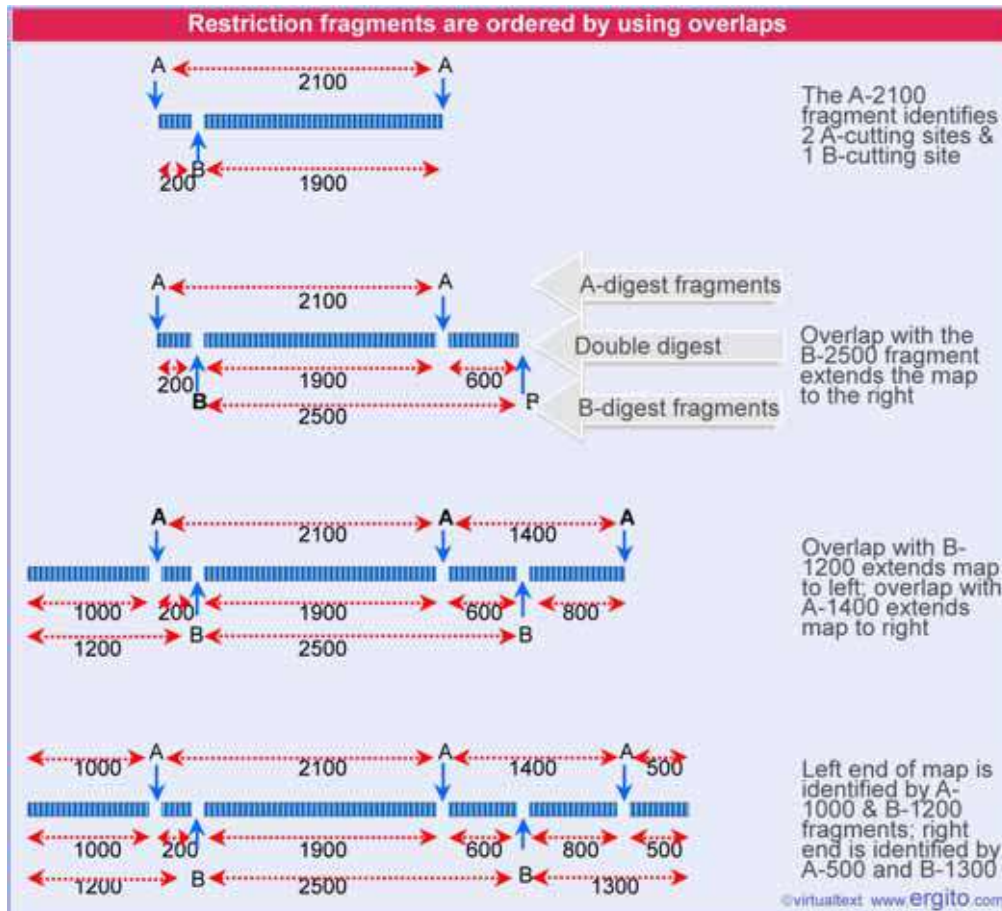

The patterns of cutting by the two enzymes can be related by several means. **Figure S 35** illustrates the principle of analysis by *double digestion*. In this technique, the DNA is cleaved simultaneously with two enzymes as well as with either one by itself. The most decisive way to use this technique is to extract each fragment produced in the individual digests with either enzyme A or enzyme B and then to cleave it with the other enzyme. The products of cleavage are analyzed again by electrophoresis.

**Figure S 35** Double digests define the cleavage positions of one enzyme with regard to the other.

We can use these data to construct a map of the original 5000 bp molecule of DNA, as illustrated by the stages of **Figure S 36**.

**Figure S 36** A restriction map can be constructed by relating the A-fragments and B-fragments through the overlaps seen with double digest fragments.

Each gel in **Figure S 35** is labeled according to the fragment that was isolated from the gel in **Figure S 34**. A-2100 identifies the fragment of 2100 bp produced by degrading the original DNA molecule with enzyme A. When this fragment is retrieved and subjected to enzyme B, it is cut into fragments of 1900 and 200 bp. So one of the cuts made by enzyme B lies 200 bp from the nearest site cut by enzyme A on one side, and is 1900 bp from the site cut by enzyme A on the other side. This situation is described by the top map in **Figure S 36**.

A related pattern of cuts is seen when we examine the susceptibility of fragment B-2500 to enzyme A. It is cut into fragments of 1900 and 600 bp. So the 1900 bp fragment is generated by double cuts, with an A site at one end and a B site at the other end. It can be released from either of the single-cut fragments (A-2100 or B-2500) that contain it. These single-cut fragments must therefore *overlap* in the region of the 1900 bp of the common fragment that can be generated from them. This is described in the second map of **Figure S 36**, which extends our map to the right to add a cleavage site for enzyme B.

The key to restriction mapping is the use of overlapping fragments. Because of the overlap of A-2100 and B-2500 in the central region of 1900 bp, we can relate the A site 200 bp to the left of the 1900 bp region with the B site 600 bp to the right. In the

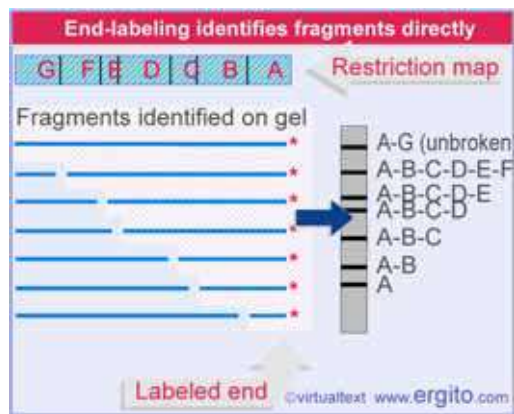

same way, we can now extend the map farther on either side. The 200 bp fragment at the left is also produced by cutting B-1200 with enzyme A, so the next B site must lie 1000 bp to the left. The 600 bp fragment at the right is also produced by cutting A-1400 with enzyme B, so the next A site must lie 800 bp to the right. This gives the third map in **Figure S 36**.

We can now complete the map by identifying the source of the two fragments at each end. At the left end, the 1000 bp fragment arises from B-1200 or in the form of A-1000, which is not cut by enzyme B. So A-1000 lies at the end of the map. Proceeding from the left end of the complete 5000 bp region, it is 1000 bp to the first A site and 1200 bp to the first B site. (This is why a B cut is not shown at the left end of the map above, although formally we treated the end as a B-cutting site in the analysis.)

At the right end of the map, the 800 bp double-cut fragment is generated by cutting B-1300 with enzyme A, so we must add a fragment of 500 bp to the right. This is the terminal fragment, as seen by its presence as A-500 in the single-cut A digest. So our completed map takes the form of the bottom map in **Figure S 36**.

The actual construction of a restriction map usually requires recourse to several enzymes, so it becomes necessary to resolve quite a complex pattern of the overlapping fragments generated by the various enzymes. Several other techniques are used in conjunction with comparison of fragments, including **end labeling**, in which the ends of the DNA molecule are labeled with a radioactive phosphate (certain enzymes can add phosphate moieties specifically to 5' or to 3' ends). **Figure S 37** shows that this allows the fragments containing the ends to be identified directly by their radioactive label. So in the fragment A preparation, A-1000 and A-500 would be placed immediately at opposite ends of the map; similarly, fragments B-1200 and B-1300 would be identified as ends.

**Figure S 37** When restriction fragments are identified by their possession of a labeled end, each fragment directly shows the distance of a cutting site from the end. Successive fragments increase in length by the distance between adjacent restriction sites.

A complex set of overlapping fragments can be generated directly by a single enzyme by using conditions of partial cleavage, as illustrated in **Figure S 38**. Of course, for mapping purposes then it is necessary to distinguish different fragments

that have the same size, and to determine overlaps. However, this is a useful technique when we want essentially to introduce random breaks into a large DNA (for example a whole genome) in order to obtain cloned fragments (see *Molecular Biology Supplement 32.12 Genome mapping*).

**Figure S 38** Partial cleavage by a restriction endonuclease generates a series of overlapping fragments.

This content is available online at <http://www.ergito.com/main.jsp?bcs=MBIO.7.32.11>

---

**SUPPLEMENTS****7.32.12 Genome mapping**

---

**Key Terms**

A **library** is a set of cloned fragments together representing the entire genome (genomic library) or all the expressed genes (cDNA library).

A **yeast artificial chromosome (YAC)** is a synthetic DNA molecule that contains an origin for replication, a centromere to support segregation, and telomeres to seal the ends. It is used as a means to propagate whatever genes it carries in yeast cells.

A **bacterial artificial chromosome (BAC)** is a synthetic DNA molecule that contains the sequences needed for replication and segregation in bacteria. This is used in genomic cloning to amplify sequences typically 100-200 kb long. They are usually derived from the naturally-occurring F factor episome.

A **contig** is a continuous stretch of genomic DNA generated by assembling cloned fragments by means of their overlaps.

**Shotgun** cloning analyzes an entire genome in the form of randomly generated fragments.

An **expressed sequence tag (EST)** is a short sequence of DNA taken from a cDNA copy of an mRNA. The EST is complementary to the mRNA and can be used to identify genes corresponding to the mRNA.

---

The principle of genome mapping is the same as restriction mapping (see *Molecular Biology Supplement 32.11 Restriction mapping*): to break a large DNA molecule into smaller molecules that are assembled in order by the principle of overlaps between their ends. Of course, there is a difference of scale when we start with a whole genome, and special tricks have to be used to assemble the fragments.

The starting point is usually the generation of a **library** of cloned fragments that represent the whole genome. This can be achieved by cleaving DNA at random, for example, by using partial cleavage conditions with a restriction endonuclease of low specificity (see **Figure S 38**). We can calculate statistically how many clones are needed for the whole genome to be represented in fragments of a given size (1441). Over the past 20 years, it has been possible to move from cloning relatively small fragments of DNA in individual plasmid or phage vectors to using synthetic chromosomes, either **YACs** (yeast artificial chromosomes) or **BACs** (bacterial artificial chromosomes). The basic principle is that the artificial chromosome consists of a long length of DNA (100-200 kb) which is able to propagate in the host cell because it has the features required for replication, segregation, and stability.

Cloned fragments are joined together by the principle of overlap, in which their ends are compared. When the end of one fragment is identical to the end of another fragment, we may conclude that the two fragments represent overlapping stretches of the genome. A series of fragments may be joined together into a **contig**, which is effectively a continuous stretch of the genome generated from overlapping

fragments. **Figure S 39** shows an example of a chromosome "walk", in which successive fragments were joined together by identifying overlapping clones from a library. A subfragment from one end of the first clone is used to isolate clones that extend farther along the chromosome. These clones in turn are used to isolate the next set. In each cycle, a new clone is selected because its restriction map coincides at one end with the end of the previous clone, but at the other end has new material. It is possible to walk for hundreds of kb, typically at a rate of >100 kb per month. Chromosome walking allows large contiguous regions of the chromosome to be represented in a library of clones.

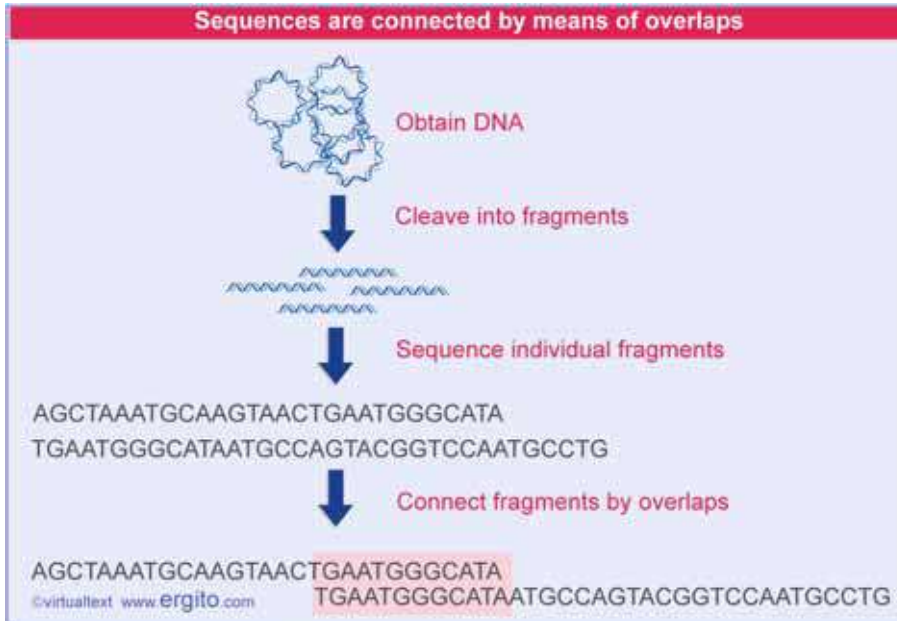

**Figure S 39** Chromosome walking is accomplished by successive hybridizations between overlapping genomic clones.

Two approaches have been taken to large-scale mapping of genomes. One is to break the genome first into a series of large contigs, as illustrated in **Figure S 40**. With the contigs in hand, each contig is then sequenced, and we know that these sequences together will add up to the entire genome. This approach was used by one of the groups that sequenced the human genome (1440). In this case, the raw material was a total of ~29,000 BACs that were assembled into ~1250 contigs. The contigs were mapped to chromosomal locations and merged.

**Figure S 40** A genome may be organized into a set of contigs before it is sequenced.

Another approach is to use **shotgun** cloning, as illustrated in **Figure S 41**. Here the entire genome is broken into random fragments that are sequenced, and then the sequences are joined by the usual principle of identifying overlaps. This requires very sophisticated computer processing to identify all the overlaps. This was also used to analyze the human genome (1439).

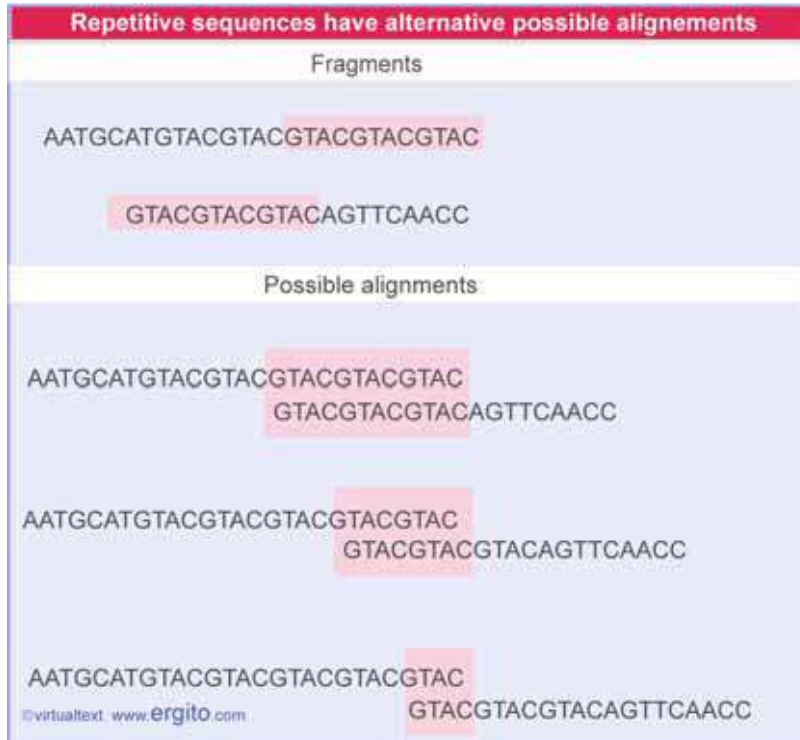

**Figure S 41** The principle of shotgun cloning is to break a DNA at random into fragments that are sequenced. Overlapping fragments are identified by sequence comparisons and connected into a continuous sequence.

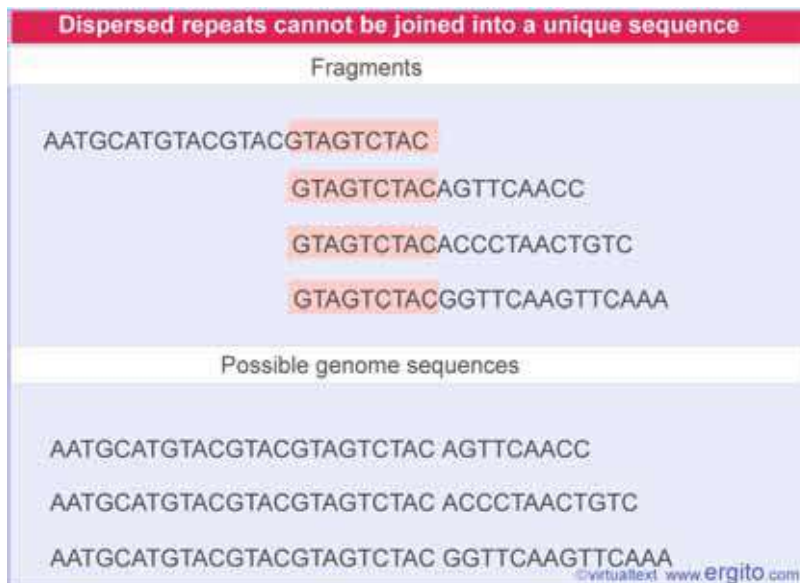

Analysis of fragments generated by shotgun cloning is usually involved at some stage. Identifying the overlaps becomes easier the smaller the size of the starting fragment. So when a contig is analyzed by shotgun cloning, the process is simpler than when a genome is analyzed, by virtue of the reduced complexity of the DNA sequences.

Joining sequences on the basis of overlaps would be relatively straightforward if the genome consisted only of unique (nonrepetitive) sequences. The major problem in practice is caused by the presence of repetitive sequences, where several stretches of DNA may be so similar that it is impossible to distinguish among them. **Figure S 42** illustrates the difficulty. In its simplest form, it is difficult to line up two overlapping fragments because we do not know how many copies of the repeating unit there are. **Figure S 43** shows the more complex condition in which the same sequences occur in multiple locations in the genome, we do not know which of any two overlapping fragments should be joined.

**Figure S 42** Fragments that overlap in a repeated sequence may have multiple possible alignments.

**Figure S 43** Dispersed duplicated sequences may have multiple possible alignments.

In the same way that genomic libraries can be prepared from genomicDNA, cDNA libraries can be prepared by reverse transcribing populations of mRNA. This is an important tool in identifying and mapping expressed genes. In principle, each RNA molecule provides the template for synthesizing a single-stranded cDNA that is

complementary to it. The cDNA is then converted to a double-stranded form and cloned in the usual way. Any individual RNA should be represented in the cloned population in proportion to its abundance in the original RNA population (although the actual proportions are distorted by the idiosyncracies of reverse transcription).

In its simplest form, a cDNA library consists of a population of cloned DNA molecules that represent all of the expressed sequences in the source cell type. However, using cDNA clones as such turns out to be an efficient strategy for identifying and mapping only the shorter genes.

More sophisticated variations of the procedure have been introduced to make it possible to automate data collection. **Expressed sequence tags (EST)** are obtained by sequencing the extremities of cDNA clones, so typically they correspond to the 5' leader and 3' trailer. They can be used to provide large data sets that allow expressed genes to be identified (2220). The principle that an EST is located on the genome by its sequence identity with a cloned sequence of genomic DNA.

The most recent development is the use of a strategy where sequences are produced from within the transcript, instead of from the ends. This is called ORF EST (meaning that the EST represents an open reading frame). This provides a better data set, with less confusion from overlapping or repeated sequences, and allows large libraries to be made that accurately represent the expressed set of genes (2219).

**SUPPLEMENTS****7.32.13 Two-component signal transduction**

---

Two-component signaling systems were discovered in bacteria, where they provide the most common form of signaling pathway that responds to extracellular events (2307). There are ~30 such pathways in *E. coli*. **Figure S 44** illustrates a generic system. They are also found in plant cells (a typical plant may have 10-15 such pathways), occasionally in yeast (~5 pathways), but are relatively rare in animal cells (there are none in mammals), where kinase cascades involving Ser/Thr and Tyr kinases are more common.

**Figure S 44** A two component system consists of a sensor that is an autophosphorylating histidine kinase and an effector that can catalyze transfer of phosphate from the sensor to itself.

The sensor protein is a histidine kinase that is located in the bacterial membrane. It can be activated by binding a ligand that is in the extracellular medium. Activation causes the kinase to autophosphorylate (that is, to phosphorylate itself). The reaction transfers the  $\gamma$  phosphate from ATP on to a histidine residue in the kinase.

The sensor interacts with an effector protein (also called a "response regulator"). The effector catalyzes transfer of the phosphate group from the histidine on the sensor to an aspartic acid residue in its own regulatory domain. This activates the effector. It is later deactivated by dephosphorylation.

The chemistry of phosphorylation by a histidine kinase is different from that of the eukaryotic serine/threonine or tyrosine kinases. **Figure S 45** shows that the phosphate is transferred on to a nitrogen atom in the histidine ring, creating a high-energy phosphoramidate bond. This type of high energy bond is used for phosphoryl transfer in many proteins. When the phosphate is transferred to aspartic acid, it generates a high energy acyl bond. By contrast, the bonds formed with serine, threonine, or tyrosine are between phosphate and hydroxyl group, generating a low-energy ester bond.

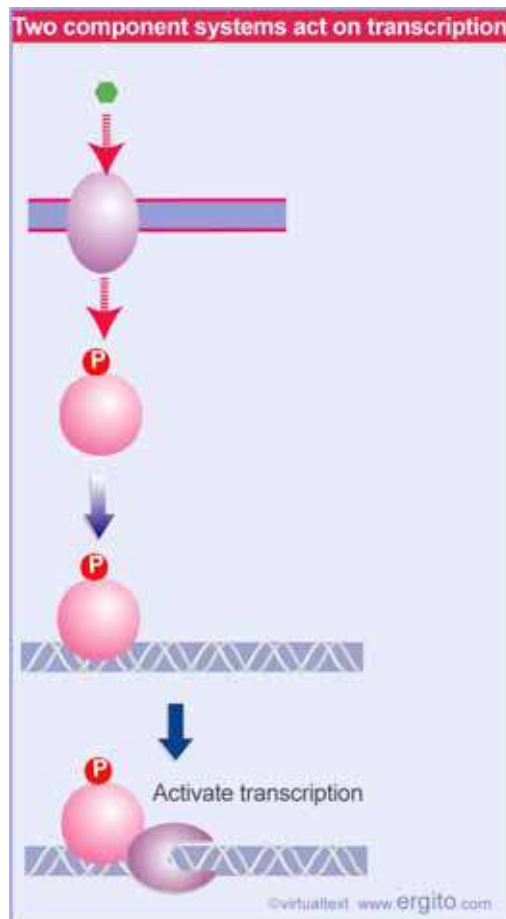

**Figure S 45** Phosphorylation of histidine or aspartic acid occurs through a high energy bond, but phosphorylation of serine, threonine, or tyrosine occurs as a low energy ester.

More elaborate versions of these systems are called phosphorelays. In such cases, the

phosphate group is transferred several times. In a typical case, the pathway starts just like a two-component system, but the second protein in turn transfers the phosphate group to another, and the process may continue (for review see 2308; 2263). The high energy bonds tend to be short-lived, which makes the response rapid and transient.

The usual end target of a two-component pathway is the regulation of gene transcription, as summarized in **Figure S 46**. In the typical bacterial pathway, the effector is the terminal component. It has two domains. The regulatory domain catalyzes transfer on to itself of the phosphate from the sensor histidine kinase (for review see 2263). When it is phosphorylated, it activates the effector domain, which most commonly binds DNA to activate or to repress transcription .

**Figure S 46** The effector protein of a two-component system has two domains. When the regulator domain is phosphorylated, the effector domain binds to DNA. This may activate transcription (as shown) or may repress it.

Several basic responses to the environment are mediated by two-component systems, in *E. coli* including the response to osmotic pressure, redox control, and chemotaxis. A two-component system is used by *Agrobacterium* when it infects a plant cell (see *Molecular Biology 4.18.14 T-DNA carries genes required for infection*). Sporulation

of *B. subtilis* is initiated by a phosphorelay system (see *Molecular Biology 3.9.19 Sporulation is controlled by sigma factors*).
